Lumbar Anesthesia.—Prof. E. KUSTER of Marburg, Germany, the guest of the association, read this paper. He said that lumbar anesthesia was used largely in Germany but seemed to be distrusted in America. Quincke of Kiel gave the initiative to lumbar anesthesia in 1891. In the speaker's clinic lumbar anesthesia was used for all operations in and below the pelvis, and also for many operations on the kidney, gall-bladder, and stomach. Regarding the injection of the fluid he spoke of the desirability of puncturing the filum terminale of the spinal cord. The injection was made in the middle line, the needle being introduced first alone and carried through the dura when the cerebrospinal fluid would begin to flow. The fluid was allowed to flow until clear if the first few drops were bloody, though if the needle allowed the escape of pure blood a second puncture was desirable. The escape of fluid was the only sure way of indicating entrance into the dural canal. At times he let 15 c.c. flow before injecting the anesthetic. The solution used was a 5 per cent. solution of novocaine with suprarenalin, supplied by the pharmacist in sterile solution in sealed ampoules. For operations on the uterus and pelvic organs they used 2 c.c., and for abdominal operations 3 c.c. Anesthesia appeared in a few minutes after the injection. There were two methods of extending the anesthetic area upwards, one by putting the patient in the elevated pelvic position for ten minutes or longer after the injection, the other ("head obstruction") by putting a bandage around the neck, so increasing intracranial pressure. The bandage was applied before the injection, and on removal afterwards the anesthetic ascended with the blood, and anesthesia of the abdomen was obtained with very litle anesthesia of the legs. Paralyses were very rare, for the anesthetic did not readily circulate in the space anterior to the ligamentum denticulatum of the spinal cord. If the patient was turned on his abdomen paralyses were promptly obtained. The operation could be begun after five to ten minutes. At the time of opening the peritoneal cavity slight pain might be evidenced, but in disarticulations of the hip very little shock was observed. The period of anesthesia lasted about forty-five minutes, after which nausea usually was felt. After an hour and a half true pain appeared, and there might be weakness in the legs sufficient to interfere with walking. These would last a few hours. Headache occurred in 12 per cent. of the first three hundred cases; this was relieved immediately by lumbar puncture, removing 10 c.c. of fluid. Another unpleasant after-effect was paralysis of the bladder, rectum, or legs, but this generally disappeared in from 4 to 8 days. There was a postoperative pneumonia in one case in which ether was also given. There was fever in one case. A great advantage of the method was that it completely prevented postoperative aspiration pneumonia. It did not upset the general health; it was safe in delicate people and those suffering from disease of the heart, lungs, or kidneys.

Dr. T. W. HUNTINGTON of San Francisco said that two years ago he began to use lumbar anesthesia with great doubts; that he tried it systematically and got results similar to Prof. Kuster's. He used the anesthetic in solution in the spinal fluid, removing about two c.c. of the fluid, dissolving in that the required dose of the drug, and reinjecting it. He considered the fluid used as the solvent as a very important element. He rarely had any headaches after puncture. There were no psychic effects. There had been no postoperative vomiting or shock, but only postoperative comfort. He believed that lumbar anesthesia had come to stay.

Dr. BRISTOE of Brooklyn said that he had tried the method a few years ago, using cocaine. Some of his patients had had persistent severe headaches; in about one-third of the cases he had not had satisfactory anesthesia; and in six of his fifty cases there had been delusions of persecution lasting two or three weeks. He modified the technique slightly by making an incision through the skin before inserting the needle.

Dr. SCHMIEDEN of Bonn, Germany, said that they had been eminently satisfied with the method at Bier's clinic and used it in all operations below Poupart's ligament, and in all kidney cases.

Dr. WILLY MEYER of New York said that he believed lumbar anesthesia was not used in the United States because of the reported bad effects, the bad technique, and the fact that in America we had special anesthetists who had improved the results of general anesthetics. He had used lumbar anesthesia for seven years, trying various cocaine salts and allies, and had also tried magnesium sulphate, but this latter drug caused paralysis of bladder and rectum. He had stopped using the method, however, after having had two deaths from tropococaine, which, after boiling, had split into atropine and hyoscine. He believed the method the best for cases of diabetic gangrene and prostatic hypertrophy.

Dr. G. E. BREWER of New York asked regarding the mortality of this method. He said that he had been going on the assumption that the mortality was one in five hundred as reported at a recent Paris congress, and had not used the method as he considered the risk too great.

Dr. W. G. MACDONALD of Albany said that he considered novocaine as bad as the other cocaine preparations, and he had seen one death on the table from the very preparation used by Dr. Kuster, and that in the dosage of

but two-thirds of an ampoule. He had seen vomiting with every drug used.

Dr. Kuster, in closing the discussion, said that he knew of no statistics for general anesthetics that took into account the deaths from the postoperative pneumonias and other complications; but that even if lumbar anesthesia did have a mortality of one in five hundred it would still be as safe as the general anesthetic.

Continuous Passive Congestion in the Treatment of Delayed Union of Fractures.—Dr. J. B. Roberts of Philadelphia read this paper. He said that he used an elastic bandage above the seat of fracture to cause passive congestion in the cases of nonunion when he was satisfied that there was no interposition of tissue between the two bone fragments. He had used the method also in recent fractures to hasten the union. At the same time he used diet, exercise, and fresh air, and frequently calcium salts, and tried also to get the psychic effect of encouragement of the patient. He thought the ulcers present in old compound fractures might be delayed by the congestion treatment, but that this delay was not to be considered in view of the acceleration of bony union. The application of the bandage should produce a cyanosis of the part distal to the bandage, but should not cause pain. It might be necessary to change it to allow for variations in position of the limb and consequent swelling.

Mr. Robert Jones of Liverpool, in discussing this paper, said that the same method had been used by Mr. H. O. Thomas of Liverpool fifty years ago, and he had personally used it in seventy or eighty cases since then with great advantage. He applied a rubber band above and another below the fracture, increasing the duration of the application as the patient could stand it.

Resection of a Sound Femur for Gigantism and Asymmetry.—Dr. R. W. Johnson of Baltimore read this paper. He proposed resection of the sound femur in women of unusual height, who by this height were conspicuously deformed. He would resect two to two and a half inches from the middle of the femur, uniting the bones preferably by square ends, and operating on one leg at a time. He also suggested resection of the femur when there was a limp from one leg being longer than the other.

Dr. J. B. Roberts of Philadelphia, in discussing the subject, said that he had recently proposed the same treatment to a candidate for the army who was debarred by a limp.

A New Method of Rhinoplasty, by Means of One of the Fingers.—Dr. J. M. T. Finney of Baltimore read this paper, in which he described a palstic nasal operation after the bridge had been lost by congenital syphilis, and in which there was absence of the bony framework and very thin skin covering. He reported two cases in which he had done the operation, showing diagrams and photographs. He chose the ring finger of the left hand as the one most easily spared, and after removing nail, matrix, and skin from the dorsum of two phalanges and the entire skin on the distal phalanx, he inserted the finger through a slit in the columns, making no incision in the skin of the bridge of the nose. After two weeks he amputated the finger at the metacarpophalangeal joint, flexing the proximal phalanx on the other two to form a new column, and leaving the two distal phalanges to support the bridge. Later small plastic operations united the soft parts, but not the bony parts. One great cosmetic advantage was the absence of scars.

Dr. C. A. Powers of Denver said that he remembered a somewhat similar case operated on by Dr. Sabine in New York in 1870, in which the result had been very satisfactory.

Treatment of the Posterior Capsule of the Thyroid in Thyroidectomy.—Dr. C. H. Mayo of Rochester, Minn., read this paper, which was based on 375 cases of thyroidectomy. He spoke of the anatomy of the capsule of the thyroid, showing layers of the capsule between which lay the recurrent laryngeal nerve, pressure upon which often produced paralysis of the vocal cord. He spoke of the parathyroids as lying behind the thyroid on the capsule, two on either side, the upper one being near the larynx. They might be in the capsule and be removed with it in extirpation of the gland. He operated always with local anesthesia and morphine, the patient being in the reversed Trendelenburg position. After the capsule had been opened the gland was brushed toward the median line to avoid taking with it the posterior capsule. He was careful to check all hemorrhage and to drain by a separate incision. In his series there had been one case of tetany and five cases of increased hoarseness. He was careful to save the posterior capsule and thus avoid many of the dangers of thyroidectomy. Dr. Mayo presented photographs of the patients operated upon and of the pathological specimens, both gross and microscopical.

Dr. W. S. Halstead of Baltimore said that one could not tell how often tetany would ensue and that therefore while he removed a large portion of the gland he never excised it all. He had had only one case in his own experience, but had seen more in the operations of others. Recent injections of the thyroid arteries had demonstrated that the parathyroids got their blood supply from the thyroid arteries and principally the inferior one. Only two of the eleven cases injected showed blood supply to the parathyroids from the superior arteries. Therefore he ligated the vessels well inside the gland.

Aneurysmal Varix; a Case of Pulsating Exophthalmos, and Two Cases of Enormous Dilatation on the Cardiac Side of the Wound.—Dr. G. T. Vaughan of Washington, D. C., presented this paper. In the case of pulsating exophthalmos the diagnosis was clear and the treatment was the only subject for consideration. Compression of the internal carotid arrested the pulsation and relieved the murmur, and so the vessel was tied. The patient developed paralysis on the second day and died, but no other form of treatment seemed available. In the two cases of varix on the iliac veins the tumor was on the proximal side of the communication between the vessels. In one patient with varix of the carotid, who died under ether, the swelling was in the jugular vein. Dr. Vaughan sought an explanation of the occurrence of the dilatation on the cardiac side of the communication and asked if it was the rule.

Graduated Vertical Traction in Its Application to Congenital Dislocation of the Hip.—Dr. O. H. Allis of Philadelphia presented this paper and showed an apparatus for the application of the traction to any measured degree, the traction being made by a screw and registered by a spring balance. The force was applied from a framework that allowed of full motion of the hip-joint during traction. After the complete relaxation of the muscles by the traction the apparatus was removed and the reduction of the dislocation was completed by gentle manipulations.

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Third Annual Meeting, Held at Washington, D. C., May 6, 7, and 8, 1907.

(Special Report to the Medical Record.)

GENERAL MEETING.

The President, Dr. Hermann M. Biggs of New York, in the Chair.

First Day, Monday, May 6.

Address by the President.—Dr. Biggs said that two years ago the first annual meeting of the National Association for the Study and Prevention of Tuberculosis was held in Washington under specially favorable auspices. The Association had completed its first year of successful

work, having been organized in Atlantic City the previous year, with a comparatively small membership, under the presidency of Dr. Trudeau. During the year, through his efforts, a considerable sum of money had been contributed for the support of the Association, and a permanent organization had been effected, with the installation of Mr. Livingston Farrand as Executive Secretary, and the establishment of permanent headquarters in New York City. The national crusade for the study, prevention, and treatment of tuberculosis had been given a very distinct impetus during these three years by the work of the Association, and popular knowledge and interest in the subject had become much more widespread. A large number of local, municipal, and State associations had been organized throughout the country, in addition to many associations especially designed to promote the establishment and maintenance of local sanatoria for the care of incipient pulmonary tuberculosis. In practically all of the older States of the Union there now existed some local or State organizations, and the general knowledge and interest in the movement was steadily extending. In most of these associations physicians had been the leading spirits in their organization, as was the case in the formation of the National Association. It had been, and was, still far more difficult to enlist the cooperation of laymen in this work than that of the physicians, and it was particularly this interest and cooperation of the laymen which was now needed to advance more rapidly the cause. The membership of the National Association now numbered about 1,300, including a large percentage of the leading physicians of the United States, and many prominent laymen. The formation and development of the local and State associations, in the very nature of things, often detracted materially from the interest which their members took in the National Association, for these local associations were concerned in extending relief in their immediate neighborhood, and had a far more personal interest. It was also considered desirable in the early history of the National Association that the membership should be most carefully scrutinized, in order that during this period particularly no persons should become members who were likely in any way through their conduct to discredit the Association or impair its reputation or usefulness. Therefore, the efforts to increase its membership had not been as great as they might have been, and outside a few of the Eastern States its representation was very small. It was believed that with the general interest which would be aroused in the subject of tuberculosis by the coming meeting of the International Tuberculosis Congress in Washington in 1908 the membership of the National Association should and could be rapidly increased five or ten-fold within the next year, and one of the first objects and efforts of the members during the coming year should be to add to the membership by personal solicitation, directed not only to physicians, but to laymen who were prominent in various localities of the country, and who, by their position, influence, and contributions, could materially aid in extending the work of the National Association. Up to this time, Dr. Biggs said, but little had been done in attempts to initiate or influence legislation with reference to tuberculosis in various cities or States, and this he believed was the line of endeavor which should now be actively followed by the National Association. In the attainment of these purposes its influence should be paramount. Not only should its efforts be directed to the initiation and encouragement of legislation, but when such legislation had been obtained, its influence and support were not less needed for the enforcement of the laws enacted. Legislation should include not only measures designed for the administrative control of tuberculosis, but also measures directed to the establishment of municipal dispensaries and of local and State sanatoria and hospitals for the treatment and care of the tuberculous poor. The movement toward the establishment of State sanatoria had gained considerable impetus, and it should be rapidly extended, and the annual appropriations for the extension and establishment of such institutions should in many States be materially increased. The attitude of the sanitary authorities generally toward the National Association and its work had been somewhat disappointing, for while there had been notable exceptions, the municipal and State health officers throughout the country as a whole had not up to this time taken any very active interest in the work of the Association. The United States was very far behind in respect to the efficiency of its sanitary organizations as compared with those of Great Britain or Germany. Unfortunately, here there was no central authority, and in a majority of the States the State Boards of Health had but limited jurisdiction and small appropriations, which often served for little more than the registration of vital statistics. The health officers were not generally appointed because of their knowledge or interest in sanitary affairs and their peculiar fitness, but on account of their personal or political affiliations. There was no institution in the United States, so far as he knew, in which a complete course of instruction was given for the purpose of fitting medical men to become medical officers of health, and the degree of Doctor of Medicine was the only requirement for eligibility. It would seem as if we had now progressed far enough along the path of higher civilization to expect and require that sanitary affairs in every locality should be administered intelligently, judiciously, and in the interests of all the people of the community by those who had special training in such matters, so that a consistent sanitary policy might be everywhere continuously followed.

Report of the International Congress on Tuberculosis, 1908.—Dr. Lawrence F. Flick of Philadelphia read this report. He stated that the International Congress on Tuberculosis came into existence in Paris in 1898; it reconvened in Berlin in 1899, again in Naples in 1900, in London in 1901, and finally, as an International Congress in the full sense of that term, in Paris in 1905. It was organized by the leaders of the crusade against tuberculosis for the purpose of directing the movement and keeping it under control. America did not participate in the organization of the Congress nor take any part in its proceedings to any great degree prior to the meeting in London in 1901. This was largely due to the lack of organization in this country. The founding of the National Association for the Study and Prevention of Tuberculosis in 1904 put this country upon a competent basis to take part in the international direction of the crusade, and America was better represented at the Congress in Paris in 1905 than on any previous occasion. A delegation of the National Association, at the direction of the association and with the endorsement of President Roosevelt, conveyed through Ambassador McCormick, extended an invitation to the International Congress to meet in the United States at its next session, and this invitation was unanimously accepted. The time was fixed in the autumn of 1908, and the place of meeting was Washington. Immediately after the adjournment of the Congress in Paris in 1905, the board of directors of the National Association appointed a committee on the Congress, with instructions to prepare plans which were to be submitted to the board of directors. In accordance with this a plan was adopted which was published in full in *Charities and Commons* of December 9, 1905, and which included, among other features, the collection of one hundred thousand dollars as a permanent fund for the scientific and philanthropic part of the Congress. Of this fund thirty thousand dollars had already been subscribed in the form of six subscriptions of five thousand dollars each. Dr. John S. Fulton of Baltimore was selected as secretary-general of the Congress. Under the plans adopted, the Congress was to last three weeks, one week of which was to be devoted exclusively to scientific work, and two weeks to entertainment and the inspection of institutions. During the three weeks thirty

lectures by the most prominent workers in the tuberculosis field outside of the United States were to be given. The fund of one hundred thousand dollars was to be used exclusively for the scientific part of the Congress, and if there was any balance left over, it was to be divided pro rata among institutions devoted to tuberculosis. The plans adopted contemplated the offering of prizes on a great many subjects in the interest of the crusade against tuberculosis. One prize had already been offered by the committee, and would be announced throughout the entire world. The prize consisted of one thousand dollars for the best evidence of efficient work done by any voluntary association since the last Congress on Tuberculosis. As rapidly as the money could be raised, other prizes would be announced. The matter of interesting medical societies and the societies for the prevention of other diseases than tuberculosis and various organizations interested in sanitary science and philanthropy was under consideration by the committee, but as yet nothing definite had been done. An effort would be made to bring all organizations which either directly or indirectly might have to do with the prevention of tuberculosis into the Congress. Such steps would have to be worked out very carefully, and thus far action regarding it had been deferred. The National Association for the Study and Prevention of Tuberculosis had made itself responsible to the world for the proper management of this International Congress, and would therefore have to maintain control of the Congress, but other organizations could be brought in to cooperate on a satisfactory plan if their cooperation was sought in the proper spirit. Every effort would be made by the committee to coordinate all the available sources for the best interests of the Congress.

Election of Officers.—The following officers were elected: *President*, Dr. Frank Billings of Chicago; *Vice-Presidents*, Drs. Mazyck of Philadelphia, Ravenel of Philadelphia, and Foster of New Haven; *Secretary*, Dr. Henry P. Jacobs of Baltimore; *Treasurer*, Dr. George M. Sternberg of Washington. Dr. Wm. H. Welch of Baltimore was chosen president of the International Congress for the Study of Tuberculosis, to be held in Washington in the autumn of 1908.

Pathological Society of Philadelphia.

At a stated meeting held April 26, Dr. H. E. Radasch presented a special apparatus for laboratory technique. This consisted in a portable rack made of aluminum for the purpose of carrying a number of slides mounted with serial sections through successive solutions. The device is simple, light, and inexpensive, and it has proved its usefulness in actual practice. Dr. R. S. Lavenson presented specimens of organic heart-lesions. He showed a series of hearts obtained at autopsies made on subjects at the Philadelphia Hospital. One was a beautiful specimen of tuberculous pericarditis, exhibiting clearly tubercles beneath the epicardium and presenting adhesions in places. Another was a specimen of mitral obstruction and insufficiency. Another was an example of mitral valvulitis with ulceration extending almost to the adjacent aortic leaflet. One was an example of aortic stenosis, with little or no insufficiency. Two of the aortic cusps were calcareous, while the third retained a certain degree of elasticity and freedom of motion. Dr. D. L. Despard exhibited a specimen of purulent pericarditis. Dr. J. A. Kelly exhibited a specimen of cyst of the appendix. The formation had attained considerable size, and it contained gelatinous material. Its communication with the bowel was cut off. Dr. Kelly presented also an ectopic supernumerary pancreas. The organ was attached to the small intestine in the neighborhood of the jejunum, and presented the histological structure of the pancreas. Dr. William Pepper demonstrated ova of the *Uncinaria duodenalis* obtained from an Italian patient in the Philadelphia Hospital who presented anemia, asthenia, and looseness of the bowels. Mature worms were developed by incubating the egg in sand or soil. Dr. G. Canby Robinson presented a communication entitled "Heart-block, with Pathological Specimens from a Case, and with Tracings from Various Forms of the Condition." The specimen exhibited was from the pathological museum of the Pennsylvania Hospital, and was obtained in 1879 from a man about sixty years old, who presented dyspnea, cyanosis, bradycardia, and convulsive seizures. Death took place suddenly, and post-mortem examination disclosed the presence of multiple gummata in the heart, one of which occupied the situation of what has since been described as the conducting bundle of His. From the clinical report and the pathological exhibit there is little doubt that the case was one of heart-block. Dr. Robinson demonstrated also a normal heart, exhibiting in a beautiful manner the conducting bundle. He also showed tracings from several cases that had come under his observation, exhibiting varying degrees of heart-block, together with the apparatus for making tracings. Dr. E. Crispin read a paper entitled "Metaplasia of Epithelium in Cysts of the Breast." He reported a case and presented the specimen in which the cylindrical cell structure of a cyst of the breast underwent transformation into stratified epithelium. Dr. J. H. W. Rhein presented a communication entitled "Syringobulbia, with Report of a Case." The excavation of the central nervous system was marked and extreme, extending from the conus medullaris to the medulla oblongata, and it was attended with degeneration of several cranial nerves and of tracts in the cord. Dr. H. E. Radasch read a paper entitled "Unilateral Absence of the Urogenital System and Its Relations to the Development of the Wolffian Duct," He traced the embryonic evolution of these structures and analyzed the comparatively small number of cases of the kind recorded in the literature. Dr. R. C. Rosenberger made a further communication on "The Presence of Acid-fast Bacilli in the Stools." He had been able to repeat previous observations on a large scale, showing the presence of acid-fast bacilli, conforming to the requirements of tubercle bacilli, in the intestinal discharges from patients clinically or pathologically shown to have tuberculosis in some part of the body. He expressed the view that such bacilli must be considered as having been excreted by the bowel, and not necessarily indicative of the existence of a lesion of the intestine. He had succeeded also in finding similar bacilli in the intestinal discharges of guinea-pigs that had received subcutaneous inoculation of tubercle bacilli in the absence of intestinal lesions and sometimes in the face of disappearance of the local lesion.

A Simple Method for Performing Resection of the Thorax.—Bayer says that although in some cases it is necessary to resort to Schede's operation in order to cure neglected cases of empyema, this operation is so bloody and severe a one that it should be employed as rarely as possible. He states that by the following procedure one is enabled to secure almost the same results as by means of Schede's very radical operation, while the tax on the patient's powers of recuperation is not nearly so great. A vertical incision beginning in the axilla and running parallel to but two inches posterior to the anterior axillary line is practically bloodless and does not divide any important muscles. Through this incision a short segment of each rib from the ninth upward is resected subperiostally and the soft parts are then cut through with the thermocautery to avoid any further hemorrhage. On inspecting the thoracic cavity it can be determined whether or not the thoracic pleura must be removed, and the resection of the stumps of the ribs can be very conveniently carried out. The author considers the rapidity of operation and the slight loss of blood achieved in this way as the principal merits of the method.—*Zentralblatt für Chirurgie.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 4, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	445	189
Diphtheria	342	38
Measles	534	12
Scarlet Fever	492	19
Smallpox	3	—
Varicella	74	—
Typhoid Fever	88	23
Whooping Cough	56	9
Cerebrospinal Meningitis	27	20
Malarial Fever	..	..
Totals	2061	310

Surgical Treatment of Thrombophlebitic Puerperal Infection.—Giuseppe Guicciardi indicates thrombophlebitic puerperal infection as a rare form that is distinct in symptoms, diagnosis, and prognosis from the other forms of puerperal infection. The fever is not an index of the pulse rate, which is independent of the height of the rise of temperature. The temperature curve is pyemic and is accompanied by severe chills that are repeated as long as the disease goes on; the general condition and color are bad, and the abdominal pain is peculiar in character; bimanual examination enables the operator to feel the thrombosed veins as hard cords. Bacteriological examination gives such different and contradictory results that it is of little value. The leucocyte formula gives little information. Ordinary obstetric treatment is useless, and only surgical intervention promises good results. Both abdominal and vaginal hysterectomy are useless and resection of the thrombosed veins is dangerous. The method of election is ligation of the veins. It results in the disappearance of the infective local process and of all pain, and ends in the recovery of a fair proportion of patients. The best time for intervention is about the twentieth day.—*Annali di Ostetricia e Ginecologia.*

Epithelioma of the Lacrymal Sac. Recurrence.—C. L. Lafon reports this case. The patient was a farmer forty-eight years old. In 1896 he noticed a condition of epiphora affecting both eyes. About the beginning of 1898 the region of the left lacrymal sac began to swell, and finally a bloody ulceration developed. Later on operation was performed. Incision showed that the growth involved the sac itself and the galvanocautery was used for destroying the diseased tissues. Histological examination of the débris showed the growth to be an epithelioma. Again in 1899 the patient returned to the hospital with a growth in the region of the wound; this was destroyed by the thermocautery. Three months later there was a recurrence. Again for the third time the patient was operated upon and recovery appeared definite. But at the beginning of 1905 the patient again appeared, showing the lacrymal region in a diseased condition. This case is of interest for several reasons. The epithelioma appears to have begun in the mucosa of the sac, a very unusual occurrence. The interval of five years and a half which elapsed after the first interventions is worthy of note. Finally, recurrence extending slowly up under the skin without appearing to have a tendency to destroy it is interesting. Lafon has the intention of operating again in order to remove as far as possible all of the diseased tissues.—*Journal de Médecine de Bordeaux.*

Spontaneous Ruptures of the Aorta.—André Bergé in his comprehensive paper on this subject speaks first of the various conditions under which the aorta ruptures or becomes perforated. Indirect violent trauma may be followed by rupture of the aorta. The aorta may become perforated secondarily as an effect of a neighboring lesion such as abscess of the mediastinum or cancer of the esophagus. An aneurysmal sac may be the cause. Finally, aside from the various causes which have been enumerated, the aorta may rupture in an apparently spontaneous manner. The first and essential cause of aortic rupture, aside from the cases of traumatism, consists in a previous alteration of the arterial wall. The most frequent location of perforation is in the ascending aorta in its intrapericardial division. Perforation is nearly always single. In the large majority of cases the alteration of the internal surface of the aorta is manifest to the naked eye. In general, the symptoms are precordial pain and syncope, and cardiac collapse. The clinical picture may present itself in one of three forms—sudden, rapid, or slow. The cause of death is probably not due to one process only. Hemorrhage, compression of the heart, and syncope by inhibition all play a part.—*Gazette des Hopitaux Civils et Militaires.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 3, 1907:

SANITARY WORK ON THE ISTHMUS OF PANAMA DURING THE LAST THREE YEARS.

By COL. W. C. GORGAS, U. S. A.

CHIEF SANITARY OFFICER, ISTHMIAN CANAL ZONE DEPARTMENT OF HEALTH.

My wish in this article is to give a general description of the sanitary conditions which existed on the Isthmus at the time the United States assumed control; to explain the methods which have been taken to improve these conditions, and to point out the results attained by these methods.

The Isthmus of Panama at the point where the proposed canal is being constructed extends from east to west. The canal course runs nearly north and south. At this point has been located the principal route of crossing since the discovery of America. The Spaniards, however, built a very good causeway for pack animals from the old town of Panama to Porto Bello. This causeway was paved with cobblestones and is still in a fair state of preservation. The old town of Panama is some six or seven miles east of the present town of that name, and Porto Bello is about thirty miles east of Colon. The advantages of the Chagres as a means of getting across the Isthmus were soon appreciated and travel was gradually transferred to the Chagres river until about the year 1670, when Morgan, the famous English buccaneer, captured the old city of Panama. After this the old overland trail to Porto Bello was abandoned, the city of Panama changed to its present location, and the Chagres almost exclusively used as a route for crossing the Isthmus. The Chagres empties into the Carribean some ten miles west of the present town of Colon. Porto Bello, which has an excellent harbor, remained the port on the north coast. All vessels crossing the ocean from Europe were unloaded at Porto Bello, the cargoes transshipped in smaller vessels to the mouth of the Chagres, where they were loaded into small dugouts and carried up the Chagres to the south some forty miles to the point where the Chagres changes its course. From this point they were carried overland on pack animals to the present city of Panama. A paved road was built from this point, Las Cruces, to the present city of Panama. This formed the main route of crossing up to the time of the building of the Panama Railroad. A large portion of the population which went from the eastern states and from all parts of the civilized world to California in 1849 and the immediately succeeding years, crossed by this route. In 1855 the railroad was thrown open to traffic. This road practically followed the former routes of crossing, went south up the Chagres to the point where the Chagres turned. From this point it followed up the valley of one of the large tributaries, the Obispo, until it crossed the divide, then followed the valley of the Rio Grande, which empties into the Pacific near Panama.

Colon is not situated at the mouth of the Chagres river. The railroad strikes the Chagres at Gatun, some ten miles from its mouth. The canal route practically follows the line of the railroad from Colon on the north to Panama on the south.

Some thirty years after the completion of the railroad a French company under the leadership of Monsieur De Lesseps commenced building a sea-level canal between Colon and Panama, following the route of the railroad. This company, after some seven years' work, and having done considerable excavation, failed.

The United States has acquired a strip of territory ten miles wide, with the canal as a central line, extending entirely across the Isthmus from Colon on the north to Panama on the south. The country is low and swampy for the first fifteen miles; the rest of the route, some thirty odd miles, is through a mountainous country. The temperature all the year round in this territory is tropical, varying very little between January and July. Conditions as to warmth are thus such that the mosquito will breed prolifically all the year round. Over the mountainous part of the route the peaks are from 100 to 1,000 feet in height, nowhere being high enough to in any way inhibit from a temperature standpoint the breeding of mosquitos. Water is abundant everywhere, in the mountainous section little streams coming from every ravine, forming ideal places for the anopheles, and in the swampy section stagnant pools of fresh water are on every hand. The towns of Panama and Colon were formerly dependent entirely for their water supply upon stored rain water. The dry season, when very little rain falls, lasts for some four months, and rain water had to be stored for use during this dry season. The large number of tanks and receptacles containing rain water thus made ideal breeding places for the yellow fever mosquito.

Now for four hundred years we have had a constant stream of unacclimated persons of the white race crossing this Isthmus. This constant stream infected the territory with both malaria and yellow fever and kept up the infection to a very much higher degree than in the neighboring tropical countries which did not have this stream of whites constantly in their territory. The travelers in a great many cases were dignitaries of importance, merchants, and people of wealth. Everybody who traveled from the west coasts of North and South America, in general, crossed at Panama, so that many important personages sickened or died at Panama. For this reason it has acquired a reputation for bad health which is second to that of no other locality in the world.

The French began the construction of a canal in this same territory in the year 1881 and kept on the Isthmus some 19,000 laborers, 2,200 of whom were whites. This large body of men remained here some seven years working on the canal. The

infection of both yellow fever and malaria being already present and other conditions being favorable, this large access of unacclimated people greatly increased the ordinary mortality, and as the project interested all the world the health conditions became widely known and gave to the Isthmus the very bad reputation it had when we came down here. The locality, however, is not naturally unhealthful. On the whole, it is a pretty and attractive country, with pleasant climatic conditions. Conditions as to temperature, rainfall, and local water supply happen to be favorable to the development of the stegomyia and anopheles mosquito, and then for four hundred years unacclimated whites were introduced in a steady stream, sometimes in very large numbers, such as during the construction of the railroad, and of the canal under the French, but I am inclined to think that such a thing would occur anywhere else in the world where the altitude was less than 2,000 feet, the minimum temperature not less than 60° Fahrenheit, and the rainfall more than thirty inches, provided the unacclimated whites had been brought there in the same way.

This, in general, had been the history of the Isthmus when the United States acquired possession in 1904. In April of 1904, just before the property was transferred to the United States, I was one of a party of American officials who spent a month on the Isthmus looking carefully into the then existing conditions. At this time there were some 40,000 people in the territory at present under our sanitary control, about 6,000 in Colon, about 24,000 in the city of Panama, and some 10,000 scattered in twenty-two villages along the line of the railroad. The principal business of the community was that connected with the railroad. The French were employing about a thousand men in digging on the canal, but they apparently were doing this only to hold their franchise. Business of all kinds was practically dead and the whole community was very poor and financially much depressed. The health conditions were about those common to the neighboring tropical countries. A case of yellow fever occurred now and then and malaria was pretty general. Two years before Panama had suffered rather severely from yellow fever on account of the introduction of a considerable body of troops from the interior of Colombia, but by the time we arrived this had quieted down to a few scattered cases. Colon had no water supply or sewage system, was built in a swamp, and every house had several water barrels for the collection and storing of rain water. Panama, though built on high, well-drained ground, was the same as Colon with regard to collecting of rain water. The French had some 2,000 buildings for the accommodation of their working force, scattered at various points along the line of the canal between Colon and Panama. The jungle everywhere had grown up to the railroad track, and on the whole the country presented a desolate scene of dilapidation, business depression, and financial failure. After considering the matter, it was clear that yellow fever was the disease that would interfere particularly with our success, and to which most attention would have to be given, and that the canal would probably not be completed unless we could protect our force from this disease. Yellow fever infection was evidently in Panama, and as our unacclimated force of whites was introduced from the United States I knew it would affect them just as it did the whites among the French force, unless we took measures to prevent it. The stegomyia mosquitos were everywhere in abundance, their breeding places were to be found on every hand, and the temperature was such all the year round that they could breed uninterruptedly. Malaria I also found everywhere. If this were not checked it would cause considerable mortality and a still larger rate of inefficiency among our forces, but even if unchecked would not have the moral effect that yellow fever would have. I know of no disease that causes the panic among the whites that yellow fever does. I found there was some dysentery, but not a great deal, considerable beriberi, principally located in the cities of Panama and Colon, and a great deal of Asiatic plague in the cities of Peru to the south of us. I also found considerable ankylostomiasis among the population, and these diseases might have to be considered in bringing a large force to the Isthmus. With the assistance of Dr. John W. Ross, U.S.N., and Dr. Louis A. LaGarde, U.S.A., I drew up plans for meeting these conditions. Major C. E. Gillette of the Engineering Corps of the Army drew up plans for water supplies and sewage systems for the cities of Colon and Panama. We introduced systems based, so far as they applied locally, on the plan we followed in Havana. We established health departments in each town, with functions in general similar to those of our health departments at home, such as sweeping the streets, disposing of garbage, and such general sanitary work as is done in a city of the same size in the United States, but our energies were principally concentrated upon the question of yellow fever. For this purpose the towns were divided into small districts, such that an inspector could get around to each house twice a week. This inspector looked after the premises, principally with regard to breeding of stegomyia. On his report a force would be sent to the house to make all water barrels and cisterns mosquito proof. This was done at public expense, and all other collections of water were either gotten rid of or oiled. All unacclimated persons sick with fever were treated as if they were suspected of having yellow fever. Physicians were required to report all such, and in case they had yellow fever they were either removed to a screened ward at the hospital or the houses in which they were sick were carefully screened. After the case was disposed of, the houses occupied, and all contiguous houses, were fumigated for the purpose of killing all infected mosquitos. A record was kept of all the unacclimated people in the city, and houses occupied by such people were visited daily by an inspector, and when he found any such persons sick he reported them at once to the Health Office. In addition to this, in both cities anopheles work was done, ditching, draining, and oiling in the suburbs. The Canal Zone, between Colon and Panama, was divided into some twenty odd districts and a sanitary inspector was placed in charge of each district. His duties were to attend to the general sanitary work of his district, look out for the proper care of night-soil, disposal of garbage, ditching, and draining for anopheles work, the stegomyia work around houses, isolating and screening for yellow fever, etc.

In order to prevent the introduction of yellow fever and other contagious diseases from the outside a strict quarantine was established at the two ends of the zone, Colon and Panama.

For the care of the sick employees a hospital system was established, but as it was of great importance from a sanitary point of view to get hold of contagious diseases early these hospitals were thrown open to the whole Isthmian population. This scheme has been elaborated for the past three years, until at present we have the Sanitary Department organized into the following divisions: The Hospital

Division, the Quarantine Division, the Health Division of Panama, the Health Division of Colon, the Health Division of Bocas del Toro, and the Division of the Chief Sanitary Inspector, which has supervision of health matters along the line of the canal between Panama and Colon.

The Quarantine Division maintains a maritime quarantine at the ports of Ancon, Panama, Colon and Cristobal. This division has been most efficiently organized under the supervision, first, of Dr. Henry R. Carter, and afterwards under Dr. J. C. Perry, both of the Public Health and Marine Hospital Service.

The Hospital Division was organized first by Dr. John W. Ross of the U. S. Navy, who, when he left on account of ill health, was succeeded by Dr. Henry R. Carter. It consists of two principal hospitals at each end of the line, Colon Hospital in the city of Colon, and Ancon Hospital at Panama. Colon Hospital is built on a coral reef, over which the sea washes freely, and is beautifully located as far as exposure to the breeze is concerned. Ancon Hospital is situated on the side of a mountain just back of Panama, and is most favorably located both as to beauty of view and accessibility to the breeze. We also have a convalescent hospital of some seventy beds, which is located at Taboga Island, twelve miles distant from Panama in Panama Bay. Between Colon and Panama, on the line of the railroad, we have some twenty-five hospitals, having a capacity of from ten to forty beds each. Colon Hospital has 500 beds, and Ancon 700. On account of the expected increase in force, we are at present extending Ancon Hospital with the expectation that by the end of the present year we shall have some 1,200 beds, the idea being to have the two base hospitals equipped with all modern appliances, with a competent nursing force and men more or less specialists in their various branches, so that any class of cases could be well cared for. The twenty-five line hospitals are only intended to care for the patients until they can be moved to the base hospitals, and for such of the seriously sick and injured whom it is thought not advisable to move. Last summer when our sick rate was at its maximum we were able to accommodate in these hospitals some 1,700 patients.

The Health Division of the zone is under the able management of Mr. J. A. LePrince, a sanitary engineer who did similar work in Havana, Cuba. He has under him some twenty-five sanitary inspectors and about one thousand laborers to attend to the ditching, draining, and sanitary work generally of the 40,000 people scattered along the line of the canal between Panama and Colon.

The Health Office of the city of Panama is under Dr. John H. Purnell, who employs some 200 men in street cleaning, ditching, draining, garbage collecting, and sanitary work in general of the city of Panama.

The Health Office of Colon is under the charge of Dr. E. H. Wheeler, who employs about 200 men in draining, ditching, and brush cutting in the swamps in which Colon is built, and attending to any other matters pertaining to the health work of the city.

As there was some yellow fever last year at Bocas del Toro, the President of the Panaman Republic appointed one of the officials of the Sanitary Department as Health Officer of Bocas. We employ some twenty men at this small port doing general sanitary work there.

This work has so far accomplished very satisfactory results. Yellow fever has apparently been entirely eliminated. We have had only one case on the Isthmus during the last fifteen months. A recent critic of Isthmian sanitary affairs has stated that this is merely accidental; that there have been times in the past when Panama was free from yellow fever for several years in succession, and that we would certainly have an epidemic of yellow fever some time in the near future which would stop the construction of the canal. It is true that Panama has been free from yellow fever for several years in succession at various periods in the past. This is the case in all small tropical cities subject to yellow fever, and it occurs for this reason: For one cause or another the native population, wherever yellow fever exists continuously, becomes immune to yellow fever. This is a well-recognized fact everywhere. Such being the case, it is the nonimmunes, or strangers, who keep up the disease. Take a place of 25,000 or 30,000 inhabitants such as Panama, and in ordinary times the strangers who settle in the community are comparatively few. They soon all have yellow fever and then the disease dies out; but a few strangers continue to come in and in the course of a few years quite a number accumulate. Then when yellow fever is introduced from the outside enough nonimmune material is present to keep the disease going for a time, but if for any reason a large number of strangers come in every year then the epidemic of yellow fever becomes continuous and keeps up as long as the strangers continue to come in. This has been exemplified at pretty much every town where yellow fever has prevailed in the tropics. At Rio de Janeiro yellow fever has prevailed continuously for the last fifty years, due to the large foreign immigration constantly coming into the city. At Havana it was present for considerably over one hundred years continuously from the same cause. At Panama the intermittent condition was well exemplified. In ordinary times they would have yellow fever for two or three years and then be free of it for two or three years, but whenever they had a considerable foreign immigration yellow fever was continuous. Thus yellow fever was continuous all during the construction of the railroad and again to a greater extent during the work on the canal by the old French company. The French, of course, brought over a large number of European employees. During the construction by the old company, from 1881 to 1889, considerable numbers of these European employees came over every year. This continuous influx kept yellow fever going during the whole time of construction by the old French company. In Ancon Hospital alone the old hospital records show that 1,200 deaths occurred from yellow fever during this period, and when it is remembered that these came from a force which at no time exceeded 3,000 men, one can appreciate what a heavy tax it was upon this force. The French during all these years, from 1881 to 1889, with a white nonimmune force which had as its maximum 3,000 men, did not pass a month in which one or more deaths from yellow fever did not occur in this force. With a nonimmune force four times as large, for we now have over 10,000 whites, if we include women and children, we have passed fifteen months with not a single case of yellow fever. The case which occurred in May, 1906, was in a man not an employee of the Commission. There never has been a time in the whole history of the Isthmus, from the time it was discovered by Columbus up to the present time, when there have been anywhere near as many men subject to yellow fever present on the Isthmus as there are now. The disease was on the Isthmus when we came in April, 1904, and remained with

us up to December, 1905. During this time we were constantly increasing our nonimmune population. I therefore feel confident that the same methods which eliminated yellow fever from Havana have accomplished the same results at Panama. I do not believe that our present freedom from yellow fever is in any way accidental. Our work here, I think, is another evidence of the great obligation mankind is under to the Army Board, of which Major Walter Reed was chairman and Lazear and Carroll were members, for establishing the fact that the stegomyia mosquito was the transmitter of yellow fever. Without this knowledge I do not believe we could have done any better than did the French, and, judging from the alarm that was caused by the comparatively mild epidemic which we had among our employees in 1905, I doubt, in case we were having the same amount of yellow fever that the French had, whether we could keep a sufficient force of white employees here to carry on the work. And even if we could keep white employees here under such circumstances, I doubt whether public sentiment in the United States would allow the canal to be built at such a sacrifice of human life.

In this connection I would like to call attention to the little credit the French white employees get for the heroism which they exhibited in coming to Panama. Every Frenchman who came to Panama knew that he was going to have yellow fever, and he also knew that every second man would die with it. To face such chances took no little courage.

The most useful result of our work, I think, however, as far as the canal work is concerned, is the extent to which malaria is held in check. While yellow fever was the fatal disease to the French, it did not affect their sick rate to a very great extent; that is, if you take their sick report day by day you would find thirty to forty men sick from yellow fever and 400 or 500 sick from malarial fever, so that malaria was causing eight or ten times the financial loss that yellow fever did. Malaria is still with us the principal cause of sickness; I mean we have a good many more men every day sick from malaria than from any other one cause, but our whole sick rate is very small. Last month (March) 1907 our sick in hospitals amounted to less than 20 per 1,000, and our total excused on account of sickness from all causes to about 23 per 1,000; that is, out of every thousand men we had absent on account of sickness in hospitals, their homes, and everywhere, an average every day during the month of twenty-three men. This is as small a rate as we would probably have if we were working in the United States, and I doubt if we are ever able to obtain a smaller rate than this. I am inclined to think that our sanitary work, as far as the sick rate is concerned, has reached its maximum efficiency, and that all we can expect to do for the future is to hold it up to that rate, though to keep this rate a great deal of work will have to be done.

The good water supply furnished all our employees has kept dysentery from being troublesome, so that I think we can claim that our sanitary work has directly controlled malaria, yellow fever, and dysentery, the three tropical diseases to which we are liable. Bubonic plague is pretty firmly established in some of the Peruvian ports to the south of us, and we have been very anxious on this subject during our occupancy of Panama. In the summer of 1905 two cases of plague occurred at La Boca, the Pacific terminal of the railroad and canal. Both men had been living there for some time and evidently contracted the disease there, but a very careful isolation and disinfection of the town of La Boca, under the supervision of Dr. J. C. Perry, Chief Quarantine Officer, eradicated the disease at this point, and we have had no cases since. Beriberi was quite prevalent on the Isthmus during our first year, but it is now entirely confined to the city of Panama, and much reduced in numbers.

I think, therefore, that the United States authorities can fairly make the following claim for their sanitary work: That when they got control of the Isthmus in May, 1904, the territory along the route of the canal was in its normal condition as to health. It was overgrown by a dense tropical jungle; the natural conditions were everywhere ideal for breeding stegomyia and anopheles mosquitos. The region was inhabited by a considerable population, which was very poor, as the result of the failure of the French canal company and the recent bloody and destructive war which had involved the whole country for some three years. Malaria, dysentery, and smallpox were prevailing among these people about as they would anywhere in the tropics under similar conditions. Yellow fever infection was present in both Panama and Colon. In fact, the conditions were more favorable for producing a high mortality upon the introduction of a large force than they had been at any time in the past. Into this region the Canal Commission has introduced the largest force ever before present on the Isthmus, some forty thousand persons, ten thousand of whom are white nonimmunes. Yet the sanitary measures taken by the United States during the period of the introduction of this unprecedented force have been such that yellow fever has disappeared, malaria been held in check, and the total sick rate in this force during the month of March, 1907, was only 23 per 1,000.

I think that there can be no reasonable doubt that there is a direct relation of cause and effect between the sanitary measures taken by our Government and the present health conditions on the Isthmus.

Ancon, C. Z.

A NEW TYPE OF ATAXIA.

By M. ALLEN STARR, M.D., LL.D.,
NEW YORK.
PROFESSOR OF NEUROLOGY, COLUMBIA UNIVERSITY

Ataxia is usually a symptom of either locomotor ataxia, or of cerebellar disease, or of disease of the tracts leading to and from the cerebellum as they pass through the medulla, pons, and cruri cerebri. It occasionally develops as a secondary symptom in ophthalmoplegia, when double vision misleads the patient as to the position of objects he is about to step on, and it occasionally appears as a temporary symptom under certain toxic conditions, as in alcoholic mulitple neuritis.

In the following patient the ataxia cannot be placed in either of these categories. The patient, a man of sixty-six years of age, whose family history is good, and who has been a healthy, strong, and active lawyer all his life, began to suffer about eight months ago from deafness, which has gradually increased and is shown by appropriate tests to be a nerve deafness, probably due to a progressive atrophy of the auditory nerve. Along with this symptom there has gradually developed a condition of static ataxia. He feels unsteady on his feet, he finds it difficult to balance himself when standing or walking, and he staggers greatly unless supported by the aid of an attendant and the use of a cane. This staggering has gradually increased little by

little as his deafness has increased, so that at present he is unable to walk without the assistance either of a cane or of an attendant. On rising from a chair he sways and would fall if not supported. In walking, his feet are placed irregularly, the steps being of uneven length and the body swaying without any special tendency to fall in any one direction. His gait is that of cerebellar disease rather than of locomotor ataxia, as there is none of the stamping of the feet or throwing of the legs in irregular directions. When seated there is absolutely no indication of any incoordination either in the movement of the legs or of the arms. His writing is perfectly good, and there is no trace of ataxia excepting in the act of standing and walking. It is impossible to stand with his eyes closed, but while this lack of balance is very marked, it is not attended by any vertigo, and it appears to be the only symptom that is present. His ocular muscles are normal and there is nothing abnormal in the action of his pupils. His vision is good and optic discs normal. He has never suffered from vertigo, vomiting or any evidence of primary cerebellar disease. His knee jerks are normal and he has never had any lightning pains or difficulty with the action of his bladder. There is no paralysis or disturbance of sensation in any part of the body.

Under these circumstances, it seems probable that along with the atrophy of the cochlear division of the auditory nerve, which has produced his deafness, there has been a progressive atrophy of the vestibular division of the auditory nerve, cutting off from his brain those impulses from the labyrinth which are necessary for the preservation of balance. It is well known that in labyrinthine disease of sudden onset, as described by Méniere, there is very great dizziness and consequent ataxia of movement and inability to walk. It seems possible, therefore, that in a progressive atrophy of the nerve the disturbance of equilibrium may appear as a symptom.

In the absence, then, of other evidences of disease, it seems warrantable to ascribe the ataxia to a progressive atrophy of the vertibular division of the auditory nerve.

Rossi[1] has recently described a primary parenchymatous atrophy of the cortex of the cerebellum present in old persons between fifty and seventy years of age and advancing progressively. The symptom in this condition is a gradually developing ataxia of movement without other symptoms. He cites three cases in support of his statements, with one autopsy.

A. Thomas[2] has described an atrophy of the inferior cerebellar peduncles and of the olivary bodies as a result of chronic arterial sclerosis, producing a gradually increasing ataxia. But in this case there were other symptoms of bulbar disease. Dejerine[3] and Thomas have also described an atrophy of the olivary bodies and pons with cerebellar tracts, causing ataxia, but there were also other symptoms indicative of bulbar disease. In our patient, however, there were no signs of any bulbar affection, which enables us to exclude such a lesion in his case, and although his age was such as to warrant the supposition of some beginning arterial sclerosis, yet the absence of cerebral symptoms, the unusual activity of his mind, his quiet sleep, and the absence of high-tension pulse, all make it unlikely that any serious atrophy of the brain from arterial disease can be in progress. The case is presented as an interesting instance of ataxia of auditory origin.

THE DIAGNOSTIC VALUE OF THE CYSTOSCOPIC EXAMINATION IN CARCINOMA CERVICIS UTERI.*

By BENJAMIN S. BARRINGER, M.D.,

NEW YORK,

ATTENDING SURGEON, CORNELL UNIVERSITY DISPENSARY, GENITO-URINARY DEPARTMENT.

In this paper I have attempted to determine what constitutes the complete cystoscopic examination in carcinoma cervicis uteri; to classify the various findings in order of their importance, and to indicate in these cases the diagnostic value of such an examination. Fifteen cases have been methodically examined. In each of these cases operation had been refused because of the extent of the growth.

The reasons why I have chosen inoperable cases are: (1) In carcinoma confined to the cervix, and manifestly operable, there is no question of bladder involvement. Only in those cases where the growth invades the vaginal wall and extends toward the bladder does the question of bladder involvement arise. (2) In such cases pronounced inoperable I had hoped to find some cases on the borderland between operable and inoperable. In reality such was the case, four of the fifteen being borderland cases. (3) Finding such borderland cases, I had hoped to determine the transitional steps between operable and inoperable cases, as shown by the cystoscopic examination.

The various modes of extension of the carcinoma into the broad ligaments, into the vagina, into the uterosacral folds, and into the rectum, may all be fairly accurately determined by palpation with one exception, namely, where the carcinoma extends anteriorally toward the bladder. When this occurs the extent of the bladder involvement and the condition of the vesicovaginal septum cannot be estimated by palpation. Winter (Lehrbuch der Gynäkologische Diagnostik) says: "These alterations [*i.e.* those of the bladder] appear to me to have value in judging the condition of the vesicovaginal septum. That portion of the parametrium cannot be accurately palpated, and even with examination by means of a catheter introduced into the bladder only the thickness of the remaining tissue layer may be accurately judged, but not the condition of the septum.

As to the necessity for the cystoscopic examination, Kelly says (Operative Gynecology, Vol. II., page 318): "In the early stages, when the cervix is not much enlarged and the uterus is probably movable, and a rectal examination shows that the broad ligaments are probably clear, the operation may be undertaken without any further investigation. Later, when the cervix is more extensively diseased, the minutest possible examination should be made before proceeding to operation."

In a recent article, Sampson says ("The Relation Between Carcinoma Cervicis Uteri and the Bladder," *Johns Hopkins Hosp. Bulletin*, May, 1904): "The nineteen instances of accidental injury to the bladder in 157 hysterectomies for carcinoma cervicis uteri emphasize the close anatomical relation between the two organs, and that the extension of the disease soon involves the bladder."

The literature on this subject is not extensive. I shall only mention the results of the work of Winter

*Read before the Eastern Medical Society, Gynecological Section.

(quoted by Caspar, Cystoskopie, 1905, page 318). He arrives at the following conclusions as the result of the examination of 43 cases of uterine carcinoma, 9 of which were recurring: "When the carcinoma approaches the bladder wall, the nearest portion is simply pushed forward, and we may have marked displacement of the bladder wall; then the mucous membrane over the affected place gradually begins to swell and to lie in thick folds which run parallel or appear with deep valleys. Sometimes the folds are bullous edematous. One often finds the larger vessels deeply injected, sometimes ecchymoses." In this series he has seen only two cases of carcinoma of the bladder wall. The bladder alterations develop only when the carcinoma approaches the bladder wall from the anterior and lateral portions of the cervix and vagina. With entirely free parametrium, and with (from general appearances) operable carcinoma, he never found bladder alterations, but in these cases the carcinoma was never limited to the anterior cervical wall. The bladder alterations occur very late, and, as a rule, only with inoperable carcinoma. Winter continues: "When one compares the alterations appearing with carcinoma to those which appear with paravesical inflammatory processes, it

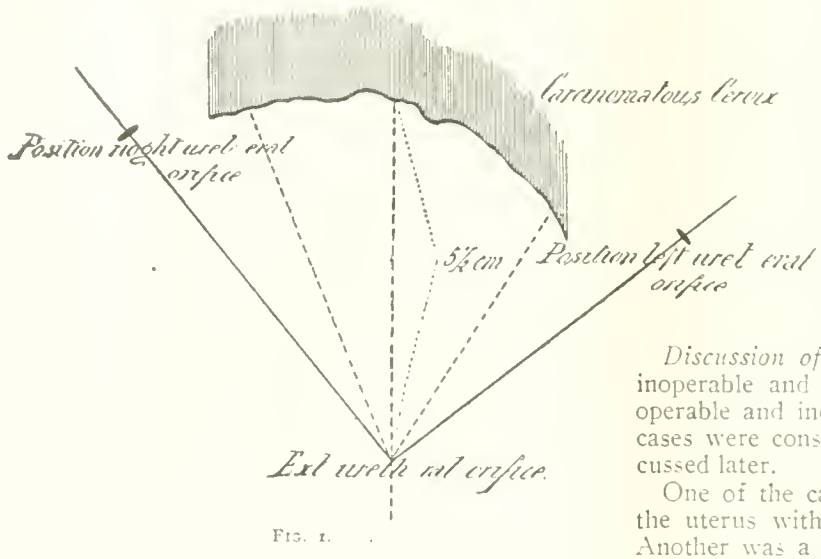

Fig. 1.

is found that, except in the rare cases of carcinomatous nodes of the bladder wall, they are similar; they depend in both cases upon the swelling of the mucous membrane caused by circulatory disturbances."

Kustner (Lehrbuch der Gynäkologie, page 230) quotes Winter and Zangemeister, and says that W. Hirts, after the examination of a large number of cases from his [Kustner's] clinic, confirms the results of Winter and Zangemeister, and adds that the conditions found with carcinoma and those of inflammatory processes are identical, and are only to be used in diagnosis when their etiology has been established.

In the cystoscopic examination of the fifteen cases the following routine has been carried out:

1. In the vaginal examination have been observed: (*a*) The portion of the cervix involved, and any encroachment on the vaginal wall. (*b*) The condition of the parametrium.

2. When the anterior vaginal wall has been involved, it has been attempted to find the relation between this involvement and the bladder. The trigone and its posterior boundaries, the ureteral openings, are the most constantly fixed portions of the bladder; also because of their anatomical position, the trigone and the vesical portion of the ureters are almost always the first parts of the bladder to be involved in the growth. Any distortion of the trigone and of the ureters, aside from simple elevation or depression, may be very accurately estimated by measuring the distance from the meatus urinarius externus to either ureteral orifice.* Using the same common point to measure from, the meatus urinarius externus, we may measure the distance in the vagina to where the growth involves the vaginal wall. These measurements give us roughly two triangles, both having their apex at the meatus urinarius, the base of one formed by the posterior limit of the trigone, and the base of the other limited by the growth. The relation between the bases of these triangles indicates fairly accurately the proximity of the carcinoma to the bladder trigone and the vesical portion of the ureters (Fig. 1).

3. Any limitation of the up and down mobility of the cystoscope in the urethra, and in conjunction with this the position of the trigone, whether normally placed or elevated. Normally, the up and down mobility of the cystoscope in the female urethra is about 90°, and the general trend of the urethra very slightly upward (Fig. 2). With encroachment of the carcinoma this mobility becomes much restricted, and may not be more than perhaps 35°, and with this restriction the general direction of the urethra always tends upward (Fig. 3). The elevation of the trigone varies directly with this restriction and upward trend of the urethra.

4. Any conditions within the bladder itself indicating involvement of the bladder by the growth.

Discussion of Cases.—In the 15 cases, 11 were inoperable and 4 were on the borderline between operable and inoperable. The reason why these 4 cases were considered borderline cases will be discussed later.

One of the cases was carcinoma of the body of the uterus with slight enlargement of the cervix. Another was a carcinoma extending to the cervix, but probably primary in the vagina. The remaining 13 were carcinoma of the cervix.

In these 13 cases the vaginal examination was as follows: (*a*) In one of the cases the anterior vaginal wall was not invaded. In the remaining 12 the anterior or lateral vaginal walls were invaded, the carcinoma extending along the vaginal wall in 2 of the cases to within 2½ cm. of the meatus urinarius externus; 3 within 4 cm.; 5 within 5 cm., and the remaining, distances varying from 5 cm. to 10 cm. The vaginal carcinoma extended to within ½ cm. of the meatus urinarius externus. (*b*) In all of the borderline cases the parametrium was not markedly involved. In each of the remaining cases the para-

*These measurements were made by means of an indirect cystoscope. When the ureteral orifice was directly in the center of field and in focus, the length of the portion of the cystoscope within the urethra and bladder was taken. This measurement is fairly accurate, as I have proved by experiment upon a clay phantom, the maximum variation from the true measurement being but three millimeters. The methods of Kelly and Sampson in ascertaining these measurements by means of the Kelly cystoscope would perhaps be applicable to these cases and would be perhaps more exact with normal or fairly normal bladders, but with the extreme distortion of the trigone in some of the cases I imagine that it would have been impossible to have found the ureteral orifices at all with the Kelly instrument.

metrium was involved, and, as a rule, markedly involved.

Relation Between the Involvement of the Anterior Vaginal Wall and the Trigone and Ureteral Orifices.—I soon found that the position of the ureteral orifices and their relation to the meatus urinarius externus was but little affected by the carcinomatous encroachment, even when this was extensive. The comparison of Figs. 1 and 4 demonstrates this. In Fig. 4 the carcinoma is but 3½ cm. from the meatus urinarius externus, while in Fig. 1 it is 5½ cm. distant. The only ureteral opening that could be found in the case which Fig. 4 represents is more normally placed than either of the ureteral openings in Fig. 1.

In the majority of the cases, therefore, these measurements were not taken, being of no value.

Direction of Urethra and Elevation of Trigone.—In the 4 borderline cases there was practically no limitation of the up and down mobility of the cystoscope in the urethra; the general direction of the urethra was normal, and the trigone not elevated.

In none of these cases was the parametrium of both sides extensively involved, although in 2 of the cases the parametrium of one side was considerably thickened.

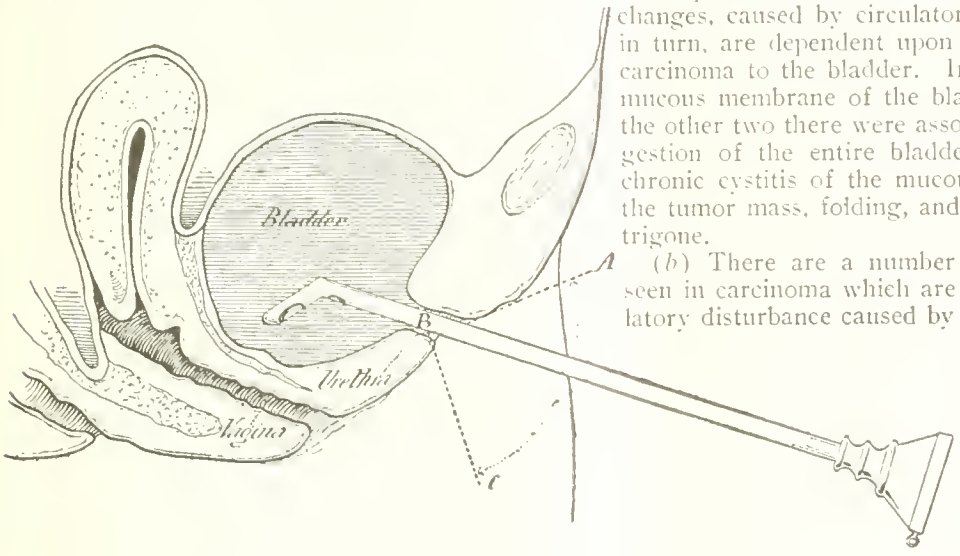

Fig. 2.—Cystoscopy: A B C, angle of cystoscopic mobility.

In the remaining eleven inoperable cases, excluding those of corporeal carcinoma and vaginal carcinoma, the limitation of cystoscopic mobility in the urethra was marked; there was a decided upward trend to the urethra, and the trigone was decidedly elevated. There was one exception to this, where the trigone and urethra were normal and the parametrium of one side only was considerably involved.

In the vaginal carcinoma, although the entire vault of the vagina was involved, the carcinoma extending to within ½ cm. of the meatus urinarius externus, the trigone was normally placed and the urethra normal, neither the cervix nor the parametrium being involved.

In these 9 cases the carcinoma was situated at varying distances—from 2½ cm. to 6 cm.—from the meatus urinarius externus.

These three conditions, *i.e.* the limitation of mobility of the cystoscope in the urethra, the upward trend of the urethra, and the elevation of the trigone, seem to be caused by, and are present with marked enlargement of the cervix, more or less extensive involvement of the anterior vaginal wall and the parametrium of both sides, and unquestionably involvement of the vesicovaginal septum. So far as I have observed, these occur only in inoperable cases. The cystoscopic examination, however, adds nothing to the knowledge that may be gained by palpation.

Changes in the Bladder.—(*a*) Tumor masses encroaching upon the bladder or retractions of the bladder caused by the adherent tumor. In one of the borderline cases in which the left parametrium was much infiltrated and the right hardly at all, just behind the left ureteral orifice there was a marked depression or pit which could not be brought into focus. This was taken to be a retraction of the bladder caused by adherence of the growth to the bladder. The bladder was otherwise normal. Operation in this case would be undertaken much more intelligently with the cystoscopic examination in mind. The surgeon would know where to expect trouble in freeing the growth from the bladder.

In three of the inoperable cases there were tumor masses encroaching upon the bladder wall, indicating adherence of the carcinoma to the bladder; in these three cases the cystoscopic findings simply emphasized the futility of operation.

These encroachments or retractions of the bladder still further indicate involvement of the vesicovaginal septum, when associated with other bladder changes, caused by circulatory disturbances which, in turn, are dependent upon the attachment of the carcinoma to the bladder. In two of the cases the mucous membrane of the bladder was normal. In the other two there were associated in one case congestion of the entire bladder, and in the other chronic cystitis of the mucous membrane covering the tumor mass, folding, and chronic cystitis of the trigone.

(*b*) There are a number of bladder conditions seen in carcinoma which are dependent upon circulatory disturbance caused by attachment of the carcinoma to the bladder, and which are entirely similar to those seen in different vesical and paravesical inflammations. These are: (1) folding and swelling of the bladder mucous membrane, giving the appearance of ridges and valleys; (2) varicosities of the bladder vessels; (3) submucous hemorrhages; (4) congestion of the bladder; (5) cystitis; (6) bullous edema.

These conditions appeared in the series with the following frequency, either alone or combined: Congestion, 3 times; cystitis, 3; hemorrhages, 2; folding of the mucous membrane, 2; varicosities, once; bullous edema, none.

Congestion or cystitis unassociated with other bladder changes does not mean, as far as I have been able to observe, involvement of the vesicovaginal septum.

A condition resembling cystitis is not infrequently seen. That is, the urine is clear; the bladder washings contain no flakes; the portion of the bladder nearest the growth gives a cystoscopic picture fairly typical of cystitis, *i.e.* swelling, folding of the mucous membrane, no vessels seen. This is probably always caused by chronic congestion dependent upon involvement of the vesicovaginal septum.

Aside from the cause, the importance of recognizing the presence of a cystitis is extremely important. Sampson says in the article above quoted: "The frequency of cystitis following these more radical operations [hysterectomy for carcinoma cervicis

uteri] is another indication of the close relation between carcinoma cervicis uteri and the bladder, and indicates that as a result of the operation the bladder is left in a condition of lowered local resistance, and that this condition is responsible for the cystitis

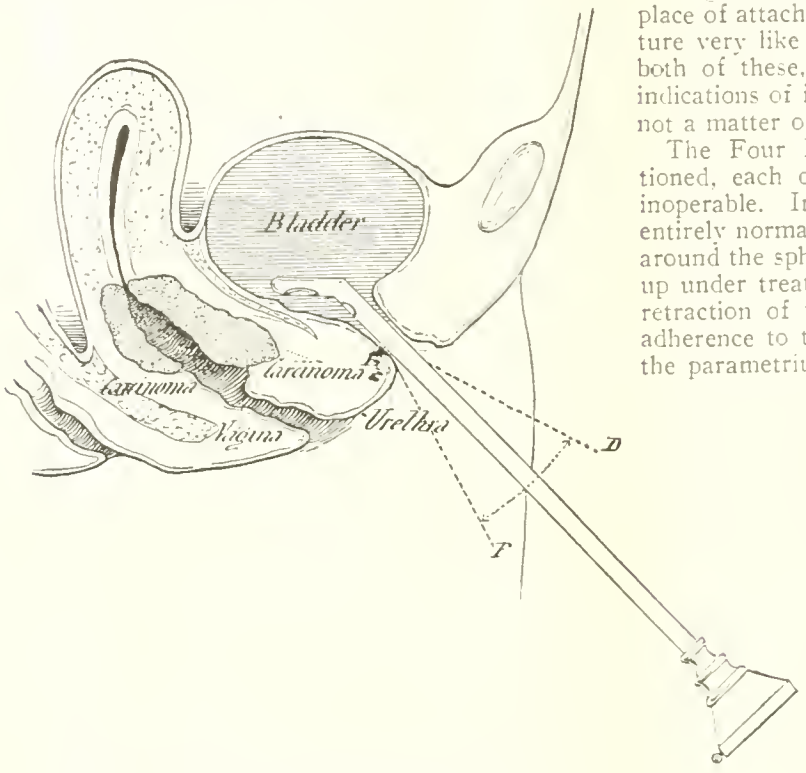

Fig. 3.—Cystoscopy; D E F, angle of cystoscopic motility.

which may later develop, as maintained by Wertheim in the report of his second series of 30 cases."

In 16 cases observed by Sampson in which the radical operation for uterine carcinoma was performed, cystitis (acute) occurred in 12, resulting in renal infection and death in 2 cases. How much more likely is it to occur if an old chronic cystitis be present. And yet how many radical operations are performed when the only means of estimating the bladder condition is through the laboratory examination of an uncatheterized specimen of urine.

As to the varicosities, in the one case in which these were observed there could be no question as to their indicating adherence of the carcinoma to the bladder and resultant venous engorgement. The vessels were large, often occupying half of the cystoscopic field, appearing around the circumference of the sphincter and radiating posteriorly. If these occur in a less marked degree, perhaps only one or two small varicosities around the sphincter, they mean nothing.

In summing up, tumor masses encroaching upon the bladder, swelling and folding of the mucous membrane, marked varicosities may all mean involvement of the vesicovaginal septum. When these appear in conjunction with one another, as they frequently do, the diagnosis is more certain.

(*c*) In 4 of the cases the bladder was carcinomatous. In these cases the carcinoma appeared as irregular tumor masses of the base of the bladder, reddish-yellow, perhaps hemorrhagic, easily bleeding, no vessels perceptible, or as grape-like masses. A description of this latter appearance, from my notes on one of the cases, is as follows: "At the base of the bladder covering an area of perhaps 9 cm. by 2½ cm., was a condition which resembled exaggerated 'bullous edema.' Large blebs, each covering one-half or three-fourths of the cystoscopic field; yellowish-red in color, translucent, no vessels. Directly next to the tumor mass normal mucous membrane appeared." Any combination of the above may occur. There are cases where the folding and swelling of the mucous membrane at the place of attachment of the carcinoma presents a picture very like carcinoma of the bladder itself. As both of these, however, usually occur in and are indications of inoperable cases, the differentiation is not a matter of importance.

The Four Borderland Cases.—As before mentioned, each of these cases had been pronounced inoperable. In two of these cases the bladder was entirely normal. In one there was a chronic cystitis around the sphincter, which could have been cleared up under treatment, and in the fourth there was a retraction of the bladder wall caused probably by adherence to the carcinoma. In three of the cases the parametrium was but slightly involved, and in the third the parametrium on one side was decidedly thickened.

In two of the cases the carcinoma extended along the anterior vaginal wall to within 6½ cm. of meatus urinarius externus. In the other two the anterior vaginal wall was not involved.

Operation upon these cases would have involved perhaps extensive dissection of the parametrium; sacrificing a considerable part of the vagina, and perhaps a portion of one or the other ureter and transplantation into the bladder, or nephrostomy; but the bladders were practically normal, as far as could be determined, not adherent to the growth, so decreasing the dangers of infection. If a more careful examination had been made the cases would probably have been operated upon. They should at least have had the chance of operation.

Conclusions.—1. In the early stages of carcinoma

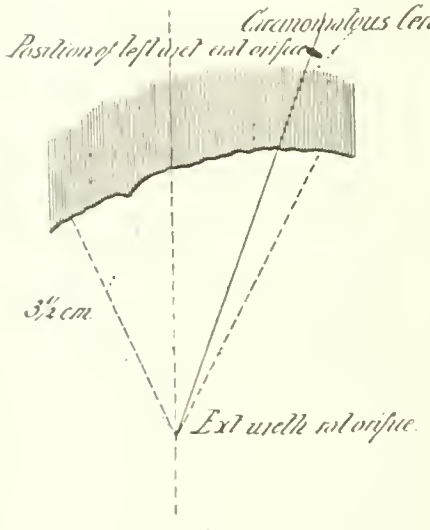

Fig. 4.

cervicis uteri, where the carcinoma is probably confined to the cervix, the cystoscopic examination is of little use other than to determine the presence or absence of a cystitis.

2. In all cases of carcinoma cervicis uteri involving at all the anterior or lateral vaginal walls, the most accurate means of ascertaining the condition

of the vesicovaginal septum is by means of the cystoscopic examination.

3. The cystoscopic examination includes (*A*) Estimation of the direction of the urethra and the position of the trigone, marked elevation of the trigone meaning practically always inoperable carcinoma; (*B*) Conditions within the bladder; [1] Tumor masses encroaching upon or causing retraction of the bladder; [2] The alterations of the bladder which are similar to those occurring with vesical or paravesical inflammations. These are (*a*) folding and swelling of the bladder mucous membrane, (*b*) varicosities of the bladder vessels, (*c*) submucous hemorrhages, (*d*) congestion of the bladder, (*e*) cystitis, (*f*) bullous edema. The most important among these conditions within the bladder which indicate involvement of the vesicovaginal septum are: Tumor masses encroaching upon or causing retraction of the bladder; folding and swelling of the bladder mucous membrane; marked varicosities.

3. Those alterations which are unquestionably caused by the carcinoma. Alone under this head stands carcinoma of the bladder.

4. Aside from ascertaining the condition of the vescovaginal septum, the cystoscopic examination is important in revealing any inflammatory conditions of the bladder, as cystitis, etc., which if unrecognized and untreated before operation might be the determining factor in causing the failure of the operation.

5. Finally, this examination becomes progressively more important as the growth extends, and the nearer it approaches the borderland between operative and nonoperative.

I am indebted to Dr. E. J. Gallagher and to the Superintendent of the House of Calvary for many courtesies extended and for the use of many valuable cases.

THE INTERNAL AND EXTERNAL REMEDIES IN URINARY DISEASES AND THEIR COMPARATIVE VALUE.*

By C. R. O'CROWLEY, M.D.,

NEWARK, N. J.

CLINICAL ASSISTANT, GENITOURINARY DEPARTMENT, NEW YORK POST-GRADUATE HOSPITAL, MEMBER OF THE AMERICAN UROLOGICAL ASSOCIATION.

WITHIN the past decade the medical therapeutics of urinary diseases has progressed so rapidly and has suffered so many fluctuations that it has been my object in preparing this paper to bring to your notice the comparative value of the drugs more commonly used in urology, especially contrasting the old and the new. My conclusions have been drawn largely from the use of the various preparations both in my office work and in the clinic. Included in this paper will be the consideration of the drugs used and found of value by competent observers in treating diseases of the urinary tract, while such therapeutic agents as rest, diet, baths, electricity, etc., will not be considered in order to avoid a too lengthy paper.

Diluents.—To begin with the internal remedies, we might speak first of the diluents, and water, no matter whether in an admixture or alone, is a true diluent. It is therefore useful in nearly all the urinary diseases, as a good diuretic and solvent, and, when taken hot, has a diaphoretic action.

Of the many mineral waters used it is doubtful whether the results claimed are due to the drinking of the water at the spring or to other agencies such as travel, change of mode of life and of habits and of doctors, although the strong saline-aperient waters, as Carlsbad, Friedrichshall and Hunyadi and some of the lithiated spring waters have quite a reputation in the treatment of the uric acid diathesis and vesical calculous affections.

The acids which are used to counteract the morbid alkalinity of the urine are few in number. Very dilute nitrohydrochloric acid, in doses of five to twenty drops, is of service in the treatment of phosphaturia. Benzoic acid and its salts occupy a prominent position, particularly in genitourinary diseases. They are used to render the urine acid, especially when there are alkaline concretions in the bladder, as phosphatic calculi. In acute, subacute, and chronic cystitis they undoubtedly prevent and moderate alkaline fermentation of urine in the bladder; sodium benzoate being our choice of the group. Lithium benzoate is intended for use solely in the uric acid diathesis. Salicylic acid is used very little, having a tendency to irritate the kidneys and is apt sometimes to produce hematuria and albuminuria. Phenyl salicylate, or salol, obtained from salicylic acid, will be spoken of under the more appropriate heading of antiseptics.

The alkalies or neutralizers are employed to lessen the acidity of the urine. A point worth remembering about the giving of potassium bicarbonate is that, if given on an empty stomach, it enters the blood unchanged, meets the neutral phosphate of sodium, and is decomposed and forms acid phosphate of sodium, thus rendering the urine more acid. On the other hand, given on a full stomach, the acids of the gastric juices decompose it, increasing the alkalinity of the blood and rendering the urine less acid. The salts of potassium with vegetable acids (acetate, citrate, tartrate, etc.) enter the blood as such, are decomposed there, forming free carbonic-acid gas, form alkaline carbonates, and are eliminated as such, alkalinizing both blood and urine. They are diuretics also, increasing the urinary water and solids, and by causing increased oxidation, decrease the amount of uric acid. Of the mineral salts potassium nitrate is a most active diuretic. Potassium acetate is the most certain diuretic, but for long-continued use it is best to employ the citrate, especially when aiming to alkalinize the urine. The untoward effects of the citrate are very slight even when used for a long time.

The sodium salts are much weaker in their action than the salts of potassium, being diffused more slowly. They are not absorbed or excreted so readily, and possess a much diminished diuretic action. The lithium salts, particularly the citrate, are of value sometimes in the treatment of stone and the uric acid diathesis.

Antiseptics.—Of the urinary antiseptics, hexamethylene-tetramine is by far the best, and is invaluable in acute and chronic inflammatory diseases of the urinary tract, in acute, subacute, and chronic cystitis, in pyelitis and pyelonephritis. In bacteriuria it has no equal. Especially good results have been obtained from its use in the uric acid diathesis as it diminishes the uric acid excretion and develops urisolvent properties in the urine. Casper found that the drug caused complete cessation of all visible phosphatic excretion in a case of phosphaturia.

The salicylic ether of phenol, called salol, is another useful remedy and is an efficient disinfectant in subacute cystitis, its component parts being ex-

*Read before the New York Reno-Vesical Society, January 30, 1907.

creted with the urine, hence coming in contact with the vesical mucous membrane for a considerable length of time. Salol should not be given when there is any disease of the kidneys, because of the carbolic acid of its constitution.

Sodium benzoate, already mentioned above as an antacid, may be justly styled a urinary antiseptic, being very mild in its action and has the advantage that it can be used for a considerable length of time with little or no untoward manifestations. Cystitis is its best field of employment. Methylene blue has been classed as an antiseptic and used successfully in chronic cystitis.

Sedatives and Astringents. — The urinary and vesical sedatives and astringents when taken internally act through the medium of the urine in a sedative manner upon the whole extent of the urinary tract. They alleviate pain, decrease the bladder irritability, and lessen the desire to micturate. The antispasmodics may also be grouped under this heading.

Opium and its alkaloids are unequaled in the symptomatic treatment of renal colic, retention of urine, and pain due to vesical calculi. Belladonna is the best antispasmodic we have, and invaluable in the trigonitis of cystitis. The bromides, hyoscyamus, cannabis indica, are good in lessening the irritability of the nerves.

The mucilaginous drinks, such as barley-water or linseed tea, and the astringents like buchu, uva-ursi, and pareira, lessen the irritation due to chronic cystitis, and such antiseptics as copaiba and cubebs act in the same manner, being carried by the urine to the bladder. Pichi, an unofficial preparation, has done good service in the hematuria and pain of renal calculus.

Antihemorrhagics.—The internal administration of antihemorrhagics is of little value. The extract of suprarenal glands, ergot and iron are the ones most commonly used. Gelatin is employed subcutaneously, but as it is almost impossible to obtain sterile gelatin, and as the tetanus bacillus and other pathogenic germs grow readily in commercial gelatin, the method is not very popular. Calcium chloride has been used internally in hemophilia, being given for a few days prior to an operation on the urinary tract. The injection of fresh human serum subcutaneously has been tried very recently by Weil of Paris for preventing bleeding in hemophilic patients. These methods may be of importance in operating upon "bleeders" with urinary diseases.

Tonics and Alteratives.—The tonics and alteratives are brought into use very frequently in urinary diseases, particularly in the chronic and complicated cases. In tuberculosis of any portion of the urinary tract, such drugs as guaiacol carbonate, cod liver oil, iron, quinine, and strychnine are indicated. In fact, most of the tonics in general use. In chronic cystitis and incontinence of urine due to want of muscular tone buchu has proven of great value.

Diuretics.—Although many of the foregoing remedies have a more or less diuretic action, I think it would not be amiss to speak of a few direct diuretics. Digitalis, though frequently used in Bright's disease, is an unsuitable diuretic. In the acute form, when used alone, it aggravates the condition, while in chronic nephritis it is still more injurious, owing to the increased arterial tension set up in the renal circulation. In such cases it is better to use a diuretic pill made up of digitalis leaves in powder, calomel, and squill, a grain of each made into pill with extract of hyoscyamus. Digitalis is one of the most efficient diuretics we have, but it must be used with much discrimination. Digitalis, in small repeated doses, acts as a diuretic, not in virtue of its effect on the kidney itself, which is practically nil, but because of the increased arterial pressure it produces. In dropsy, in which it is principally used, there is a stasis in the renal circulation. The drug, by increasing blood pressure, causes an excess of urine to be secreted and thus relieves the dropsy. We must remember, however, that an overdose may cause a spasm of the renal vessels and thus produce suppression and cumulative effects of poisoning. For these reasons the infusion, which contains a small dose of the drug, is preferred by many as a diuretic preparation, though the tincture, given in small amounts, is preferable, being more staple. When there is disease of the renal tissue, as shown by casts, albumin, etc., digitalis should be combined with more active diuretics as caffeine or squill. In giving digitalis it is important to watch the pulse and the heart's action as well as the quantity of urine. Thus we can detect at once suppression or exaggerated tension. We must remember that digitalis is contraindicated in arteriosclerosis and fatty hearts.

Sodiotheobromine salicylate is supposed to be a very good diuretic and is practically a theobromine rendered soluble by sodium salicylate. The theobromine compound is really inferior to caffeine in its diuretic powers and is not a stimulant as caffeine is. It should not be given in acute nephritis, as it has a stimulating effect upon the renal secreting structures. In very chronic cases, in which the tissue of the kidney is largely destroyed, it is, of course, useless, as it acts directly upon renal tissue.

Caffeine, an alkaloid from coffee, is a heart stimulant and diuretic, especially valuable in dropsy, but should not be used in acute nephritis because it is also a stimulant to the kidney. It dilates the renal vessels also and increases both solids and liquids in the urine.

Antiblenorrhagics.—Our treatment of urethritis has been greatly enhanced since we have found a specific microorganism as the most common etiological factor. Copaiba was first given internally by Markgraf and Pison (1648) and introduced into the treatment of urinary diseases by Daniel Turner (1729) and J. Thorn (1827). Ricord (1849) and Roquelle (1854) showed that it merely acts locally, by passing into the urine. The urine, saturated with the balsam or its disassimilative products, passes through the urethra and thus produces its action. Both of these writers treated specific urethritis patients who were suffering from urethral fistula with copaiba internally. That portion of the urethra situated behind the fistula, and which was constantly being washed by the urine, recovered; the portion in front of the fistula remained blenorrhagic and did not heal until injections of the patient's urine were made into it. Ricord then administered copaiba to a patient in his clinic who was not suffering from blenorrhea, and injected a few urethritis patients with his urine. This virus proved effective, a distinct evidence of the topical action of the balsam. Sandal wood oil was first brought into use in urinary diseases by Henderson (1865) and Panas (1865).

The antiblenorrhagics, also known as the balsamics, have gained great prestige in recent years, particularly in treating genitourinary diseases. The balsamics are given to relieve the subjective symptoms in acute urethritis, and tend to lessen the pain and tenesmus and diminish the discharge and make the urine thinner. They inhibit the growth of gono-

cocci by rendering the soil less favorable and prevent complications, as Finger has shown. The remedies most commonly used in this class are sandal-wood oil, balsam of copaiba, cubebs, extract of kava-kava, oil of cedar, oil of turpentine, oil of juniper, buchu, matico, and pichi. Of these, sandal-wood oil and copaiba are the best, although the unpleasant irritating symptoms often produced, particularly by copaiba, such as pain in the kidneys, nausea, and skin eruptions, restrict its use for any length of time in a great many cases. Vieth (*Medizinische Klinik*, 1905) found that these irritating symptoms, on the part of the kidney and stomach, depended largely upon the proportions of terpenes in these balsams. To a lesser extent they depended upon the proportion of terpene alcohols, and to a still lesser degree upon the resin acids. It is interesting, therefore, to know that, according to chemical analysis of the various balsamics, one can ascertain in advance the amount of unpleasant symptoms they are apt to produce. Thus the most irritating substance of this group is turpentine. East Indian sandal-wood oil, or that ordinarily employed, contains 6 per cent. of terpene and 94 per cent. terpene alcohol. Copaiba balsam, the best variety of which comes from Maracaibo, contains 55 per cent. of terpene and 40 per cent. of resin acids. Extract of cubebs has 05 per cent. of terpene and 10 per cent. of resin acids. It will be seen from this that the last-mentioned drug is the most irritating to the stomach and kidneys; copaiba is next, and least of all sandal-wood oil. Unfortunately, the skin eruptions sometimes occurring in patients taking these drugs do not seem to depend upon the chemical constitutions of these balsamics, but to the idiosyncrasy of the skin. When we speak of copaiba we mean the balsam. The oil of copaiba is a decided renal irritant. The balsam also has a cathartic effect upon the bowels. In prescribing sandal-wood oil one should be sure it is the product of the East Indies one is using and beware of the kind sometimes substituted by unscrupulous dealers, because the latter contains from 30 to 35 per cent. of terpene. Even the best sandal-wood oil is not an ideal remedy, as it often disturbs the appetite and may cause renal pain.

In order to eliminate or decrease to a minimum the unpleasant symptoms occurring in patients taking the balsamics, various pharmaceutical manufacturers have tried to extract the active principle of sandal-wood oil and endeavor to increase its therapeutic value by the addition of some synergistic remedy, such as salol, the active principle of kava-kava, etc.

It is a question whether the admixture of any drug improves the action of sandal-wood oil, and it has been my experience that when sandal-wood oil is given judiciously and its action carefully watched in every individual case, there will be very little complaint on the part of the patient.

The indications for the use of the balsamics are not altogether definite in spite of the many years these remedies have been employed. Many of the older authors and a few of the recent ones (Leedham-Green, Treatment of Gonorrhea in the Male, 1900) recommend the balsamics in the acute stage at the very onset of the disease, when no local treatment is to be used. Others, as Taylor, say that they should be used in the subacute stage, and not before, and are contraindicated in the acute form of a urethritis. At the New York Post-Graduate Clinic we have been in the habit of prescribing our antiblenorrhagic mixture upon the first visit of the patient with an acute discharge, and for the most part with gratifying results. After the discharge has become scanty and the process is beginning to become chronic these remedies should be discontinued, as they are of no further value.

Specifics.—Among the local remedies used in urology the most prominent are the newer silver compounds regarded as specific in the treatment of urethritis. There are quite a number of these now upon the market, and the manufacturers of each are anxious to impress us with the superiority of their particular product. One point seems certain, however, that the bactericidal powers of these remedies have little to do with their clinical value in specific urethritis. The various synthetic compounds of silver which have come to our notice in the past decade, if used early enough in acute urethritis and in sufficient strength, in many instances will abort the attack or shorten its course, without causing the urethral irritation produced by silver nitrate. One of the chief characteristics claimed for the various organic silver salts is the fact that solutions of these salts do not coagulate in albuminoid solutions, with which the urethral mucous membrane is covered, and many observers point to the fact that there is a greater penetration of these solutions into the urethral submucosa, and thus exert a direct bactericidal effect upon the gonococci lodged there.

The extensive study of clinical cases rather disproves this theory, and a recent report of the comparison of the various silver compounds as bactericidal agents, sent to the Therapeutic Committee of the British Medical Association (August 18, 1900) embodies the fact that the amount of silver which a compound may contain is no criterion of its bactericidal power, and that a few of these salts which possessed practically no bactericidal action whatever had given the best results, and it seems impossible to attribute the good effects which many clinicians have obtained with them to their bactericidal action.

The non-irritating effect of these salts is the most favorable feature about them, and some of them can be used in very high strengths without producing any unpleasant symptoms. They seem to diminish the urethral discharge in a vast majority of cases to a marked degree, and the actual course of the disease is shorter than by any other local treatment. Solutions should always be made up freshly, and used as soon as possible after the appearance of the discharge, and the treatment kept up as long as any flow containing gonococci is visible, at which time we are to change to one of the astringent solutions. Solutions of these silver salts can be given in deep instillations two or three times a week in chronic posterior urethritis, or they can be employed as irrigations to both urethra and bladder.

Drugs Used for Irrigating.—A warm saturated solution of boracic acid is used to irrigate the urethra and bladder for cleansing purposes prior to an operative procedure for the recovery of shreds. Solutions should always be made with sterile distilled water. Formalin solutions in strengths of 1-10000 to 1-8000 make an excellent medium for irrigating and filling the bladder in preparing patients for cystoscopy. Potassium permanganate in solutions 1-8000 to 1-2000 is still used by some in the treatment of acute and chronic urethritis. At the clinic we never use it for irrigating purposes, as we have found it produces complications. Acute cases should not be irrigated anyway, as treatment with either salts gives much better results. Permanganate is useful in treating non-specific or septic urethritis in which the silver salts do not seem to do much good.

Silver nitrate is resorted to by some in obtaining

an abortive or quick curative treatment in acute anterior urethritis of gonorrheal origin. The surface of the anterior urethra is endoscoped for a distance of about three inches and an application of an aqueous solution of nitrate of silver, fifteen grains to the ounce, is made from within outward as the instrument is withdrawn. This procedure is attended with such intense pain and ardor urinæ, and for the most part with unwarranted results, that it has practically fallen into disuse. In chronic urethritis and cystitis, however, silver nitrate solutions in strengths from 1-16000 up to 1-2000, given by the Janet method, have proven of great value. Instillations, by means of an Ultzman syringe, of silver nitrate solutions 1-500 to 1-250 are excellent in treating posterior urethritis. Ayres has had excellent results in treating catarrhal pyelitis, by renal lavage, with mild solutions of silver nitrate in a boric acid medium (*New York Medical Journal*, August 11, 1906).

Astringents.—In addition to the office treatment in the chronic stage of gonorrhea we give astringent injections which, of course, act upon the anterior urethra alone, but seem to aid in curing the disease. The astringents are only indicated when the discharge has stopped and there are no gonococci present. Zinc, either the sulphate or the sulphocarbolate, is the best urethral astringent. It is better to combine it with alum, hydrastis, or liquor plumbi subacetatis, when prescribing for urethral injections.

Anesthetics.—Cocaine is used in the bladder in one-tenth of one per cent. strength. On account of such a large area as the bladder walls, absorption is apt to take place rapidly, and for this reason cocaine is used very little in the bladder. Instillations of a two to four per cent. solution are sometimes given to the posterior urethra when we experience difficulty in passing instruments into the bladder. This method is very useful in cystoscopy. Solutions in five to ten per cent. strengths can be safely used in the meatus prior to a meatotomy. Always have the solutions freshly prepared with sterile salt solution with the addition of a few drops of adrenalin. Several substitutes, as eucaine, beta-eucaine, etc., are available, but a cautious use of cocaine will answer our purpose.

An ethereal oil, made from a plant growing in New Caledonia, and containing a camphor-like menthol substance which gives it a cooling taste and odor, is said to be antiseptic and anesthetic and is used in twenty to fifty per cent. strength. In urology, it is chiefly used as an aid in passing different instruments as filiforms, etc., through difficult strictures and acts as a lubricant. It is also used in injections and instillations into the bladder in various forms of painful cystitis, particularly in tuberculous cystitis with ulcerations. It not only relieves pain, but also creates a pleasant cooling sensation in the bladder and diminishes the frequency of urination. It is, of course, a palliative remedy, but a useful one.

I have tried in the above lines to confine myself to the practical side of urinary therapeutics, and wish only to add a plea for a more thorough appreciation of the value of some of the old as well as the new remedies useful in this branch of medicine, for a deeper study of their action and the indications for their use, and for a due conservatism in accepting the statements of manufacturers or enthusiasts whose motto seems to be "*de novis nil nisi bonum.*" A thorough trial by competent and impartial observers should be the basis for the acceptance of a new remedy into our list of drugs.

12 Lombardy Street

TWENTY-FIVE YEARS' EXPERIENCE IN THE TREATMENT OF MALIGNANT NEW GROWTHS WITH ESCHAROTICS.*

WITH PRESENTATION OF CASES.

By WALLACE E. BROWN, M.D.,

North Adams, Mass.

At this my first available opportunity, it is my purpose to place before you and the medical profession throughout the world, a method of treatment that in my hands has effected permanent results in all forms of cancer and other malignant as well as benign new growths that are situated outside of the thoracic and abdominal cavities. This may to you seem presumptuous, particularly so in view of the current literature on the subject, much of which has been based upon ideas that could not possibly have been gleaned from clinical observations. Many of you know the circumstances that led my father to this special field of practice, so I will not relate them at length. Escharotics have been used with varying success for ages, but I believe my father was the first to employ them with a view solely to their mechanico-chemical, rather than elective qualities. Up to the time that he began his experiments various escharotics had been used, and applications were confined strictly to the new growths, the adjacent infiltrated area not being attacked, consequently cures were more or less of an accidental nature, rather than based upon a logical calculation. Early in the year 1878 I entered my father's office as a student. He was a dentist, having selected that profession in 1862 so that he might better equip himself, if possible, to cope with a very troublesome tumor that had been in the roof of his mouth from the thirteenth year of his age, and had been cut and otherwise unsuccessfully treated many times. These facts are well known to all of the older physicians of this city. This tumor we successfully removed in 1884 by the use of escharotics, and we had before this removed many other new growths in various situations, and they had not reappeared. Encouraged by our results, we entered this special field of practice.

There is no disease or class of diseases that presents more diagnostic features than does cancer, all views that may be expressed to the contrary notwithstanding, and a clinician can readily differentiate between a malignant and a benign new growth by macroscopic and digital observations. With the utmost respect for that most valuable of all instruments, the microscope, as yet its use in this particular disease does not imply science, nor will it until the microscopist combines with it his personal clinical observations. This point affects neither the utility of the instrument nor the eyes of practical observers. As a rule, cancer attacks persons that are otherwise in perfect health. In its incipiency it never presents premonitory symptoms, nor even a slight sensation, nor a rise in temperature either local or general. In short, it is a disease of health, something of a misnomer but nevertheless true, consequently there can never be a successful precancerous treatment.

It is conceded by all that cancer is primarily a local disease, and curable if the last vestige can be removed. Its incipient stage of invasion is microscopical. When it first attracts our attention we find a grouping of cells very diverse in size, shape,

*Paper read before the Berkshire (Massachusetts) District Medical Society and the Medical Association of Northern Berkshire at their December meeting, held jointly at North Adams, Mass., December 27, 1906.

and color, so much so that our nomenclature fails to describe them. In these heterogeneous masses which are distinctly palpable, and discernible to the naked eye, we have what is designated as true malignant disease, or cancer, a word without histological meaning. This is a permanent change, and undoubtedly due to a perversion of cellular activity or dynamics of the cells. In my opinion this structural change will never be logicaly explained, so in justice to sufferers from cancer I feel that they should have the full benefit of the means at hand. We have to-day but two methods by which such growths can be removed—the knife and escharotics. I can in no better way explain the effect of the former than by quoting the exact language of that distinguished surgeon and teacher, Prof. Maurice H. Richardson. In an article on cancer read before the Obstetrical Society of Boston, he says: "The prognosis as to recurrence in even the most radical operation upon a cancerous cervix is bad; for, under the most favorable circumstances, the margin of healthy tissue seems utterly inadequate. A small cancerous nodule in the center of a large breast demands excision of the whole organ, and even then recurrence is the rule. An infiltrating epithelioma of the lip requires in its proper removal the broadest possible margin of healthy tissue, and if that margin is a close one we look upon recurrence as almost certain." These views as expressed by Dr. Richardson concur with those of many other distinguished surgeons in this and other countries.

In attempts to increase my armamentarium therapeuticum, many escharotics have been tried, but experience has taught me that those agents which are the most actively hygroscopic produce the most perfect granulating surfaces, and to-day I use in combination those most active of all escharotics, potassium hydrate and zinc chloride (granular). These are equally applicable both to skin and to mucous surfaces. In the mouth and throat I use a combination of chromic and carbolic acids which I will explain later. Potassium hydrate, the most destructive and least painful of all escharotics of which I have knowledge, is prepared by me as follows: Take one or more pounds, place it in a mortar, add just sufficient water to dissolve it thoroughly; this is best accomplished by keeping it agitated with the pestle. When dissolved add a sufficient quantity of ground hydrastis canadensis to make it assume the consistency of a paste that will not gravitate readily, when placed upon a perpendicular surface. The advantage of the hydrastis lies in the fact that it does not cake or dry up, making a perfectly stable mixture, one that will keep for years and not lose its destructive properties.

The zinc chloride is prepared separately in the same manner, with a view at all times of making them as near saturate as is possible, a quality which produces a degree of anesthesia in the tissues attacked rather than pain, the difference being analogous to that between the red-hot iron and one heated to a white heat when applied to flesh. The one notable point upon which I wish to center your attention is the fact that these escharotics when applied to any given area of tissue cut off all circulation and completely occlude all lymph vessels, which in my opinion are the main channels for the dissemination of cancer. This is a point that demands more thought on the part of the medical profession than has heretofore been accorded it, and which is an element that contributes largely to the success of the escharotic treatment. Of this there can be no doubt.

I cannot dwell at length upon any particular point, as time will not admit of it, but I wish to refer in a general way to the diagnosis of new growths, and can best do this by quoting the following from a clinical lecture by Prof. John C. Minor, M.D., of New York City: "Educate yourselves and your patients to a proper detestation of tumors, and, although you may be unable to prove that the case which you suspect to be one of cancer is so without doubt, yet I am confident that among a number of tumors removed in their early stages of development never to reappear there will be a large proportion of genuine cases of cancer."

The technique of my work in all cases is to outline the growth by palpation, seeking its most distant ramifications. This done, I make an application of the potassium hydrate, completely covering the entire growth, and extend the application in all directions as far beyond its most remote infiltrations as the situation of the growth will admit of doing, never with a view to conservatism. The application should be graded in thickness according to the depth and consistency of the growth, gradually lessening the thickness at the outer edges, using great care and design to have as much symmetry as possible, leaving a clean-cut edge. After this is applied, cut a piece of lint the exact size of the area you have covered. Just beyond your lint on the healthy tissue apply a heavy petroleum product. Then surround the application with a quantity of absorbent material sufficient to catch and hold the watery elements that will be attracted by the hygroscopic qualities of your escharotic, and which, if not prevented, will cause the escharotic to gravitate and destroy tissue wherever it reaches. This application will do its full work in from fifteen minutes to five hours, varying according to the nature and size of the growth and resistance of the skin of different patients. During the time that this application is in place the patient should be kept very quiet, particularly so in extensive growths, such as those of the breast.

The application should be removed, as above stated, in from fifteen minutes to five hours, and after removal the parts destroyed will be found in a perfectly soft pulpy gelatinous mass. The pain, which is very slight—but emphasized differently by each individual—immediately subsides, and there has not been produced the slightest soreness, swelling, or inflammation. In extensive cases of cancer of the breast this is absolutely true, and the patient sleeps that first night and is perfectly comfortable without the use of opiates.

The following day I make an application of the zinc chloride in exactly the same manner that I applied the potassium, except that I do not extend the zinc to a point of contact with the healthy or undestroyed skin. If the application is thus made with care there will be absolutely no pain resulting from it, the patient remaining perfectly comfortable. This application of zinc chloride penetrates the first completely, also hardens and contracts the eschar made by the potassium, causing more or less tension on the edges according to the extent of the growth; this traction causes inconvenience, not pain, and is probably the condition that has characterized escharotic treatments as drawing plasters. The eschar thus produced exfoliates in time ranging from four to twenty-one days, varying in each individual case.

After the eschar has exfoliated you have left a smooth and perfectly healthy granulating surface, absolutely bloodless, and perfectly free from any obscuring elements. It is not sensitive to the touch, all sensory nerves having been destroyed. Before the eschar is exfoliated the edges show marked signs of healing, and these edges are so far wide of

the diseased area that should you have failed to reach all of the disease in the deeper tissues it will be discernible to the eye, and easily felt by a slight touch of the fingers, the cancerous cells having a decidedly hard and shot-like feel, the same as metastatic growths that appear in the skin surrounding advanced cases of carcinoma. To all such cells repeated applications of the zinc can be made, the applications causing no pain, nor do they retard the healing process. The care of these wounds is very simple, but demands the attention of the operator daily, so that any evidences of disease that may remain can be recognized at once. I use a dressing of wood wool, which is a perfect absorbent. First wipe the wound lightly with absorbent cotton, then cover freely with a petroleum product which is of such high melting point as not to be absorbed. This is used for the dual purpose of excluding air and protecting the delicate granulations. Should giant granulations appear, treat them as you would the stray cell of malignant disease; continue these dressings daily until the wound is perfectly healed. The time necessary for this treatment varies according to the extent of the disease and amount of tissue necessary to be removed, ranging from two to sixteen weeks in early discovered cases. In the more advanced cases the larger the area circumscribed, and the longer the time required for healing, the greater safeguard does the patient have.

The combination of chromic and carbolic acids above referred to I use in cases of malignant and benign growths in the mouth and throat and on the tongue, and small benign growths and granulations that appear upon the cervix uteri. The remedies should be used in saturated solutions only. First making an application of the carbolic acid completely covering the growth and adjacent healthy tissue, then at once apply the chromic acid with the utmost care, keeping well within the area circumscribed by the carbolic acid. When the remedies come in contact destruction of that portion of the growth reached is immediate and the patient suffers no pain. Should you fail to destroy all of the growth by your first applications, make repeated applications in the manner described.

In cancerous growths of the womb I use the combination of potassium and zinc chloride; little or no pain is experienced by the patient if care is observed in protecting the vaginal walls, and the results of this method of treatment in that situation are successful.

In my experience no patient has ever been confined to his or her bed or room a single day from the effects of the escharotic treatment. With an early diagnosis and prompt treatment, there should be as large a percentage of recoveries by this method as are recorded in any class of the more serious diseases that afflict the human family, such as eruptive and continued fevers. Taken in its incipiency (and by this I mean the earliest stage at which the new growth may be discovered and observed macroscopically), there should be absolutely no failures to cure, except such as come through complications or causes extraneous to the cancer itself. With this method we can operate in many places where the knife cannot go, and in all places where it can be used, and with a more certain isolation and separation of all cancerous elements. As in all modern surgery, this is a line of work which gives best results under institutional rather than home treatment, and the necessary qualifications are the same as required to become a successful surgeon, namely, a thorough knowledge of anatomy, a delicacy of touch, a constitutional steadiness of nerve, and mechanical order of mind. In selecting cases for clinical demonstration, I have taken those that best demonstrate the size of the growths that can be successfully removed and those that show the work in its various stages from the making of a first application to the completion of the healing, and which demonstrate that we have no disfiguring cicatrices left as unpleasant reminders.

Case I.—Tumor first discovered in upper border of the right breast about seven years ago. When I first saw the patient the growth extended from the center of the breast (which was extremely large) to the lower border of the clavicle, and from the inner border of the left breast to, and involving the right axilla. The mass in that situation was fully four inches in diameter. The entire growth was nodular, presenting two high points at the upper extremity, near the clavicle, that were necrotic. From a surgical point of view the case was inoperable. Ten physicians of this city examined the patient before treatment was commenced. In making the first application of potassium hydrate, I covered 127 square inches of surface; the following day the same surface was covered with an application of zinc chloride. The eschar that resulted from these two applications weighed four pounds and nine ounces, and represented about one-half of the entire growth. The patient has not been confined to her room a single day from the effects of treatment, nor has she failed to sleep nights. No opiates or other remedies have been administered. As seen to-night she is in perfect general health, and as there are no glandular involvements or other evidences of cancer remaining, I believe the treatment will be permanently successful. I shall give the case daily attention until circulation is fully established in the new tissue. This case plainly shows that the treatment leaves little evidence of the work accomplished. The surface treated shows no cicatricial tissue, and the patient has perfect use of her arm, and has not been reduced in flesh.

Case II.—Tumor in right breast, first discovered about two and one-half years ago. Examinations were made by three physicians at her home in the West, all agreed as to the nature of the growth, and pronounced it to be cancer of scirrhus type. She arrived here on December 14, 1906. The following day I called three local physicians, who examined the patient, and concurred in the opinion given by her home physicians. The case presented many characteristics that were diagnostic, including marked drawing of the surrounding tissues toward the tumor, atrophy of the breast, complete retraction of the nipple, etc. On December 16 I made an application of potassium hydrate covering an area of fully thirty square inches of surface; this was followed on the next day by an application of zinc chloride. As seen to-night the entire breast seems to have been destroyed. The patient has not lost a night's rest from the effects of treatment, and she shows no signs of physical disability. No opiates or other remedies have been administered. The eschar is fast exfoliating, and there is no inflammation or swelling in the surrounding tissues.

Case III.—This case shows involvement of the glands in the left axillary space, and metastatic growths along the line of incision following a previous surgical operation for cancer of the breast. The application of potassium hydrate was made December 10, 1906, followed by an application of zinc chloride on the 20th. The eschar exfoliated completely on the 25th. To-night, eight days after the first application, we have twenty-one square inches of open area. This case illustrates many

points mentioned in my paper. It shows a bloodless surface, is not sensitive to the touch of the fingers, as all can plainly see, and the evidences of remaining disease within the circumscribed area are perfectly visible to the eye and touch; the edges are flat and show marked signs of healing. This case also shows the rapidity with which some eschars exfoliate as compared with others with the same treatment and under similar conditions.

Case IV.—This patient came under treatment on October 23, 1906, afflicted with a very extensive cancer of the right cheek. With its infiltrations, it covered an area extending two and one-half inches from the nose across the cheek, and from the upper lip to, and involving the lower eyelid. This growth was examined by two of the physicians here to-night, and the applications were made in their presence on October 24 and 25. There is evidence of disease remaining, but it would not be recognized by a casual observer. This will necessitate another application, and when the disease is all removed, and the wound healed, I believe there will be no cicatricial tissue or drawing of the eyelid or lip. This patient has an additional growth on her forehead, which is of the same character as was the growth on her cheek. She has given me permission to make the first application to this growth to-night. I have covered the growth and the infiltrated area surrounding it, a space three-quarters of an inch in diameter. The potassium hydrate was applied, and after fifteen minutes the remaining escharotic and dressings were removed and the growth found to be completely destroyed. The patient declared that no pain or inconvenience was experienced, and the surrounding tissue showed no evidence of swelling.

Case V.—This patient came under treatment June 19, 1906. Four of the physicians present saw the case before I commenced treatment. The breast was completely necrotic, the axillary glands were involved, and the tissues surrounding the breast were also extensively involved. To cover the diseased area, and reach healthy tissue on all sides of it, required an application twenty-nine inches in circumference. The case was inoperable from a surgical standpoint and had been treated by the *x*-ray before coming to me. I show the case to-night simply as evidence of what may be accomplished by this method in very extensive cases of cancer without depleting the patient's general health and preserving perfect mobility of the arm following invasion by escharotics of the entire axillary space.

Case VI.—This patient came under treatment November 1, 1906. I introduce him to show what can be accomplished in cancer of the lip. This was a typical case, and had been treated at his home with the *x*-ray, over one hundred exposures. That treatment disseminated the disease. I found the free border of the lip extensively involved. As you see him at this time the wound is perfectly healed, the lip is not shortened, and its contour is perfectly preserved.

Case VII.—I have invited this patient here to-night to show those present the delicate character of the work that can be accomplished with escharotics and its permanency. He was treated here ten years ago. The case was cancer of the penis; he had been unsuccessfully treated for several months by his family physician and others. When I first saw him about one-third of the organ was involved, and the disease was infiltrating rapidly. To go wide of the disease I found it necessary to make my application at the root close to the pubes. I made an application of potassium hydrate completely encircling the organ, and followed this the next day with an application of zinc chloride. During the time of exfoliation of the eschar, the patient did not experience the slightest difficulty in urinating, nor has he since. I have seen the patient but once, before this evening, in ten years. There has been no treatment of any kind since he was discharged in 1897.

Case VIII.—The history of this patient's case may be of interest. At this time, twenty years after treatment for sarcoma of most malignant type, we find her in perfect general health, and but little evidence to be seen that would show what had been accomplished. The growth completely covered the right popliteal space. She was first examined by a prominent surgeon in the eastern part of this State, who advised an immediate operation. When I saw the case a degenerate change had taken place; the greater portion of the center of the tumor had assumed an osseous condition. Its gross appearance resembled honeycomb and its consistency that of a very thin egg shell. The outer edges of the tumor had so involved the muscles as to make it most difficult to place the heel upon the floor when walking. The same remedies I employ to-day were used in this case, but not in saturated strengths, consequently there was more pain and inconvenience attending the treatment; however, she was not confined to her room from its effects. The tumor was removed and the wound healed in thirteen weeks. There was no hemorrhage during treatment. There is no muscular contraction and she has perfect use of the limb.

The first patient treated for cancer of the breast by this method is alive and in perfect health after a period of thirty years. No subsequent treatment has been necessary. She resides in Springfield, Mass., and would have been here to-night but for a misunderstanding as to the date of this meeting.

PREOPERATIVE RADIATION AND SURGICAL TREATMENT OF CANCER.*

By WILLIAM JAMES MORTON, M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM AND OF ELECTROTHERAPEUTICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Based upon the conclusion that cancer is at first a focal and consequently a local disease, surgery has rightly demanded the very earliest possible extermination of the small offending tumor. But surgery seldom has an opportunity to operate as soon as it would desire. The patient fails to notice the tumor early or fails to appreciate its deadly significance. Likewise, the conservative attending physician is loath to arrive at a prompt decision. Hence, by the time that what is apparently an early operation is decided upon, the tissue in the immediate neighborhood of the small tumor is already infected and quite possibly, by the way of the lymphatic vessels and the blood circulatory system, fairly distant tissue is also infected. Hence, if by the older practice, the small tumor alone is now removed, there is almost inevitably a recurrence in the neighboring tissues due either to the "soiling of the wound" or to actual nonremoval of diseased areas.

This state of affairs led to the adoption of the sweeping plans of general removal, as in carcinoma of the breast, of the entire breast, and underlying muscles and glandular contents of the axilla. By this plan a far higher percentage of ultimate cures was secured, thanks to the teachings of Heidenhain

* Read at the seventh annual meeting of the American Therapeutic Society, New York City, May 4, 1906.

of Berlin, Halsted of Philadelphia, and Willy Meyer of New York. It is claimed by Redman of Philadelphia that out of a total of 629 individuals operated upon by American surgeons 44.16 per cent. survived the three-year limit. Certainly, the complete operation and the recognition of the importance of early operation have very largely augmented the number of ultimate survivals. Such was the thesis of cancer up to the time of the appearance of the *x*-ray upon the scene.

A new problem was now presented. The *x*-ray showed a hitherto unknown but indubitable action upon cancer growth. It seemed at first, judging from its effects upon comparatively superficial growths, that all cancer might be cured by it, especially if applied in an early stage, and indeed many cases have been cured by it, for the neoplasm cell is more vulnerable to radiation than its neighbors.

But with experience and time it was found there were limits to the depth at which an absorption of the curative portion of the total output of the Crookes tube would take place. These limits surely could not be a limit of penetration, for the fluoroscope reveals penetration through the densest bodily tissues. It would appear rather that a given intervening mass of tissue can screen out that class of rays which destroys cancer cells. But at what depth *x*-radiation ceases to act no one can as yet say. I have seen nodules one inch beneath the skin disappear and large tumors of the abdomen become greatly reduced in size. I maintain, therefore, that *x*-radiation is indicated in such growths—not to the exclusion of operative procedure, but preparatory to it.

I contend, as I have long contended most strongly, that radiation should precede every operation for cancer. In epithelioma of the face, in carcinoma of the breast, or in sarcoma of the skin, the case may go on to a complete cure without any surgical interference. If after six weeks to two months operation is necessary, it may then, in my opinion, be performed with a greatly diminished prospect of recurrence, or what is equally of importance, the area of operation may be reasonably limited.

Preoperative radiation would undoubtedly improve the statistics relating to the ultimate success of surgical intervention.

Against this plan of preoperative radiation it has been urged:

1. That the patient "loses valuable time." *Per contra* many an inoperable case of cancer of the breast is rendered operable by reason of the great reduction of the area of the disease, and many a so-called operable case, by reason of the same reduction, may undergo a safer operation, so far as ultimate recovery goes, or may undergo with safety a limited operation. The wandering cancer particle, as in carcinoma of the breast, is deprived of at least some of its virulence by reason of the radiation. In operable deep-seated tumor it is no doubt better to operate at once.

2. That radiation itself produces cancer or aids its growth. In support of this contention, examples are cited of intense *x*-ray burns in the case of several zealous *x*-ray workers, who have burned themselves to the point of, or almost to the point of, necrosis. Epithelioma has then developed. The authors of this contention are to be congratulated upon having discovered the causation of cancer; the discovery of its radical cure should surely follow. Perhaps a more rational view would be that one generally received that a constant source of severe irritation frequently offers a favorable site to the development of cancer.

Certainly no radiotherapeutist to-day ever repeats upon his patient the mutilations which those martyrs of science in the early days of experimentation unwittingly produced in their own persons. Such instances have been accidents of experimental physics, and have never occurred as a result of skilled radiation therapeutics.

3. That Roentgen toxins are produced and thus the patient's vitality is reduced. The objection has been raised that the breaking down of the neoplasm sets free a toxic débris causing nausea and rise of temperature, with general reduction of the patient's vitality. I have never seen such a case due to the action of the *x*-ray. On the contrary, I have frequently observed the entire disappearance of the patient's cachexia and return to good general health, due without question to the influence of radiation.

4. That metastases are established. Metastases, sooner or later, are the inevitable accompaniment of cancer. They may occur early, but not manifest themselves for a long time. Radiation, for instance, may be initiated at any time during the latent (to our senses) period of metastasis. How unjust, therefore, to refer the metastatic developments, when at last obvious, to a coincident radiation. The charge rests upon mere conjecture and is contrary to the views of the majority of the best authorities on *x*-ray therapeutics. As a rule, in the case of many of the patients referred to me, undoubted, but possibly not very obvious, metastatic conditions have been overlooked. In self-defense the *x*-ray operator should examine every case as to this point with great care.

5. That gangrene may develop in the wound after operation upon a case which has been previously *x*-rayed. This may be true, if the patient has been *x*-rayed prior to operation up to the point of necrosis—a very improbable supposition. But I have referred many cases to surgeons for operation after a preliminary course of *x*-ray, and I have yet to see the first case of gangrene as a result of radiation. Nor have I observed delay in the healing of the wound. It would seem in many cases that the process of cicatrization was accelerated. I quote a case to substantiate this view, and could quote many more.

Mrs. W. R., age 40, wife of a physician. Primary carcinoma of the breast. Tumor size of a large walnut. Peremptorily and continuously refused operation; *x*-rayed beginning September 6, 1905, 40 times in 1905, and 27 times in 1906, up to the very day of limited operation, which she at last consented to. Operation by Dr. J. N. West in September, 1906. Dr. West reports that the wound healed promptly by first intention, that there had been no discharge, that the stitches were removed on the fifth day, and that he had never known a wound to heal more kindly or more promptly. The remaining cicatrix is excellent.

Dr. West, who has performed probably a dozen operations for me, after the extensive use of the *x*-ray on my part, authorizes me to say that in all cases he has had union by primary intention and without the slightest trouble, with the exception of one in which failure to unite promptly was due to other causes. He also states that these cases heal as quickly, if not more quickly, than the average case, and that he has seen more instances of failure to unite in cases which never had had the *x*-ray than in the above series of cases which have had it.

Concerning one such case, however, which has been often quoted to sustain the allegation that gangrene of the wound may result from preoperative radiation, I will say a word. The case was one of my

own, and the surgeon to whom I referred it for operation is the one who cites it. The patient, a woman, had developed in less than six months an enormous tumor of the breast. It was of the encephaloid, or rapid-growing, type. When she began *x*-ray treatment with me the case was already inoperable. A distinguished surgeon of this city gave it as his opinion that operation would be followed by immediate and extensive recurrence. The center of the tumor was extensively broken down into a foul smelling and deep gangrenous mass. After four months of the use of the *x*-ray the tumor shrunk fully one-half in size, two large purplish foci on the point of breaking down disappeared. I then thought that if the remaining and still large bulk of the tumor could be removed, including the huge gangrenous area, the chances for continued treatment by the *x*-ray would be better. The operation was decided upon and was performed. I was present. The gangrenous contents of the large ulcer were squeezed out by the necessary handling of the operator and his assistant, and hands soiled with this material delved into the clean tissues of the axilla and elsewhere during the dissection. I should add, in all fairness, that an attempt was made to obviate this untoward result by covering over the gangrenous ulcer with cotton and superficially-applied collodion. But this flimsy barrier quickly broke loose, and was of no avail to pen in the gangrenous fluids. It naturally followed that the virulent microorganisms of the preexisting gangrene were planted in the new soil, and as the surgeon naively says in his report, "the patient almost lost her life in consequence." To say the least, it seems to me that a better case than this should be cited by the operator to prove the allegation that the gangrene was due to the prior use of the *x*-ray.

The patient's welfare certainly is not promoted by extreme views, and it is against such views that I would protest in this paper, while claiming at the same time the patient's right to the advantages of preoperative radiation. But there prevails, fortunately to a limited extent, in this country, an ultra surgery which, as regards cancer, will listen to no claims for the benefits of radiation, if possibly we may except a grudging acknowledgment of the benefits of postoperative radiation. To what extent this spirit of intolerance may go is illustrated in the following quotation. "In advising such treatment [*x*-ray] after operation, the patient * * * * should not be kept ignorant of the fact that in a number of cases the prolonged exposure to the *x*-rays had caused cancer in a previously healthy individual."

Testimony from all over the civilized world has demonstrated that recurrent cancer has been, in a great number of cases, benefited by *x*-radiation. If cancer may be about to occur, does not the same rule hold good, and is not the hope of prophylaxis well founded?

This class of surgeons is contented to ask of radiation, what cases have you cured? May not radiation equally ask what cases have *you* cured? Can either claim an overwhelming mass of cures? It is exactly this uncompromising position which I would protest against. I claim that radiation and surgery should not be arraigned against each other as mutually opposite methods, but rather that each should mutually sustain the other, that each should harmoniously walk hand in hand to the attainment of as successful an ultimate result of cure of cancer as modern science, up to the present moment, offers. The *x*-ray should be as much of an adjunct to surgery as the knife—the ultimate result of safety to the patient is in neither case a positive one—but the two agencies conjoined will prove to be the patient's greatest present advantage.

Cytodiagnosis of the Cerebrospinal Fluid.—Gioacchino Maiella has made clinical and experimental observations as to the cytological changes in the cerebrospinal fluid in cerebral abscess and meningitis produced by the injection of streptococcus. There is always in any form of acute meningitis a regular series of cytological changes in the fluid, beginning with polynucleosis, and going through the regular stages of mononuclear leucocytosis and lymphocytosis to return to the normal later. This series of changes is most marked in pyogenic meningitis. In cerebral abscess as long as the abscess is confined to the white substance there are no cytological changes, but as it approaches the cortex and reaches the meninges the regular series of changes begins. Lymphocytosis is the most delicate indication of meningeal reaction. In chronic meningitis there is lymphocytosis, especially in the presence of syphilis. In neuroses, cerebral tumors, and peripheral neuritis, as well as in cerebral focal lesions, there is no meningeal reaction and no lymphocytosis. In tuberculous meningitis lymphocytes are present. In tabes and paralysis there are numerous lymphocytes and some mononucleated leucocytes.—*Giornale Internazionale delle Scienze Mediche.*

Periodic Vomiting with Acetonuria in Children.—Vincent Dickinson describes the abrupt onset, the absence of previous gastrointestinal disturbance, the absence of anorexia, the absence of gastric pain, and the slight elevation of temperature, which, together with the character of the vomiting, are the most important signs to be considered in this affection which he has so carefully observed. The vomiting is produced by regurgitation, and is generally watery. The vomited matter is at first abundant, but diminishes by degrees. The attacks occur several times a day, either spontaneously or excited by movement. During the attack the breath has a distinct smell of acetone. The urine is scanty, and analysis shows a definite amount of acetone, and also often of indican. These attacks occur in the midst of perfect health in a child who is usually of a nervous or arthritic diathesis. The prognosis is almost always favorable. Different authorities advocate different methods of treatment, the only specific one founded on a conception of the pathology of the condition being that of Edsall. He considers it due to an acid intoxication, and gives a diffusible alkali, such as bicarbonate of sodium, in large doses.—*The British Journal of Children's Diseases.*

The Causation of Renal Dropsy.—F. A. Bainbridge concludes that the causation of renal dropsy is still very obscure, but he sums up the factors concerned in its production as follows: (1) A scanty output of urine which has been observed by Dickinson, and the fact that in chronic nephritis the onset of cardiac hypertrophy and increased urinary flow are often accompanied by diminution of the dropsy. (2) The retention in the body of sodium chloride and possibly other salts, owing to deficient excretory power on the part of the kidneys, as a result of osmotic changes, retention of salts necessitates the retention of water as well. (3) Increased katabolism in the muscles in consequence of a partial or complete loss of control over muscular metabolism by the kidneys; this excessive katabolism brings about the accumulation in the muscles and tissue-spaces of waste products. These waste products by a process of osmosis attract water from the blood into the tissue-spaces; when the amount of the latter in the tissue-spaces cannot be carried off by the lymphatics, oedema appears. As a rule, none of these factors is in itself a sufficient cause of dropsy, but at least two of them are always involved.—*The Practitioner.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 18, 1907.

TYPHOID BACILLI CARRIERS.

THE general acceptance of the dogma of the water-borne character of typhoid fever, so eloquently preached by the late Mr. Ernest Hart, did much to open the eyes of sanitarians to what must still be regarded as one of the chief sources of typhoid infection, nevertheless a too great insistence upon this as practically the only mode of extension of the disease has worked harm in a way, by retarding the recognition of other sources of infection. The great epidemics of typhoid fever, excluding those instances of camp infection occurring through the agency of insects, are usually no doubt traceable to contamination of the water supply, but we are beginning to appreciate the fact that there are also other sources of infection which must be recognized and guarded against if we are finally to succeed in exterminating this disease.

It has long been known that convalescents from typhoid fever may harbor for a time the specific bacilli, and that consequently the excretions from these persons may be a source of danger, but it is only recently that it has been discovered that the intestinal canal or the gall-bladder of a perfectly healthy person, who may have had the disease at some remote period or who has merely been in intimate relation with typhoid patients, may afford a more or less permanent culture place for the Eberth bacillus. Such persons, all unconsciously to themselves and to others, are constantly excreting typhoid bacilli which may find their way into the food prepared in the houses where they dwell or which may be carried into the water supply of a community and so initiate an epidemic the origin of which appears inexplicable. Kayser of Strassburg reported last year an instance of this sort in the person of the proprietress of a bakery. She had had typhoid fever two years ago, but had recovered and was in apparently perfect health. It was noticed, however, that almost all of the employees of the bakery suffered from intestinal troubles soon after beginning their work, and several died of typhoid fever. Suspicion was at last directed against her, and an examination of her fecal discharges revealed the fact that they were loaded with typhoid bacilli. The employees took their meals in the bakery, and these were usually prepared by the proprietress.

At a recent meeting of the Biological Society of Washington a similar case was reported by Dr. George A. Soper of this city. The account which he gave was one of a household epidemic of typhoid fever occurring in Oyster Bay, N. Y., during the summer of 1906. Of 11 persons 6 developed positive cases of typhoid fever between August 27 and September 3. Several suspected sources—water, milk, vegetables and fruit, and soft clams—were excluded by careful study and examination. Repeated sanitary analysis of the water supply and failure to detect subsoil pollution by fluorescein tests of the drainage showed the infection was not water-borne. Typhoid fever was unusual in Oyster Bay, and there were no cases immediately preceding or following those under consideration. The milk and food supply of the infected household was common to others of the village without the occurrence of other cases. None of the patients had been absent for several weeks prior to the outbreak, and they therefore must have acquired the disease at home. The house and surroundings were in an entirely hygienic condition. The investigator inferred the occurrence of some unusual event prior to August 20, and found it in a change of cooks August 4. The new cook's term of service with this family covered a period of three weeks prior to and three weeks subsequent to the outbreak. She refused to give any information tending to connect her with the cases, but an independent investigation of her previous service disclosed a startling and significant history of typhoid fever. Despite the fact that her record for nearly two of the past five years is yet unknown, 26 cases of typhoid fever, including one death, are known to have been associated with her service in seven families during this time. The cases were almost entirely among the servants, and the initial case frequently occurred soon after the arrival of the cook. She did not admit to Dr. Soper that she had herself suffered from typhoid, but to three persons she is said to have previously testified to a mild attack. The evidence indicating the cook to be a competent cause of typhoid, she was taken into custody by the New York City Department of Health, March 11, 1907, and at the detention hospital a bacteriological examination was made. She was a large, healthy Irishwoman, 40 years of age. The urine was free of typhoid bacilli, but the stools showed great numbers nearly every day for the several weeks of observation. The blood gave a positive Widal reaction. Thus a healthy and vigorous subject was shown to be a chronic typhoid fever producer. It is probable that the gall-bladder harbored the offending organisms, but as the gall-bladder could be reached without operation this remains a conjecture.

The discovery of the existence of these bacilli carriers raises the question of what is to be done with them to protect the community from the infection which they carry. It is evident that they cannot all be segregated and kept prisoners until they consent to the removal of the gall-bladder, which is assumed to be the chief, though very possibly not the only, culture place of the typhoid organism. It would be difficult to obtain popular sanction to such interference with the liberty of apparently healthy individuals, and even if the measure were recognized as justifiable the number of the bacilli carriers would render it difficult of execution. An examination in Germany of 1,700 persons who had at some more or less remote period suffered from typhoid showed the persistence of the specific organism in the discharges of 3 per cent. If that proportion holds

throughout the community, the number of infection distributors must be very large, and it is probable that they play no inconsiderable part in preventing the reduction of the typhoid morbidity, despite careful inspection of the water supply and other usual sources of infection.

ACUTE DILATATION OF THE STOMACH.

This is a condition to which apparently little attention has been extended in this country, although numerous references to it are to be found in foreign literature. The condition is one of considerable clinical interest and importance, for it may be met with during normal convalescence from operations or from severe illness, and may be of such acute onset as to change the whole aspect of a given case. In most of the cases which have been reported the disease has progressed rapidly to a fatal termination, but with accumulated experience it is found that life may be saved by timely recognition and suitable treatment. The most recent study of the subject from the cases known in the literature has been made by L. A. Conner (*American Journal of the Medical Sciences*, March, 1907), whose analysis includes these to the number of one hundred and two. In a case observed by the author, the symptoms were of remarkably short duration, and vomiting was entirely absent. No immediate cause for the dilatation could be discovered, the only other pathological condition being an acute general miliary tuberculosis. Conner thinks that the dorsal position in which the patient was constantly kept, and the almost complete abstention from food favored the production of mesenteric obstruction of the duodenum, and that this may have been a causative factor in the production of the acute dilatation of the stomach.

A study of the collected cases shows that acute gastric dilatation is especially frequent after operations under general anesthesia. In a majority of the cases there was an associated dilatation of the duodenum. The most common cause of such duodenal obstruction is apparently a constriction of the lower end of the duodenum between the root of the mesentery, which crosses in front of it, and the vertebral column. This can occur only when the mesenteric root, with the superior mesenteric artery which runs in it, is stretched tightly across the duodenum. Such a state of affairs is apparently possible only when traction is exerted by the small intestine hanging over the brim of the pelvis. The development of mesenteric constriction is favored, therefore, by whatever facilitates the entrance of the small intestine into the true pelvis. Such conditions are the dorsal position, a mesentery of suitable length, and an empty and collapsed state of the gut. In addition to these, we have those factors which render the duodenum more liable to compression, such as increased lordosis of the lumbar vertebræ and a low position of the duodenum. It is uncertain whether the dilatation of the stomach or the mesenteric obstruction of the duodenum constitutes the first step in the vicious cycle by which both conditions are made worse, but there seems to be little doubt that in some cases at least the duodenal obstruction is primary.

The physical signs and symptoms of acute gastric dilatation are usually so distinct that the diagnosis should not be difficult if the possibility of such an occurrence be kept in mind. The mortality is high, 72 per cent., but there is evidence at hand that the condition can be controlled and cured if the diagnosis is made and suitable treatment instituted before complete collapse of the patient has occurred. The effectiveness of such measures will depend to a large extent on the time at which they were applied. The first thing to do is thoroughly to empty the stomach, and this should be repeated at regular intervals. Nutrition should be maintained by rectal feeding. As duodenal obstruction has been found to be present in 36 per cent. of the fatal cases, it is well to assume that it may be present in more, and postural treatment should always be tried. This consists in allowing the patient to rest on the abdomen instead of on the back. The results of operative treatment have not been satisfactory as a general thing.

THE SUBCUTANEOUS INJECTION OF SALT SOLUTION IN CHILDREN.

In no department of medicine should therapeutic simplicity be so assiduously cultivated as in pediatrics. The infantile organism is particularly susceptible to infection and intoxication and the manifestations of both of these conditions are more sudden and violent, cause greater febrile disturbance and marasmus, and are also more frequently accompanied by grave adynamic conditions in the child than in the adult. The heart, although its resisting power does not appear to be inferior, is apparently more apt to be attacked by toxic action, whether of exogenous or endogenous origin. This fact is especially evident in those forms of disease which are characterized by excessive drain of fluid from the body, in which we have to deal not only with the intrinsic action of the toxic substance on the heart, but also with the difficulty of maintaining the normal circulation of the blood under the abnormal conditions present.

The free use of stimulants was formerly the common mode of combating these conditions, although now we have come to recognize the value of diluents to restore the normal density and physiological condition of the blood, and thus to ease the strain on the heart muscle. The introduction of physiological salt solution into the blood stream by direct infusion or hypodermic injection seems the method *par excellence* for accomplishing this purpose. Baginsky (*Folia Therapeutica*, January, 1907) again calls attention to the particular value of saline infusions in preventing damage to the heart in a variety of conditions, and also in replacing fluid lost through diarrheal or other diseases. He reports a number of cases in which the method was employed with signal success. The most effective manner of application, according to this author, is with a large hypodermic syringe, by means of which from 100 to 200 c.c. may be injected at a time. Even in the case of very young infants of only a few weeks, conditions of extreme prostration and marasmus were successfully treated by this method.

The Effect of German University Life on the Heart.

A dissertation of peculiarly Teutonic flavor appears in the *Münchener medizinische Wochenschrift* of January 8, 1907. Its author, Dr. Bingel, has made it his task to investigate the condition of the heart and blood-vessels of a large number of university students, particularly with a view to determining whether or not the conventional overindulgence in beer and the unduly violent exercise embodied in the student duels was followed by any immediate and demonstrable bad results. It appears that a very considerable proportion of the students during the first months of the university career suffer from mild symptoms of circulatory disorder, such as uncomfortable sensations in the cardiac region, palpitation, sensations of thoracic compression, gastric disturbances, bodily fatigue, etc. The occurrence of these symptoms the author explains by the complete change in the manner of life that takes place when the young man leaves his home and begins his university course. As three potent factors he recognizes the consumption of large quantities of alcoholic beverages, principally beer, the unwonted physical exercise attending the customary pursuits of fencing and horsemanship, and finally, the active social intercourse that is so important a part of German student life. As the result of his examinations of a considerable number of students made at varying intervals, and also in conjunction with fencing contests, he arrives at the consoling conclusion that the conditions above mentioned, while sufficient to give rise in some cases to a certain degree of subjective disturbance, are not likely to have any actually damaging effects on a previously healthy heart. On the other hand, if this organ has already been subjected to severe strain or actual injury as the result of infectious diseases or other factors in early life, there is a distinct danger that a condition of cardiac insufficiency may arise. The question of the effect of violent exercise on the circulatory system has already been made the subject of extensive study in the cases of our own college athletes, with results that in general are in accord with those of Bingel; but it must always be remembered that overexertion or abuse of any sort consistently persisted in in early manhood, even if it gives rise to no immediate lesions that can be demonstrated, may, and undoubtedly often does, predispose to a breakdown later in life.

The Public Control of Tuberculosis.

The committee on the prevention of tuberculosis of the Charity Organization Society of the City of New York, in a recent bulletin, calls attention to the widespread public interest in the subject of tuberculosis and notes how systematically and energetically the work of organization is being pushed forward throughout the whole country. At the meeting of the National Association for the Study and Prevention of Tuberculosis, held last week in Washington, it was reported that 15 States are now actively working along State lines to prevent tuberculosis, while in 8 other States definite steps have been taken which it is expected will lead to similar organizations within the year. An equally encouraging outlook is presented in the secretary's report of city organizations. Nine of these local committees have been formed among cities of over 100,000 population in the past year, and definite plans are under way in Toledo, St. Paul, Los Angeles, and Fall River, so that of the 38 cities of this class only San Francisco, Kansas City, Omaha, St. Joseph, and Memphis remain without local organization at the present time, and of these only Omaha and Memphis are without plans for the early formation of such organizations. While carrying on this work communities of lesser population have not been neglected, definite organizations having been formed during the year in 42 cities and towns, Massachusetts and New Jersey heading the list in this respect, each with 10 local societies. The movement for organization is also well advanced in 20 other cities, and there are now 23 States and nearly 100 cities and towns in which there are active societies or definite plans for forming such.

Dr. Knopf Misquoted.

In a report of the recent meeting of the Tuberculosis Association in Washington, the Philadelphia *North American* quoted Dr. Knopf of this city as favoring the use of morphine in the last stages of tuberculosis in order to hasten the inevitable end. The remarks of Dr. Knopf were misinterpreted by the reporter of the lay journal. He advocated the use of morphine in doses sufficient to relieve the patient's sufferings, but that, as every medical man knows, would prolong life instead of shortening it. It is unfortunate that representatives of the lay press can publish reports of medical meetings without having these previously submitted to some one competent to revise them when necessary, and it is strange that the editors of these journals do not see that such revision would be to their own advantage in insuring the accuracy of the reports. What the accounts would thereby lose in sensationalism they would gain in truthfulness, and physicians would be spared the pain of misrepresentation. The instance here noted is a familiarly flagrant one, as Dr. Knopf was reported to be in favor of shortening life when he really advocated measures for prolonging life to its utmost limit.

News of the Week.

The New Medical Examination Law.—Governor Hughes of this State has signed the bill abolishing the three existing State board of medical examiners and providing for a single board of examiners to be representative of the various schools. The new board is to be composed of nine members. Under this act the osteopaths for the first time secure recognition in this State. The bill recognizes as "practising" osteopaths the three hundred now exercising their calling in this State, but in future all persons desiring to practise osteopathy must pass an examination before the State Board of Examiners.

Child Labor Bill Signed.—Governor Hughes has signed the Page child labor bill, which provides that no minor under sixteen years of age shall be employed or permitted to work in any factory in this State before 8 A.M. or after 5 P.M., or more than eight hours in any one day. At present the permitted hours are 6 A.M. to 7 P.M. The act will not take effect until January 1, 1908.

Hospital Transfer Bill Vetoed.—Mayor McClellan has vetoed the bill recently passed by the Legislature prohibiting the transfer, under certain conditions, of patients from the different hospitals of the city to Bellevue Hospital.

Defeat of the Osteopathic Bill in Illinois.—A bill to place an osteopath on the Illinois State Board of Health failed of passage in the House, May 2. Another bill introduced was designed to establish

a standard for medical and osteopathic schools, to license osteopaths without examination, and to confer on them all the rights and privileges which physicians in the State now have. This bill, like many other osteopathic bills introduced in the Illinois General Assembly since 1897, was killed.

A Temperance Movement.—Under the auspices of the American Medical Society for the Study of Alcohol and Other Narcotics it is proposed to hold at the Atlantic City meeting of the American Medical Association a so-called temperance lunch, at which the alcohol question is to be discussed in a more or less informal way. The lunch will be given at the Hotel Marlborough-Blenheim on June 5 at one P.M., and all members of the American Medical Association and their families are to be invited to be present. A number of prominent physicians and ex-presidents of the American Medical Association will make brief addresses. The president of the American Medical Society for the Study of Alcohol and Other Narcotics is Dr. Henry O. Marcy, and the secretary is Dr. T. D. Crothers.

For an International Language.—The Delegation for the choice of an International Auxiliary Language, an organization having its headquarters in France, has issued an appeal requesting learned societies, professional associations, chambers of commerce, and other kindred organizations, to record their approval of the project of encouraging the adoption of a universal auxiliary language, and to name a delegate to act in the matter. The organization is prepared to send to the offices of societies a supply of circulars giving all useful details of its organization, and to send blanks for the signatures of individual University professors. The Secretary for the United States is J. F. Twombly, 34 Green street, Brookline, Mass.

The Bicentenary of Linne.—The two hundredth anniversary of the birth of Linnæus will be celebrated by the University of Upsala and also by the Academy of Sciences in Stockholm, beginning May 23. The name of Linnæus is closely connected with the Stockholm Academy. Before he was appointed to a professorship in Upsala he lived in Stockholm as a practising physician, and together with five other men founded the Swedish Academy of Sciences, of which organization he was the first president. In connection with this celebration the Academy will issue a number of publications, among which are important writings of Linnæus now out of print, and also a series of discussions of Linnæus's work in different branches of natural science, notably botany and zoölogy, geology, mineralogy, and medicine. In addition the Academy is having a set of Linnæus medallions struck in gold, to be given as special prizes for noteworthy work in the natural sciences. The botanical seminary of the University of Nebraska is also to celebrate the anniversary.

Vegetarian Recruits in Germany.—Some curious statistics are reported as having been gleaned in southern Baden during the recent enrollment of recruits. In the Lindau and Allgau districts out of 604 young men liable to service only 20 were found to be up to the physical standard of the military authorities. Two hundred and seventeen were placed on the doubtful list, and the unusual number of 367 were put aside as wholly unfit for active service. It is stated that the peasantry of those districts were at one time among the most robust in the empire, but owing, in the first place, to the dearness of meat and the fact that milk, which once was a staple article of food, is now carefully collected for the cheese factories, their physique has sunk to a dangerously low level. Their principal food for years has been potatoes and skimmed milk.

Genius and Hydrocephabus—Professor von Hanseman of the Berlin University, who has recently examined the brain of Theodore Mommsen, the historian, states that he, like Hermann von Helmholtz the physiologist, and Adolph Menzel the painter, was the subject of hydrocephalus. He suggests that on this basis an explanation may be offered of Mommsen's eccentricity, Menzel's extreme irritability and occasional fainting fits, and the spasmodic seizures from which Helmholtz suffered.

Health Statistics in New Jersey.—According to the monthly report of the New Jersey State Bureau of Statistics, the total number of deaths in that State during April was 3,053, an increase of 512 over the previous month and 812 more than the monthly average for the past nine months. In explanation of this increase it is suggested by the Bureau that the unusual weather conditions of the month may have played a part in the high mortality.

Vacancies in the Naval Medical Service.—Owing to the lack of applicants for positions there are now sixty-four vacancies in the naval medical service, and Congress is to be asked to take measures to make the positions more attractive. Surgeon General Rixey of the Navy has undertaken to give temporary appointments as acting assistant surgeons" to candidates who will pass a satisfactory preliminary examination and come to Washington for instruction. They will receive six months' special training at the Naval Medical School and Hospital, recently established there, or at the Mare Island Naval Hospital. At the end of that course they will receive appointments as assistant surgeons, with an annual salary of $1,700, supplemented by allowances for mileage, and other inducements.

Syphilis in Monkeys.—Geheimrat D. Neisser, who has been conducting a series of experiments on the syphilization of monkeys in Batavia, has been granted a further leave of absence until October. He will then return to Breslau, where he will continue his investigations.

To Study the Tsetse-Fly Disease.—Dr. Schilling, the chief of the Department of Tropical Disease in the Berlin Institut für Infektionskrankheiten, and his assistant, Dr. Jaffé, have been sent to Togo, where they will conduct a series of experiments on immunization against the tsetse-fly disease.

Famine Relief in Russia.—The Czar has signed a bill appropriating $3,000,000 for the relief of famine sufferers. Most of the amount is to be used for medical assistance in the scurvy stricken provinces.

Chinese Lepers in Canada.—The entire leper colony on D'Arcy Island, near Victoria, consisting of eighteen Chinese, has been sent to Canton, China. This comes as a result of an agreement between the Chinese and the Dominion Government. The Dominion held it was unfair for it to treat foreigners for a disease contracted in a foreign country.

A Suit for Slander.—The *Pacific Medical Journal* states that the College of Physicians and Surgeons of San Francisco has entered suit for $75,000 damages against Dr. Dudley Tait, former President of the Board of Medical Examiners, and Dr. Philip Mills Jones, editor of the *California State Journal of Medicine*, for slander and libel.

Filth in Cheap Lodgings.—Violations of all the laws in the city code or State statutes on the subject of health and comfort in the lodging houses of

Chicago were discovered by Inspector James T. Sullivan, of the Sanitary Bureau, during a recent inspection of West Side houses. Mr. Sullivan acted under orders of Health Commissioner Evans. Houses where eighty men slept in stifling rooms, with no ventilation, no fire escapes, but a narrow wooden stairway leading down from the front, walls caked with dirt, and floors covered with filth of every description were some of the things found. Commissioner Evans will endeavor to have these conditions corrected.

Clinic For Mothers.—It is believed that Chicago is to be the first city in the United States to have a regularly established system of mothers' clinics for the free instruction of parents in the care of children. Plans have been prepared for a building in which this novel scheme is to be inaugurated, and building operations will soon begin. The plan of establishing such a clinic is a direct outgrowth of a kirmess held last fall by the Children's Memorial Hospital. With the $25,000 raised by the Cribside Committee, a pavilion is to be erected as a part of the hospital's projected new equipment. In a specially equipped room of this building the first of the clinics will be held.

Antitoxin for Gratuitous Distribution.—The Illinois State Board of Health has been allowed $15,000 annually for free distribution of antidiphtheritic serum outside of Chicago. The appropriations of the State Board of Health have been materially increased by the Legislature, the sum of $119,200 having been appropriated for the work of the board. This is very gratifying, when the General Assembly, in 1905, only appropriated the sum of $83,320.

New Prize Fund in Laryngology.—At the recent meeting of the American Laryngological Association in Washington, announcement was made of the establishment of a prize fund of five hundred dollars by gift of the retiring President, Dr. A. W. de Roaldes of New Orleans. Further announcement as to time and conditions of the award of the prize will be made when such details shall have been considered by the Council of the Association. The fund will be known as the de Roaldes Prize Fund.

To Combat the Plague.—The Japanese Government has announced its intention of accepting President Roosevelt's proposal for the holding of an international conference at Tokio to consider measures for stamping out the plague.

Changes in the Columbia University Faculty.—At the last meeting of the Trustees of Columbia University Dr. Frederick R. Bailey, Adjunct Professor of Histology and Embryology, was assigned a seat in the Faculty. The resignation of Dr. George H. Fox, Professor of Dermatology, was accepted. Dr. Francis Huber was appointed Professor of Clinical Medicine, Dr. Frederick Peterson, Professor of Psychiatry, Dr. Andrew J. McCosh, Professor of Clinical Surgery, and Dr. Pearce Bailey, Adjunct Professor of Neurology.

Medical Department for Louisiana State University.—According to *Science*, it is said that the Louisiana State University will establish this year a medical department in New Orleans.

Board of Surgeons for Fire Department.—Fire Commissioner Lantry has formed the surgeons of the Fire Department into a board resembling that of the Police Department. The following are the officers of the board: *President*, Dr. E. B. Ramsdell; *Vice-President*, Dr. Joseph E. Smith; *Secretary*, Dr. Herman L. Reis. Newly appointed surgeons are Dr. Robert W. Hall and Dr. John J. White.

Dr. A. Rose of this city has been elected a corresponding member of the Medical Society of Athens. The honor was conferred in recognition of his efforts in behalf of reform in medical nomenclature.

Dr. O. H. Pinney, class of 1903, Medical College of Ohio, now of Madisonville, has been appointed by the Presbyterian Board of Foreign Missions as Medical Missionary to Benito, a port on the west coast of Africa.

Dr. E. S. McKee of Cincinnati has been elected a member of the New York Medico-Legal Society and appointed one of the editors of the *New York Medico-Legal Journal*.

Dr. William L. Richardson, Dean of the Harvard Medical School, has handed in his resignation, to take effect on September 1, 1907. Dr. Richardson has been professor of obstetrics since 1886, and dean since 1893.

Dr. L. Blake Baldwin of Chicago has been appointed City Physician by Mayor Busse.

International Congress of Physiologists.—The seventh International Congress of Physiologists will be held this year at Heidelberg, August 13 to 16, under the presidency of Professor A. Kossel. The previous congresses were held at Basle, in 1889; Liége, in 1892; Berne, in 1895; Cambridge, in 1898; Turin, in 1901, and Brussels, in 1904.

Polish Men of Science and Physicians.—The tenth congress of this organization will be held this year at Lemberg some time between June 16 and July 24. There will be a scientific and medico-hygienic exposition in connection with the congress.

Norfolk South (Mass.) District Medical Society.—At the annual meeting of this society, held in Boston on May 2, the following officers were elected for the ensuing year: *President*, Dr. N. S. Hunting of Quincy; *Vice-President*, Dr. O. H. Howe of Cohasset; *Secretary, Treasurer*, and *Librarian*, Dr. Charles S. Adams of Wollaston.

Essex North (Mass.) Medical Society.—At the meeting of this society held in Lawrence on May 1 officers were elected as follows: *President*, Dr. W. J. Sullivan, Lawrence; *Vice-President*, Dr. C. E. Durant, Haverhill; *Secretary* and *Treasurer*, Dr. M. D. Clarke, Haverhill; *Corresponding Secretary*, Dr. R. D. Hamilton, Newburyport.

Southeastern Michigan Homeopathic Medical Society.—Officers were elected as follows at the meeting of this society held in Detroit on April 26: *President*, Dr. E. J. Kendall; *First Vice-President*, Dr. Hale of Memphis, Mich.; *Second Vice-President*, Dr. E. L. Orneman; *Secretary*, Dr. F. E. Thompson; *Treasurer*, Dr. James I. Murray.

Taylor County (W. Va.) Medical Association.—At the meeting of this association held in Grafton on April 30 officers as follows were elected: *President*, Dr. C. A. Sinsel; *Vice-President*, Dr. D. C. Peck; *Secretary*, Dr. J. H. Doyle; *Treasurer*, Dr. A. H. Thayer.

Cuming County (Neb.) Medical Association.—At the meeting of this society recently held at West Point officers were elected as follows: *President*, Dr. W. H. Francis, Bancroft; *Vice-President*, Dr. C. S. Grabin, Beemer; *Secretary-Treasurer*, Dr. H. L. Wells, West Point.

Missouri Institute of Homeopathy.—This organization, at the meeting held in Kansas City on April 25, elected the following as officers: *Presi-*

dent, Dr. F. M. Martin of Maryville; *Vice-Presidents*, Dr. Edward Andruss of Holden and Dr. J. H. Gilkerson of Warrensburg; *Secretary*, Dr. MacLay Lyon of Kansas City; *Treasurer*, Dr. D. M. Gibson of St. Louis.

Jackson County (Ark.) Medical Association.—At the recent meeting of this organization held at Newport, the following officers were elected: *President*, Dr. H. O. Walker; *Vice-President*, Dr. O. A. Jamison; *Secretary*, Dr. G. K. Stephens; *Treasurer*, Dr. O. E. Jones.

Maine Medical Association.—By a vote of the censors of this society the date of the annual meeting has been changed so as not to conflict with the meeting of the American Medical Association. The new dates are for Wednesday, Thursday, and Friday, June 12, 13, and 14, 1907, at Lewiston.

"The Diagnostician" is the title of a new monthly medical journal which has made its appearance in Cincinnati.

Hospital Bequests.—By the will of the late James Henry Smith, who died suddenly in Japan a few weeks ago, St. Luke's Hospital and the Orthopedic Hospital, of both of which the testator was a trustee, are to receive the sum of $100,000 each.

The Late Dr. Otis.—The following resolution was passed at the recent meeting of the Society of Genitourinary Surgeons:

Resolved, That in the death of our President, Dr. William K. Otis, we have lost an honored associate, active, talented, and devoted to the interests of his profession. More still, we have lost a sincere and true friend who had endeared himself to us all and whom we shall greatly miss.

Voted, That this Resolution be sent to Dr. Otis' family with assurances of our sincere sympathy and regard.

Obituary Notes.—Dr. MARVIN S. BUTTLES of this city died on May 9 after a long illness. Dr. Buttles was born in Otis, Berkshire County, Mass., in 1833, and was graduated from the medical department of the University of the City of New York in 1864. He was for some years president of the East River Medical Association, and was also professor of obstetrics in the medical department of the University. From 1865 to 1872 he was surgeon of the 71st regiment, New York State National Guard, and was the founder of the Olivet Female Infirmary. He had been for many years president of the Hotel Savoy Company, and president of the Hamilton Fire Insurance Company.

Dr. GEORGE NICHOLS of Northfield, Vt., died on April 27 of nephritis. He was born in Northfield in 1827, and in 1851 was graduated from the Vermont Medical College at Woodstock. He served as surgeon in the 13th regiment Vermont Volunteers, and in 1865 was appointed Secretary of the State of Vermont. He had also held numerous other official positions. He retired from active life about ten years ago.

Dr. WILLIAM H. LEONARD of Minneapolis, Minn., died on April 28 at the age of eighty-five years. He was the oldest practising physician in the city and came to St. Anthony Falls in 1855. He served in the Civil War as surgeon, and was the first health officer of the city after the union of Minneapolis and St. Anthony. For twenty-five years he was a member of the State Board of Health, and was prominent in the establishment of the State Board of Charities and of the State Lunacy Commission. He was three times president of the Minnesota State Homeopathic Institute. He was a graduate of Yale University, and of the University of the City of New York.

Dr. JOHN T. MAIN of Jackson, Mich., died on May 1 at the age of seventy-six years. He was born in Albion, Me., and was graduated from Harvard University in 1857. He had practised in Michigan for nearly fifty years, and had served as president of the State Medical Association. He served as a member of the Jackson Board of Health and in other official positions.

Dr. THOMAS M. MARCELLUS of Charlottesville, Va., died on May 7 of cancer of the stomach, at the age of fifty-six years. He was born in Canada, and after spending his boyhood in Minnesota was graduated in medicine in the University of Michigan. For seventeen years he practised in Sleepy Eye, Minn., but about twelve years ago removed to Charlottesville on account of failing health.

Dr. JOHN MACMILLAN of Pictou, N. S., died on May 2 at an advanced age. He was a native of London, but came to Nova Scotia about fifty years ago, and had practised in Pictou for over thirty years.

Dr. J. N. MEDBERRY of Webster City, Ia., died on May 1 at an advanced age. He was the oldest practising physician in that part of the State, but two years ago was obliged to give up active work on account of a paralytic stroke. He had been a resident of Webster City for thirty-two years.

Dr. S. G. MILNER of Detroit, Mich., died on May 2 at the age of sixty-one years. He was graduated from the University of Michigan in 1872. After practising in Grand Rapids he removed to Detroit in 1900.

Dr. JOHN W. BRENNAN of this city died at the age of seventy-eight years on May 10, after a long illness. He went to California in 1849, but later studied medicine, and in 1862 was graduated from the College of Physicians and Surgeons of this city. During the Civil War he was surgeon to General H. Berdan's regiment of sharpshooters, and was wounded at Gettysburg.

Correspondence.

THE TRUE "MORRIS APPENDIX"

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Notwithstanding the detailed description of harmful involution of the appendix, in the MEDICAL RECORD for April 6, 1907, a physician recently explained to another in my presence that "the true Morris appendix was one in which scar tissue following inflammation entrapped nerve filaments." An extract from one of the journals also gets the thing wrong, although the MEDICAL RECORD was probably in the hands of the writer of the note. It seemed to me that the description which I gave was clear enough to avoid the possibility of misquotation.

If physicians are bound to call a certain type of appendix by my name, it puts me in a responsible position. The appendix that I am trying to bring to the front is not one in which scar tissue following inflammation entraps nerve filaments. The scar tissue is hyperplastic connective tissue, representing a process of evolution, and resulting in involution of the appendix. Not only does the involution change not follow inflammation (according to my observations), but it is an actual safeguard against infection, because it removes the structures which are involved in the infections. The hyperplastic connective tissue irritates nerve filaments which persist, and it sends patients to the doctor with "intestinal dyspepsia" and a question about the appendix, but it does not put patients in bed. The part which this type of appendix plays in some chronic digestive disturbances was noted rather accidentally. In going over some specimens of normal looking appendices which had given chronic symptoms, I noticed under the microscope that persisting nerve filaments were surrounded by such groups of new cells that a high degree of irritation must have been present, and the subject was worked out backward from this observation

A "scar appendix" following an inflective process is another affair altogether. Such appendices often do cause digestive disturbances, but chiefly, I think, because of mucous inclusions and adhesions, rather than from irritation of entrapped nerve filaments, as in the appendix which is undergoing harmful involution. The "scar appendix" causes occasional digestive disturbance. The appendix which I describe causes persistent discomfort, and so-called intestinal dyspepsia, and is probably the most common factor in obscure cases of this sort of dyspepsia. Almost any physician engaged in general practice can find from one to ten of the appendices which I describe among the patients at present under his care.

ROBERT T. MORRIS, M.D.
610 MADISON AVENUE, NEW YORK.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GLASGOW UNIVERSITY AND INFIRMARY—SILVER FILIGREES IN HERNIA—ABSCESS IN MUSCULAR TISSUES—SERUM FOR APPENDIX CASES—UTERINE HEMORRHAGE—STYPTOL-MERCURY—HYGIENIC AND TEMPERANCE CONFERENCE.

LONDON, April 20, 1907.

THE Prince and Princess of Wales, who are visiting near Glasgow, drove into that city on Tuesday to open the new buildings of the University and fulfill some other public engagements. The additions will be devoted to the accommodation of the departments of physiology, materia medica, forensic medicine, natural philosophy, and public health, and have cost £100,000. The Prince made an effective speech, mentioning that the money had been found by the ever generous west of Scotland, and saying that if in years to come further extensions should be required he was confident they would be carried out in the same generous spirit which had characterized the undertaking of which the completion was that day celebrated. The Prince and Princess had the degree of Doctor of Laws conferred upon them, and there was great enthusiasm as they ascended the dais in their academic robes to be capped by the Chancellor, Lord Kelvin. Other distinguished persons also received honorary degrees. Their Royal Highnesses had previously received the freedom of the city with all the ancient ceremonial and the enthusiasm of all present, the Prince thus becoming a burgess and the Princess a burgess and Guild Sister of the City and Royal Burgh of Glasgow. Their Royal Highnesses signed the roll, and the Prince returned thanks to the city and corporation for the cordial welcome they had received, and expressed pleasure that one of their first duties as the youngest burgesses was to lay the foundation stone of what would be a complete reconstruction of their Royal Infirmary, a work which testified to the liberality of the richer members of their community in providing the best means of alleviating the sufferings of the sick poor.

On Wednesday the Prince and Princess again went to Glasgow from Blythswood House, and were again received with the utmost enthusiasm. The first ceremony that day was the laying of the foundation stone of the reconstruction buildings of the Royal Infirmary. On both days the weather was proverbially royal, and the lavish decorations of the route were therefore unspoiled and the gaiety of the proceedings throughout a satisfaction to the enormous crowds. The foundation stone of the existing Royal Infirmary was laid in May, 1792, and the silver trowel presented to the Prince recorded the fact. The new buildings will cost about half a million sterling and will provide for 600 patients. The Prince, having "truly laid" the foundation stone, replied to an address presented in another speech, in which he referred happily to the value of such institutions, the necessity of keeping pace with discoveries like those of Lord Lister, whose eightieth birthday we have lately celebrated, and of whose work at this hospital you are so justly proud. He congratulated Glasgow on making the reconstruction a memorial to Queen Victoria, as nothing would have more appealed to her heart, and said every year's experience impressed him with the importance of guaranteeing to the public, through whose liberality these institutions are maintained, a wise, sound, and businesslike administration. He concluded by commending this "splendid work to all who can afford assistance toward its completion." A review at Govan and other public engagements were duly carried out amid the greatest enthusiasm, but as they have not the claim on your space of the medical and university schemes, I must pass them by.

Mr. Lawrie McGavin has introduced to the Clinical Society a modified method of applying prepared filigrees of silver wire for the cure of very large or recurrent inguinal hernia in males. The success of Bartlett's method of dealing with abdominal hernia had led him to modify that method of implantation to meet the requirements in inguinal hernia, the object being to establish an operation which would justify the term a "radical cure," and do away with the use of a truss. This object had been effected in cases beyond the scope of ordinary operation, and no complication had arisen in any instance. Pain and discomfort had been entirely absent. Mr. Spencer said he thought the plan an important advance in surgical technique. He was supported by Mr. Drew. Mr. Barker thought the plan might be valuable in bad cases, though he had no experience with filigrees.

Mr. W. G. Spencer described a case of solitary acute suppuration in the psoas and iliacus muscles in a healthy boy of thirteen, who died four days after the onset without being relieved by incision. There had been no strain. The pus yielded a pure cultivation of *Staphylococcus pyogenes aureus*. At the postmortem no other lesions were found and no distant septic focus, such as has been discovered in other cases. There are a number such on record, but there seems no explanation of them, and it may be supposed to be a distinct affection.

Mr. Symonds had seen two cases, and attributed them to a general infection with a local strain. One had occurred in the pectoral muscle after a very slight injury. Mr. Drew had seen three cases, which followed impetigo in children. Dr. Wynter described a case which ran a typhoid course, and was found after death to have been infective suppurative psoasitis. Dr. Gordon Watson compared the cases with osteomyelitis, and described two occurring during the puerperium. Both recovered after incision of the abscess.

Messrs. Makins and Sargent presented a tabular statement of twenty-five cases of acute appendical peritonitis treated by injections of a multivalent serum from different strains of *Bacillus coli communis*. The cases were all severe, and six of them apparently such that no good could be expected. Of the twenty-five, recovery occurred in nine. In all the others improvement followed, toxic symptoms were relieved, localization of the infecting area was effected, and in the fatal cases death was delayed beyond the usual period. The improvement in the patients' comfort, the quietude and sleep that ensued, with a fall of temperature and pulse, justified extensive trials. Relief from vomiting in many cases was also obtained. The treatment appeared to be curative and was in no way dangerous. A successful case of treatment by this serum of an acute infection of the urinary tracts with *Bacillus coli communis*, under the care of Dr. H. G. Turney, was attended to, also report on the treatment of three cases of puerperal sepsis by Dr. Gordon of Manchester. Dr. L. Dudgeon thought the serum of great value if used early enough, but that it was no use in chronic cases without constitutional symptoms.

The use of drugs to restrain hemorrhage maintains its interest for every practitioner, and in estimating their value the majority will probably be influenced by their effect in menorrhagia. It is easy to say that in every case the cause of the bleeding should be determined before attempting treatment, which should be placed on a pathological basis. There are, however, a number of cases in which the most experienced physicians and expert gynecologists are unable to arrive at a positive diagnosis. Some enlargement of the uterus may be present, but it often is without producing hemorrhage. Want of tone in the uterine muscle is only a conjecture. The most careful bimanual examination finds no sufficient cause. Surgery being excluded, what are the remedies? The whole list of so-called astringents has been freely administered with more or less success in various cases. Sir A. E. Wright's researches have brought about a change in practice by showing that the coagulability of the blood may be increased by chloride of calcium. In the course of some operations surgeons have found that the blood has a watery appearance and its coagulability was below normal. The administration of calcium chloride is therefore being given with a view of inducing a more normal condition, and so lessening the tendency to hemorrhage. Gynecologists report that the calcium treatment is of great use in menorrhagia. Handfield-Jones combines with it gelatine phthalate with the best results where the excessive uterine hemorrhage cannot be shown to depend entirely on the condition of the mucous membrane, or to be to some degree due to morbid state of the blood. If permanent good is expected, he says it must be continued for a long time. Dr. Jervois Aarons of the Hospital for Women has also used the remedy with good results in a variety of cases, and has scarcely ever found it to fail to arrest bleeding—in climacteric cases never. Abel has used this drug locally in inoperable cancer, and thinks it is analgesic as well as astringent.

Speaking of drugs reminds me of the rehabilitation of mercury which has been going on for some years; not that we are likely to return to the excesses at one time practised, but that it is common enough now to hear "altera-

tive action" ascribed to the drug, though a few years ago such expressions were mostly regarded as behind the age. It is not unusual to see small doses given as "correctives of the liver," and, again, repeated small doses or inunctions as absorbent. A person in my room spoke of the use of ¼-grain of calomel as an excellent "hepatic," and that elicited the remark of another that he had for many years given in doses of 1/5 gr. for that purpose.

Professor William Carter lately stated at the Liverpool Medical Institute that he thought mercury too much neglected as apart from syphilis. He cited cases of peritonitis, meningitis, and other diseases in which he had seen it of value. Where organic change rendered recovery impossible it might afford relief. He showed specimens of bile alone, and others to which calomel had been added, the former very offensive, the latter not so. Both had been kept about ten days. To a third specimen calomel had been added after decomposition, and had deodorized it. He remarked that its insolubility allowed the drug to reach the duodenum unaltered, and there it came into contact with the bile, and might render absorbable toxins harmless. Dr. Carter's views were indorsed by several members, one remarking that it was difficult to overestimate the alterative action of mercury, another commending it in chronic valvular disease of the heart when compensation seems about to fail, a third saying it was the best intestinal antiseptic, but considering this effect as indirect, being caused by the increased flow of bile produced. One gentleman mentioned the occasional salivation set up by small doses, especially in old patients with septic mouths. How different this discussion seems to what some of us heard when mercury was said to be discrowned and podophyllum about to take its place!

A conference on the teaching of hygiene and temperance in all the universities and schools of the British Empire was held here on Tuesday. It was attended by many doctors, some of the Colonial premiers and ministers now in London, and some enthusiasts about education. Among the latter, some who think themselves experts did not do justice to their assumption, but, on the whole, the conference will be useful, for it showed us what the colonies had done in the matter. Lord Strathcona, presiding at the morning sitting, said that the teaching of these subjects in Ontario had been productive of great good. Mr. Deakin, premier of the commonwealth of Australia, said that there, too, the importance of such teaching was not only recognized but acted upon as a matter of administration. Sir Philip Jones, Sir William Collins, and Sir J. Cockburn all spoke in the same sense. In the afternoon session papers were read showing what had been done in France and Scandinavia. Sir Victor Horsley urged the need of reform in the Board of Education. He held there ought to be an anthropometric survey and medical inspection of all the children, all available facts to be collected for the benefit of the education minister. As to temperance, he said 72 per cent. of the secondary schools might be truthfully described as total abstinence schools. They owed thanks and appreciation to those masters who had quite quickly trained the nation in temperance by their precepts and example. It was amazing what senseless habits were persisted in by some old established schools, where custom froze up intellect and boys were given alcohol. They could not conceive how this could be, but it was simply continuing an ancient custom. The whole system of education needed revision from a medico-scientific point of view. After some discussion a resolution was adopted to the effect that to meet the responsibility of the State, it is essential that a medical department be instituted in the Board of Education.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE TREATMENT OF SLEEPING SICKNESS—HEMOSTASIS IN HEMOPHILIA—DIET IN DIABETES—NECROLOGY.

PARIS, April 15, 1907.

AT the Académie de Médecine Prof. Laveran made an interesting report on the treatment of sleeping sickness. He recommended the use of atoxyl as indicated by Wolferstan Thomas of Liverpool. Under the action of this drug the febrile attacks disappear, the swollen glands diminish in size, the nervous symptoms improve, the patients increase in weight, and the trypanosomes disappear from the body, except from the cerebrospinal fluid; but relapses occur if the treatment is withheld too long. For the administration of the atoxyl the hypodermic injection seems to be the best method, using a 1 to 100 solution. For serious cases intraspinal injections are made.

At the meeting of the Société de Chirurgie, Broca read an interesting paper on Dr. Paul Emile Weil's work on hemostasis in cases of hemophilia. Although hemophilia is somewhat rare, it is not so much so but that surgeons sometimes find themselves confronted by an uncontrollable hemorrhage or find it necessary to perform emergency operations on patients suffering from hemophilia.

The principal blood change in hemophilia consists in the great slowness of coagulation, which does not take place in less than from one to nine hours. The important fact demonstrated by Dr. Emile Weil is that in cases of hemophilia the serum of man or of animals used when fresh favors coagulation to a marked degree, so that it takes place regularly within five or ten minutes. To check a hemorrhage in an adult, 10 to 20 c.c. of serum from fresh blood injected into the veins, or 20 to 30 c.c. injected subcutaneously is ordinarily sufficient. Sera from the blood of man, rabbits, horses, and cows are equally good so long as they are fresh. Following the report of Broca, Tuffier spoke of the well-known action of artificial serum on coagulation. As artificial serum consists of a solution of sea salt in the proportion of 8 to 100, and this solution can easily be prepared at all times, he thought that even if its effect was not quite so good as that of other sera, still that its use should be advised and it should be considered as a useful agent.

Dr. Marcel Labbé presented an interesting communication to the Société Médicale des Hôpitaux de Paris on the comparative value of the different foods prescribed in the dietaries for diabetics. According to Mossé the potato seems to be one of the best articles of diet and superior to the other carbohydrates. It proves more acceptable even in large amounts, it can be used instead of bread, and lends itself to various preparations in which a large amount of fat can be used. Oatmeal is also easily taken by diabetics, but has several drawbacks. Patients tire of it quickly, and it can be taken only in small quantities, and, moreover, it often causes diarrhea or indigestion. Dry vegetables are extremely good and may be prescribed in the dietary. They contain a large proportion of albuminous material as well as mineral salts and so are very good articles of diet. Cakes of rice are also pleasing to the diabetic patient, and on account of their digestibility can be used as a substitute for bread. Milk is not to be recommended, and bread also has always been found an unsatisfactory article of food for diabetics' dietary.

Berthelot, the world-renowned and illustrious chemist, has just died at the age of eighty years, thus bringing to a close his marvelous and fruitful scientific career. The work which he has done is well known, but for two things he is especially famous. The first is thermochemistry, which, entirely built up by Berthelot, permits one to see *a priori* the results of chemical reactions. The second is his research work on synthetic chemistry. He was the creator of organic synthesis and on account of that he deserves to be called the founder of organic chemistry. With his extraordinary ability to work and his unusual memory Berthelot was able to do an almost inconceivable amount of investigation upon explosives, the formation of alkaloids, on the persulphates, on electricity, and on the chemical reactions caused by radium, etc. He received many honors and distinctions; he was President of the School of Pharmacy, Member of the Académie de Médecine, Professor of the Collège de France, Member and Life Secretary of the Institute. As Minister he fulfilled the various and diverse duties of his position. His entire life was a splendid lesson of work, of perseverance, and of disinterestedness, for he made no financial profit from his discoveries. He has been given the honor of burial in the Pantheon.

Professor Hergott of Nancy has also died and with him there is lost one of the great figures of the old French School of Strassburg. He taught obstetrics and put and will be remembered on account of his work on the treatment of fractures and the invention of the plaster splints which bear his name.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

SEGREGATION OF LEPERS—ROENTGEN-RAY TREATMENT OF LEPROSY—MEASLES AMONG SOLDIERS—ARTESIAN WELLS—CHOLERA—PERSONALS.

MANILA, P. I., April 1, 1907.

THE work of concentrating the lepers of the Philippine Islands at the Culion Leper Colony is being steadily pushed forward by the Bureau of Health as rapidly as the necessary appropriations for this purpose become available. It is proposed, during the early part of April, to send out a vessel to gather in the remaining cases from those islands from which lepers were removed heretofore. If the plan

followed by the Bureau of Health for freeing the islands of leprosy results as contemplated, there should not be many more cases of leprosy occurring in such islands in the future. In addition to the foregoing, it is proposed to remove all the lepers from the islands of Samar, Leyte, and Marinduque, to Culion. With the clearance of these islands fully one-third of the territory of the Philippine Islands will then be free of this disease.

The treatment of leprosy by the *x*-ray is still being continued at the San Lazaro hospitals in Manila. Of the seventeen lepers who have been under treatment during the past few months, all show signs of considerable improvement. In two cases it has not been possible to find leprosy bacilli for the past two weeks in the skin scrapings taken from places in which they had been abundant heretofore. It is stated that as soon as this work is further advanced a complete detailed report will be published.

The transport *Logan*, which arrived here during the early part of March, had on board two cases of measles among soldiers, and upon their being transferred to Fort McKinley several additional cases occurred. Owing to the prompt measures taken by the military authorities, no further spread of the disease took place. Measles is a disease that is rarely encountered in the Philippines, and there is no record of authentic cases occurring, except by direct importation, so that, whether this disease does not flourish in a tropical climate, or whether it has simply been due to good fortune that measles does not gain a foothold here, is an open question. There are several instances on record during the past few years in which cases were imported, but no special measures looking toward their isolation were observed; yet the disease did not seem to spread among the native population. The records of the San Lazaro contagious disease hospitals, however, show that a few cases occurring in Filipinos have been admitted.

The drilling of artesian wells in the provinces is going on continually, and several more artesian well-drilling outfits have been ordered from the United States. The value of this great hygienic boon is gradually being appreciated by the Filipino people themselves, and from many towns applications are received requesting to have wells installed. The geographical formation of some sections of the Philippines is such that they are well adapted to this form of water supply. Experience in the past has demonstrated that in the Philippines particularly, where so many forms of intestinal parasites occur in such profusion, great improvement takes place in public health in almost all places in which they are exclusively used.

The committee which was appointed by the Governor-General for the purpose of making an investigation into, and fixing the blame for the inoculations which were made by Dr. R. P. Strong upon some prisoners in Bilibid prison last November, has rendered its report. The Coroner has also submitted his report to the Governor-General, but the contents of neither of these documents has yet become public property. It is generally understood, however, that the Coroner exonerated Dr. Strong from all blame, but that the general committee appointed by the Governor-General did not make its report quite so favorable. It is announced that the reports will soon be made public, and when this is done, more detailed information will be given.

Cholera in the Philippine Islands has practically disappeared, a few sporadic cases being reported from remote districts in the provinces of Occidental Negros and Capiz. Repeated efforts have been made to have these diagnoses confirmed by bacteriological examination, but, owing to the remoteness of the places in which they occur and the lack of facilities on the ground, these efforts have so far not met with success.

Major William F. Purviance, Surgeon, U. S. Army, who has been on duty as visiting physician in the city of Manila, has completed his tour of service in the Philippine Islands, and returned to the United States on the transport *Logan*, which sailed from here March 15.

Dr. J. R. McDill, the surgeon of the St. Paul's Hospital, who has been in the Orient for the past seven years, left on the steamship *China* for a vacation to be spent in Chicago.

Appendiectomy. Duval has operated with success on three cases of appendicitis, using the transverse incision which has been proposed by Chaput. In the region of this incision the muscular fibers of the internal oblique and the tranversalis are parallel; no muscular fascia is cut and there is less chance of eventration. There is a better opening from this incision than from that of McBurney. Besides, in case of need the incision can be easily prolonged to the median line. No nerve filament of the rectus is sacrificed and the integrity of the abdominal wall is best preserved by this method. Finally this incision allows drainage in all directions.—*Gazette des Hôpitaux Civils et Militaires.*

Progress of Medical Science.

New York Medical Journal, May 4, 1907.

Raynaud's Disease.—J. V. Shoemaker reports one case, his patient being a woman of thirty-four years, seen in the second or congestive stage of the disease, her fingers being swollen, red, and cold to the sense of touch. The author states that the affection may be mistaken for diabetic or for hysterical gangrene. In diabetic gangrene the onset is rather sudden; there are signs of weakness and malaria, emaciation is marked, sugar is found in the urine, and the gangrene is rarely symmetrical. In Raynaud's disease, on the other hand, the onset is insidious, general health remains good, there is no emaciation and no sugar, while the gangrene is always symmetrical. In hysterical gangrene, there is the history of hysterical attacks, pain is constant, and gangrene is symmetrical. There is periodic pain in Raynaud's disease and no hysterical history. In the author's case the etiology may be referred to a long-standing diarrhea disturbing the vascular and hematopoietic systems. The blood was pale scarlet in color with normal coagulability, erythrocytes 3,240,000, leucocytes 7,400, hemoglobin 70 per cent. The treatment of such cases should be hygienic, dietetic, electrical, and medicinal.

Mental Responsibility and Crime.—A. Gordon sums up his ideas on this subject in the following propositions: (1) The legal conception of responsibility is not in accordance with the principles of science, and does not satisfy the practical exigencies of life. (2) The dogmatic principles of law should be replaced by more real and vital, viz., by biological principles. (3) A special psychiatric service should be established in prisons for study of all criminals, or else an alienist be attached to prisons, reformatory schools, houses of refuge. (4) The function of the law should be not only to find criminality, but also to correct the criminals themselves. (5) Legal instruction should consist of study of crime as a special phenomenon, and of criminals as individuals. (6) Administration of justice in such cases should be confided to a jurist and to an alienist. (7) Administration of houses of correction should be placed in the hands of alienists and pedagogues, because the majority of criminals bear stigmata of degeneracy which require special attention. (8) Youthful criminals should be isolated and placed in special institutions in which proper medical and pedagogic measures will prove to be most beneficial.

Mucous, Mucomembranous, and Membranous Colitis.—J. P. Tuttle presents an elaborate discussion of the various features of this malady and says that the treatment is usually medical and along the following lines: Diet: Meat or fish twice daily, animal broths, a limited amount of dry toast or crusts of bread, rice, hominy, green vegetables, milk, butter, and salads. No sweets, potatoes, peas, shelled beans, or alcoholic drinks are allowed. Regular catharsis, preferably by castor oil and glycerin, every three days. Colon flushing with normal saline, sodium bicarbonate, or weak silver nitrate solutions. Intestinal antiseptics such as phenyl salicylate, boric acid, or zinc sulphocarbolate. Regular hours for business, exercise, and rest, and sometimes, if need be, change of climate. Some of these cases, however, especially those due to latent or remittent amebic dysentery, do not yield to this treatment. When such is the case we are forced to employ surgical measures such as Gibson's cecostomy or appendicostomy. The author prefers the latter.

Journal of the American Medical Association, May 11, 1907.

Recent Studies in Heredity.—E. B. Wilson gives an account of some of the more recently developed facts in regard to heredity and of the methods of research employed. The studies have thus far followed three principal lines; the statistics or biometric, the experimental method from which the Mendelian principle or law of the persistence of the parental dominant and recessive characters in the germ cells of the hybrid by which the results of crossing may be predicted with approximate accuracy has been deduced, and, lastly, the method attempting to study in detail the physical basis of heredity in the germ cells. It is to this last method that he particularly addresses himself, and as a preliminary he reviews the more striking facts of Mendelian inheritance in some detail, as shown by color inheritance in mice. In Mendelian inheritance the so-called unit characters behave almost as if they were material substances that can be combined in definite proportions. This, he says, would be intelligible if the material bases of the characters in the germ cells were also separable and capable of combination. These are sought for in the chromosomes, and Wilson gives the facts that point to the connection of these bodies with the transmission

of the unit characters and the general close relationship of the Mendelian principle to chromosome characteristics. Thus it seems to be pretty definitely proven that a certain chromosome in some of the insects has to do with the inheritance of sexual characters, thus affording a definite basis for the assumption, amply warranted by other facts, that the other chromosomes are concerned with the transmission and development of still other characters. The double series of chromosomes in the nucleus, their maternal and parental origins, respectively, which have been practically proven, and their behavior in synapsis also shows the closed parallelism to the behavior of the unit characters in Mendelian heredity and afford a rational basis for a working hypothesis, if not quite sufficient for a fully demonstrated theory.

Bacteriology of the Respiratory Tract.—D. J. Davis gives his conclusions as follows: 1. Influenza-like bacilli are commonly found in the upper respiratory tract in various infectious diseases, and especially in whooping cough. Occasionally they occur in normal throats. 2. Various organisms occur in the discharge of otitis media, the streptococci being the most common; occasionally influenza bacilli are found. 3. The *Micrococcus catarrhalis* is a common inhabitant of the respiratory mucosa in infectious conditions and is sometimes found in almost pure culture. It does not seem to produce specific lesions. 4. The influenza-like bacillus of whooping cough is pathogenic for man; its specificity is dubious. Present data permit us to consider these bacilli as secondary invaders wherever they are found. The possibility of a primary invasion should, however, be considered. 5. Influenza-like bacilli are readily taken up in the test tube by unwashed leucocytes and less readily by washed leucocytes. This spontaneous phagocytosis is not affected by varying the concentration of the salt solution between 0.6 per cent. and 1.4 per cent. 6. Injection of these bacilli into animals causes the production of specific agglutinins and probably also an increase of opsonins in the serum. Because of the occurrence of spontaneous phagocytosis and agglutination in such sera the determination of the opsonic index for these bacilli is rendered unreliable.

The Gradual Cure of Hysterical Paralysis.—H. T. Pershing says that the sudden cure by suggestion or otherwise of hysterical paralyses, however practicable and tempting in cases in which one can be sure of the diagnosis and of his power to impress the patient, is not the one to be generally chosen. Failure may compromise future success, and too prompt success may have its disadvantages in depriving the patient of the discipline and enlightenment that are necessary to a permanent cure. The safer way is more gradually to arouse and exercise the dormant kinesthetic centers, overwhelmed by inhibitory impulses from other centers, due to the perverted emotional conditions and ideas, by first raising the emotional tone, encouraging the patients to believe they will recover, and if such cheering is opposed or resented, appealing to their *amour propre* by judicious suggestions. The physical measures—rest, food, tonics, and sedatives—while of great importance, are sometimes overvalued, he thinks, but both mental and physical treatment should be employed in these cases in harmonious combination. While doing this, the dormant kinesthetic centers can be acted on specifically by sensory stimulation. Hysterical anesthesia is not absolute and strong faradic currents, applied to the skin and muscles, followed by vigorous and even rude, passive motion of the affected limb, have a powerful tendency to restore the lacking sensations and ideas of motion. The patient's close attention should be directed to the anesthetic part and every slightest beginning of sensation noted. This will tend to bring the cortical sensory centers again into relation with the other centers in the cortex. After awakening some degree of normal sensibility and overcoming inhibitory fears, the cure can be completed by exercises in voluntary motion. If the paralysis is nearly total it is as well to let the first attempts be favored by gravity, which will assure some motion and encourage the patient to increase it. A beginning once made, the attempts can be gradually increased, every encouragement being given, till at length some normal control is obtained, and the patient is able to practice some assigned exercises in the physician's absence. The length of time taken in accomplishing the cure may be made an advantage by using it to carry on a reeducation in composure and self-reliance, without which permanent recovery is impossible. Two cases of typical hysterical paralysis are briefly described in which this method had been employed with complete success.

Conservative Surgery of the Limbs.—J. E. Cannaday publishes several case histories illustrating the value of conservatism in the surgery of the arms and legs. Whenever the circulation is fair in the limb there is a possibility that it can be saved, and the modern advances in the surgery of the blood-vessels give promise of better results in the future in what were formerly considered hopeless cases. The age of the patient has also much to do with the establishment of collateral circulation, and by grafting very extensive damage to the skin can be repaired. He objects to haste in operation, the use of the tourniquet, and too meddlesome first-aid methods, and states his conclusions substantially as follows: 1. The conservative treatment of severe injuries to the limbs is essentially modern, and primary amputations should be avoided (except when the limb is held only by a few shreds), and we should wait for shock to pass and the patient regains strength. 2. Normal salt solution should be used for irrigation instead of antiseptic solutions. 3. Bones should not be permanently sutured and too much should not be attempted in the beginning. 4. Moist gangrene calls for radical treatment. 5. Drainage is usually necessary and the rubber tube is to be preferred. 6. Good functional results can be obtained in spite of great apparent odds, and a saved limb is better than a stump.

Buttermilk Feeding.—H. C. Carpenter reports twelve cases of babies with infantile atrophy, gastroenteritis, etc., in whom he had generally good results from the use of the following mixture: Buttermilk, 1 quart; wheat flour, 3½ teaspoonfuls; granulated sugar, 15 teaspoonfuls. The ingredients were carefully mixed, heated up to the boiling point but not boiled, and then rapidly cooled and kept till used. Full directions are given for the preparation, precautions against curdling, etc. The cases were not selected as likely to do well, but in every case regular milk mixtures had been tried and failed before the buttermilk was begun. The ages ranged from one to fifteen months; the average gain in weight during the use of buttermilk was eight ounces a week. Carpenter remarks the advantage of cheapness in the buttermilk feeding and believes it a most excellent food for infants suffering from intestinal indigestion, enteritis, and marasmus. He has observed no unpleasant effects from its use; children almost invariably take it well. A few, when first put on the diet, vomited slightly, but, with one exception, this ceased in a day or two. The point he specially emphasizes is that the success is not so much due to the absence of fat as to the great ease with which the proteid of buttermilk is digested. He has observed this in almost every case. Several of the infants who were unable to digest 0.75 per cent. of calcium casein digested perfectly the 2 or 3 per cent. of casein lactate in the buttermilk.

Cardiac Murmurs Developing in Biliary Colic.—D. Riesman reports two cases recently observed by him of systolic murmur originating during attacks of biliary colic, and reviews the literature of the subject. The cases reported by Gangolphe are reproduced in brief abstract, and other observations and the theories proposed to account for the symptoms are referred to. Riesman thinks that the transitory character of the murmur and the absence of signs indicating grave infective lesion renders endocarditis unlikely as a cause, while the symptom usually appears too early in the case to be accounted for by anemia. If jaundice were responsible it ought to be more common, and, moreover, the murmur usually outlasts the jaundice. The bile acids and bile salts may cause changes in the cardiac innervation or in the myocardium, but pain, he thinks, is the principal factor in the production of the murmur. The excruciating pain of hepatic colic, he says, may cause dilatation of the heart with a temporary insufficiency of the mitral valve; perhaps also of the tricuspid. There must, however, be a predisposition, the heart must be potentially dilatable. This does not account, it is true, for the murmur in Gangolphe's cases of emotional jaundice nor for that sometimes observed in catarrhal jaundice and hepatic cancer. With regard to the last he holds that anemia and cachexia constitute an adequate explanation; he can not say what the factors are in the rather dubious emotional jaundice, which he has never seen. The practical importance of the murmur in these cases is the evidence it gives of a somewhat abnormal condition of the cardiac muscle which enforces some caution in the choice of the anesthetic and possibly also in the operative technique. A too prolonged operation might be dangerous. On the other hand, the finding of a murmur might lead to the error of assuming that an old endocarditis existed, a belief that might readily influence a surgeon's advice. The knowledge that such a murmur may arise *de novo* in cases of biliary colic, and that it is an index of a weakened myocardium, a weakness that may not be serious, will be of value in the treatment of a given case.

Torsion of the Great Omentum.—W. W. Richardson reports a case of twisted and acutely strangulated great omentum, partially included in the sac of a postop-

ective hernia, which was successfully operated on. He reviews the subject generally, classifying the cases according to their association with hernia and intraabdominal and extraabdominal location, and also according as one or more points of torsion exist, and describes the mechanism and etiology. The essential condition for the occurrence of an omental torsion is the formation of a matted mass at its free end or the formation of an adhesion of this free end to some other structure. A hernia is the most frequent factor in the production of these torsions, as is shown by the published cases, and it can not always be excluded in those in which it is not mentioned as existing. Symptoms of strangulation only appear when the torsion is sufficient to obstruct the return circulation, and in most of the cases this occurs suddenly. Diagnosis is difficult; in only one published case—that of Rudolf—was it correctly made before operation. It is impossible, therefore, to make positive statements regarding the prognosis, as we do not know how many patients may have recovered without operation. That unaided recoveries may occur is probable from what we know of strangulated epiplocele, in which many such have occurred. As in other cases of strangulation of abdominal organs, the mortality depends on the stage of operative intervention. In all the cases in which early operation was done, without exception, recovery ensued. Several of the cases reported in the literature are briefly reproduced and cuts are given illustrating the varieties of the condition. The desirability of accurate and full reports of future cases is mentioned. If the possibility of omental torsion is borne in mind in every case in which the symptoms point to strangulation of some abdominal organ, there will be more correct diagnosis in the future.

Blocking of Auricular Extrasystoles.—A. W. Hewlett, reports a case of arhythmia due to blocking of the extrasystoles on their passage from the auricles to the ventricles, a type that, so far as he is aware, has not hitherto been described. He is inclined to explain the absence of the ventricular contractions by a failure of impulses to cross the auriculoventricular junction rather than to a lack of contractility on the part of the ventricles. Every extrasystolic first sound was followed by a second sound indicating that the ventricular contractions, when present, were sufficient to send the blood into the aorta or pulmonary artery. The article is illustrated by sphygmographic tracings, which are elaborately explained.

Puncture and Disinfection for Abscesses.—DeWitt Stetten advocates puncture and disinfection for abscess instead of incision and drainage, in order to avoid mutilating scars and slow convalescence. His method is as follows: 1. After careful disinfection, and under infiltration anesthesia, he punctures the most dependent portion with a large trocar or pointed scalpel and gently expresses the pus. This is better than aspiration. 2. The cavity is then thoroughly irrigated through the trocar with a 1-1000 solution of corrosive sublimate. This can be used in large quantities, as the abscess wall does not absorb. He has found this strength most satisfactory. 3. The remnants of the corrosive sublimate solution are carefully squeezed out and the abscess is partly distended with a solution of from 5 to 10 per cent. iodoform glycerin. A moist dressing with a firm pressure bandage is then applied. He uses this method in every form of acute external abscess, following the principle originally laid down by Henle for cold abscess. To date he has treated thirty-seven cases with good results in all except abscesses of caseous tuberculous glands, which generally required a secondary curetting, though they were none the worse for the preliminary conservative treatment.

The Lancet, April 27, 1907.

Suggestion for Treatment in Snake Bite.—W. H. Haw records two cases of snake-bite, one recovering and one proving fatal. With regard to treatment he says that the great difficulty is to keep the venom out of the circulation. If this could be effectually done until such time as the venom might be destroyed, it would be possible to save some cases now lost. The usual method of preventing the venom entering the circulation is the ligature, and one is advised to slacken it occasionally to allow of the poison being worked off in small nonlethal doses. It seems to the author that if the circulation be brought to a standstill at the seat of injection it might be possible, if this be done early enough, to prevent any venom at all entering. The venom would be imprisoned, as it were, and could be dealt with by permanganate of potash and incisions. He suggests, therefore, that in cases seen early enough the part be frozen with ethyl chloride spray during the making of the incisions and the rubbing in of permanganate of potash. Where the subcutaneous cellular tissue is loose the part containing the imprisoned poison might be shut off from the general circulation by ligature should needles and thread be handy. All the operations would be painless. A tube of ethyl chloride would not be a large addition to a snake-bite outfit.

Recent Development in the Therapeutical Applications of Arsenic.—J. St. Aman states that the great value of alteratives in therapeutics is that they often change pathological processes brought about by disease into physiological processes. Their failure frequently arises from the circumstance that they introduce into the body their own toxic pathological processes. This is exceedingly well exemplified by arsenic, which is able to produce a mimicry of several diseases, much to the discomfiture of diagnosticians. In the nervous system we may have peripheral neuritis with rapid muscular atrophy, or definite myelitis. The intestinal canal may present appearances closely resembling cholera, with granular changes proceeding to fatty degeneration in the epithelial lining, the interstitial tissue and Peyer's patches being invaded by large round granulated cells. The liver may be affected in such a manner as to suggest a diagnosis of acute yellow atrophy. The skin may be the site of lesions the number of which is almost legion. Every anatomical manifestation known to dermatology from a slight erythema to a bulla is represented. The most characteristic appearances, however, are pigmentation, herpes zoster, and hyperkeratosis of the palms and soles. Hutchinson maintains that these thickenings may develop into true epitheliomatous growths. The sphere of action of arsenic is obviously very extensive when it is allowed to act on the general healthy organism. Its danger lies in its tendency to cause fatty infiltration and degeneration, and its therapeutical applications are accordingly very much hampered, though practical medicine still indicates a considerable field for its employment. The art of employing arsenic successfully consists in gaining control of its pharmacological action and making it subservient to therapeutic aims.

Goiter Removed Under Cocaine Anesthesia.—J. L. Thomas presents a series of cases. He has operated fifty-five times under local anesthesia (cocaine 1 per cent.), including one case in which no anesthesia was used. All these recovered. He has used a general anesthesia seventeen times, including five Graves' cases. Of this latter series, three died; one from respiratory complications, one from hyperthyroidism (both Graves'), and one from sepsis. Another Graves' case died suddenly just as she was about to be operated on but before any medicament had been used. The cause of death was unknown. The author always uses Kocher's collar whenever possible, as it gives ample room and exposes the blood-vessels at right angles to their courses, and leaves a scarcely perceptible scar. The position of the patient is on an inclined plane, the higher end being under the shoulder while the head rests slightly extended on a cushion. Full operative details are given by the author. Everything being ready, the neck is marked by drawing the edge of the scalpel very lightly round it in the position which later forms the collar incision; by this maneuver no pain is inflicted but sufficient blood exudes to form a thin red line under which from one to two drachms of a 1 per cent. solution of cocaine are injected by means of Kocher's syringe from end to end so as to form a continuous subcutaneous ridge. As soon as the injection of cocaine is completed the collar incision is made at once and the upper flap is first dissected upwards and consists of skin, subcutaneous tissue, platysma myoides, and the fascia covering the anterior surface of the neck muscles. Every blood-vessel exposed is first clamped by two Kocher forceps and divided between them so that the amount of blood lost is a mere trifle. The lower flap is then formed. The author notes that in certain cases it is necessary to divide the sternohycid and sternothyroid muscles in order to facilitate the delivery of the goiter; in order to prevent atrophy of these muscles they must be divided near their upper or lower ends according to the exigencies arising, and by so doing the nerve supply to the muscles will not be interfered with. In order that the condition of the neck should be restored as nearly as possible to its normal appearance, one must endeavor in the first place to restore to their normal conditions every divided muscle by carefully reuniting the ends, and in the next place to sew the skin together by means of a very fine needle to avoid puncture scars, and lastly the drainage-tube must be removed at the expiration of from eighteen to twenty-four hours, together with the skin sutures. Special attention must also be given to accurate apposition of the edges of the aperture left by the removal of the drainage-tube, otherwise slight puckering will take place.

British Medical Journal, April 27, 1907.

Calcium Iodide in Leg Ulcers.—A. G. Peter commends the use of this remedy, stating that in his experience, ulcers which have for years stubbornly resisted all kinds of treatment, and whose owners have without avail been simply saturated with potassium iodide, in a week or two showed clean granulating surfaces, and have in almost all cases healed up. Two or three cases, which are healing more slowly, though immensely improved, are due, the author thinks, not to any deficiency in the drug, but to the ingenuity displayed by their owners in counteracting its effects—to put off the evil day of their discharge from hospital. In all cases the induration around the ulcers greatly diminished or entirely disappeared. He also observed in a few cases of syphilitic necrosis of the nasal bones considerable benefit from its administration, and great relief was obtained in headaches associated with syphilis. The dose given in all cases was two grains in mixture three times a day, and there did not appear to be any increased advantage from augmenting the dose. Any mild external application seemed equally efficacious; in most cases he used a mild mercurial or iodoform ointment.

Muscular Spasm Under Chloroform Anesthesia.—A. C. Stark refers to the case of a primipara of twenty-six years, to whom chloroform was administered from a mask until the corneal reflex was abolished. The moment the fingers touched the vulva the legs were violently extended and became so rigid that the united efforts of the assistant and himself were insufficient to flex them. The anesthetic was pushed, and another attempt made to introduce the finger, only to reproduce the same phenomena. It was only on the establishment of deep anesthesia that delivery was effected with considerable difficulty. The patient made an uneventful recovery. The same specimen of chloroform had been given to other patients without any unusual incident. The author remarks that although muscular rigidity in the early stage of chloroform anesthesia is common enough, such reflex spasm as that described, after the loss of the corneal reflex, seems sufficiently rare to be worth reporting. The spasms appeared to be limited to the legs, and he assumes the cause to be a reflex impulse from the lumbar centers, these centers having failed to reach the general level of depression of the rest of the cord. The reasons for this failure are not easy to find.

Lesions of Spinal and Cranial Nerves Experimentally Produced by Toxins.—D. Orr and R. G. Rows record their experiments on rabbits. Their method consisted in filling a celloidin capsule with a broth culture of a certain organism. The sciatic nerve being exposed, the sealed capsule was placed in apposition with it, after which the gluteal muscles were stitched in their original position and the wound closed. As toxins are known to diffuse through the wall of these capsules, we assumed they would find their way into the ascending lymph stream of the nerve and so to the cord, where their presence would be demonstrated by the ensuing degeneration. The organisms they first employed were *Staphylococcus pyogenes aureus*, *Bacillus pyocyaneus*, Gaertner's bacillus, and the *Bacillus coli*. They present the following findings: (1) Toxins readily travel up spinal and cranial nerves to the central nervous system. (2) While these nerves in their extramedullary portion possess a neurilemma sheath and are protected by its vital action, in their intramedullary part, having lost their neurilemma, they immediately undergo degeneration. (3) The first change is a primary degeneration of the myelin; axis cylinders and nerve cells are evidently affected later.

Oatmeal in the Dietary of Children.—Basing his opinion on the results of feeding of oatmeal to rats with a resultant thyroid overgrowth, C. Watson makes a plea for the liberal use of oatmeal in the dietary of children after the third year. Breakfast is the meal into which it should most largely enter, the best form of administration being porridge and milk, which should be followed by a glass of milk and some bread and butter. It is not, in the author's opinion, advisable to supplement the meal by meat in any form, for two reasons: First, because it is not necessary and may be harmful; and, secondly, because the use of the meat tends to create a distaste for the more wholesome but less appetizing meal of porridge. If a child be given for its breakfast a little porridge, followed by bacon, it is certain that in nine out of ten cases, the chief element in the meal is, in the child's opinion, the bacon. Two facts, however, must be remembered. In the first place, a porridge diet *per se* is not good for children on account of mastication not being essential for this diet. This fault may be counteracted by including in the diet crusted bread, rusks, Vienna rolls, and the like, which should be taken "dry," and not merely washed down with fluid, as is often the case. The inclusion of such articles of diet in the breakfast will ensure that due attention is paid to the development of the muscles of mastication, salivary glands, and jaws, a point of very great importance in the dietary of children. Secondly, clinical experience teaches us that certain children cannot properly digest and assimilate oatmeal. This feature is, in the author's experience most frequently observed in the offspring of typically gouty parents. The parents of such children tell us that they cannot take porridge because of its "heating" properties, the objective indications of disturbed nutrition being found chiefly in a concentrated urine and in various skin eruptions. These symptoms are, however, much less frequently observed if the porridge forms the main article of the meal and is not followed by other highly nitrogenous food, such as bacon and eggs, as is frequently the case. There are, however, some children who cannot properly digest and assimilate porridge, and these are better without it, but if careful attention be paid to the details of the dietary as a whole, it will be found that these cases are much rarer than is commonly supposed.

Maniacal Chorea.—J. M. Faring follows a case history with a general review of the history of this particular variety of chorea in medical literature. His patient was a girl of seventeen years and the most important features of the case were the following: Rheumatic pains in the legs for a fortnight, upon which chorea supervened. A mitral systolic murmur, audible on admission, of varying loudness, and lasting up to the ninth day—the day of her death. The pulse quiet and regular, about 80 each day up to the last three days, when it rose to 110, 130, 140. The temperature normal or subnormal until the day before death, when it touched 103.4°. The choreic movements were slight for about forty-eight hours, and then became so violent that two special nurses were required to watch her and prevent her from falling out of bed and from striking her limbs against parts of the bed. (The idea of treating her by placing her mattress on the floor, with pillows around, was considered, but discarded in favor of the bed with nurses at either side.) The psychical phenomena were prominent, out of all proportion, and at first quite overshadowed the motorial. They differed, however, by the absence of incoherent speech and wild garrulity, from the forms one is accustomed to associate with the acute delirium of fever or acute mania. Another point worth noting was the occasional, though temporary, mental calm, which the physician's visits, once or twice a day up to the last three days of her life, seemed to produce. At these times she would cease shouting, the movements became quieter, she could always understand what was said and occasionally she made intelligent replies. Treatment by medicines totally failed to have any effect on the course of this terrible disease, and the only help it gave was by securing some hours of sleep, and muscular rest during sleep. The drug which seemed most useful for that purpose was chloral. On two days 1-200 grain hyoscine hydrobrom. (once repeated) was successful in calming the violence of the delirium, but it failed to have any effect the last two days of her life; while morphine hypodermically was practically useless. The occurrence of a systolic murmur at the mitral area, which was considered on admission to be probably due to rheumatic endocarditis of some two or three weeks' duration, must now, in the light of the autopsy, be judged to have been dynamic, and due to simple and acute ventricular dilatation. It is not to be explained on the grounds generally accepted—namely, anemia and choreic cardiac excitement. The heart was somewhat atrophic but showed no other changes.

The Value of an Abnormal Rise in the Average Level of the Diaphragm as a Guide to the Volume of the Blood in Active Circulation.—The object of the paper of T. S. Wilson is to bring forward clinical evidence in favor of the following propositions: (1) When, from any cause, the total volume of the blood in circulation is materially diminished, the total bulk of the intrathoracic viscera is correspondingly diminished by the relative emptiness of the thoracic blood-vessels, especially those of the lungs. This diminution in the bulk of the intrathoracic contents shows itself by an elevation of the diaphragm, which has to be maintained at a higher average level than the normal in order to adjust the cubic content of the thorax to the altered volume of its contained viscera. (2) That such a rise of the diaphragm may frequently be detected clinically, and, when present, is of value in diagnosis, and affords important indication for treatment. The position of the diaphragm can be recognized clinically by ascertaining the upper level of the gastric resonance in the left nipple line, or of the upper border of the liver in the

right nipple line. The author prefers the gastric method for the following reasons: (1) There is much variation in the upper level of the liver dullness of healthy individuals, dependent upon the degree to which the lungs have been expanded by exercise or athletics, etc. (2) The respiratory movements of the lower edge of the lung render exact accuracy of record as to its level impossible. (3) The level of the diaphragm on the right side is more apt to be interfered with by ill-defined pathological conditions of the lung than is the case with the level of the central tendon which underlies the heart. An elaborate series of photographs accompanies the paper. The author considers the high diaphragm an important danger signal in some severe typhoid cases. It is a useful guide as to the extent to which rectal feeding may be pushed. It must also be borne in mind because in cases of suspected rupture of a gastric ulcer the absence of a liver dullness cannot, as is now well recognized, be relied on as an indication of free gas in the peritoneal cavity. In heart disease also the level of the diaphragm is a useful guide as to the condition of the circulation. If the weakness of the heart muscle be the prime factor, we shall expect a high diaphragm, unless, as in advanced age, the tissues be too rigid to yield easily; if, on the other hand, some obstruction to the circulation, such as valvular defect, be the chief cause of failure, there will be excess of blood in the veins of the thorax, and a normal or a low diaphragm would be found.

Berliner klinische Wochenschrift, April 22, 1907.

Experimental Researches on Diabetes.—Zuelzer presents the results of his recent investigations with reference to the experimental production of diabetes with suprarenal gland extract. The writer has studied the manner in which this toxic action occurs and the point at which the invasion takes place. The effect of suprarenal extract was first studied on the liver because this organ stands in intimate relation to the production of sugar in the organism. In dogs which had received the suprarenal extract, the blood from the liver showed a marked increase in sugar. Where the pancreas had been extirpated, the increase in sugar was considerably less. The same effect seems to be obtained therefore with the subcutaneous injection of suprarenal gland as with extirpation of the pancreas. The writer thinks that under normal circumstances the secretion from the suprarenals is neutralized by the pancreatic secretion. It would seem therefore that by the simultaneous injection of artificial pancreatic and suprarenal extracts, the appearance of a glycosuria might be prevented. In order to obtain a pancreatic preparation free from marked toxic action, the various all ummoid bodies must be eliminated. The experiment previously indicated was performed in a number of rabbits and it was found that the subcutaneous injection of pancreatic extract prevented a glycosuria in animals which had previously presented this phenomenon after the injection of suprarenal substance.

Münchener medizinische Wochenschrift, April 16, 1907.

Treatment of Bone and Joint Tuberculosis by Hyperemia.—Deutschlander, in an extended article on this subject, considers that the elementary principles involved may be summarized as follows: The hyperemia must be of short duration, not more than one-half hour daily, and should give an appearance similar to an acute inflammation. It must not give rise to pain or to edema. After several weeks of treatment, it is wise to omit the same for several days before resuming. Where fistulæ or abscesses are present, the congestion hyperemia may be favorably combined with that produced by the vacuum cup. In every case treatment should be started as early in the disease as possible and continued for a considerable period after all active symptoms have subsided, in order to provide against recurrences. The ordinary acute abscess should be incised early, but cold abscesses and accumulations of fluid may be punctured while suction is being applied without using iodoform injections. Immobilization is not required where hyperemia is employed; on the contrary, moderate movements of the joints are of value in preserving their functions. Tuberculous joints must always be protected and favored. The writer looks upon the Bier method as a most valuable one and the most conservative we possess at the present time. For it not only produces a cure in cases of joint tuberculosis, but does this with resulting movable joints of good function. Operative interference is by no means eliminated when this method is employed, but when necessary, these will be found to be of a more limited extent and not of the usual mutilating character.

Treatment of Severe Anemias with Transfusion.—Morawitz refers to the loss in popularity which this procedure has sustained in recent years. He thinks that it is especially indicated in those cases of anemia where there is a deficient regenerative action of the bone marrow, which may, however, be stimulated to proper activity. Although arsenic will often produce the required result, there are cases in which no effect is obtained, and in these, Morawitz thinks that the transfusion method is indicated. He employed the procedure in six cases of grave anemia due to various causes and in only one did he fail to obtain a result. Here the patient was too far gone and subsequent autopsy showed that the marrow was in such a condition that regeneration of red cells was impossible. In three of the cases the results were surprising as the patients were steadily declining under other methods of treatment. In all of the cases from 150 to 200 cc. of defibrinated human blood were injected directly into one of the arm veins. Complicating after-effects failed to appear, except in one case where there was some dyspnea, but nothing more.

A Method for Determining the Mobility of the Heart.—Herz describes an ingenious and simple method for determining the mobility of this organ. Usually the apex beat and the area of cardiac dullness are examined with the body in different positions. Changes in the position of the organ may be due to adhesions of the pleura, to emphysema; the sclerosis of the aorta and an abnormal degree of mobility is also noted in certain cases of neurasthenia. Herz proposes that, instead of making use of changes in position, changes in attitude of the body be employed. The patient is examined in a standing position as to the position of the apex beat and the left boundary of absolute cardiac dullness. Unless the patient has been told, he is very apt to assume an attitude of relaxation. He is then asked to stand erect "in a military fashion," and the same signs determined. It will be found that under normal conditions the apex beat and the left border of cardiac dullness will be moved over towards the right, and this usually amounts to 1½ cm.

Deutsche medizinische Wochenschrift, April 18, 1907.

Treatment of the Gouty Diathesis.—Ebstein considers that a common basis underlies gout and adiposity and the treatment of the two conditions is practically the same. As the two are so often associated both are benefited and the plan is one which it is not difficult to enforce. Albuminous material should be given in considerable amounts, it being immaterial whether that of plant or animal origin is employed. Fat should also be administered in sufficient quantity, anywhere from 60-100 gm. daily. The ingestion of carbohydrates must be restricted, for these not only influence the gouty state but also tend to the production of adipose tissue. Thorough intestinal activity must always be provided for. These are all the dietetic precautions considered necessary and a strict vegetarian diet such as has been advocated in certain quarters is entirely unnecessary and useless.

Inoculation of Animals with Lepra.—Jezierski refers to the many unsuccessful attempts which have been made to transmit this disease to animals for experimental purposes. The material was obtained from a boy who was the subject of the tubercular form of the disease. This was introduced into the bodies of rabbits and guinea pigs in various ways, but the results were invariably negative, no matter what method was pursued. This is in accord with the results obtained by most of the other investigators who have made similar experiments.

"A Sure Cure for Asthma."—Alfred Terry Short describes the following curious remedy. The patient was a young woman who had been afflicted with asthma since childhood. She was a native of Luzon, P. I. Large sums of money had been spent for treatment, but the family finally reached the conclusion that the disease was incurable. About this time the patient's sister went to the cemetery and selected some pieces of bone of a skull which were dry and bleached. These she washed and pulverized in a mortar, adding the powder to a quart bottle of water. A teaspoonful of this mixture was given to the patient three times a day. By the time half of it had been taken, her condition was very much improved. This solution had a watery chalk-like appearance. Before the bottle was finished the asthma had almost entirely disappeared and the treatment was discontinued. Since then about two and a half years have elapsed, but there has been no recurrence. The girl has continued in the best of health.—*Journal of the Association of Military Surgeons of the United States.*

Book Reviews.

A Text-book upon the Pathogenic Bacteria. For Students of Medicine and Physicians. By Joseph McFarland, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Philadelphia Hospital and to the Medico-Chirurgical Hospital, Philadelphia; Fellow of the College of Physicians of Philadelphia, etc. With 190 Illustrations, a number of them in Colors. Fifth Edition. Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1906.

In this fifth edition of Dr. McFarland's work on the Pathogenic Bacteria a large amount of new matter has been added, and at the same time much that was out of date has been eliminated. The chapters on Infection and Immunity have been entirely rewritten, and they contain an accurate and up-to-date presentation of these most important subjects. The volume contains a brief but sufficient account of the technical procedures necessary for a proper study of bacteriology, a short account of the life history of all the important pathogenic bacteria, and a description of the pathological lesions caused by the invasion of these bacteria. The book is nearly twice the size of the first edition, issued ten years ago, and while the original plan is still adhered to, the successive editions have indicated the progressive march of this most progressive science. As it now stands, the work fulfils the intention of its author; it contains all the essential facts of the subject; it indicates the literary sources from which the facts, theories, methods, and suggestions are gleaned, and it is written in such a way as to retain the reader's interest. For use in the laboratory and also in the library this volume can be confidently recommended to the medical student and to the practising physician.

Karl Weigert und seine Bedeutung fur die medizinische Wissenschaft unserer Zeit. Von Dr. Robert Rieder. Berlin: Julius Springer, 1906.

This little publication is more than a mere biographical sketch; it is not limited to a description of the life and the works of this distinguished master of pathological anatomy, but it shows how Weigert's numerous contributions to medical literature were developed, and their relation to each other and to the conceptions of pathology which were in vogue when he began to write. The book is divided into chapters dealing with pathological histology, general pathology and biology, bacteriology neurology, and microscopical technique. In the final chapter, entitled "Weigert as Investigator, Teacher, and Man," Rieder appears as the champion of his teacher, who for many years was misunderstood, ridiculed at times, and insufficiently appreciated. Although among the ablest of men, Weigert, by a chain of unfortunate circumstances, was kept from realizing the height of his ambition—a call to a professorship in one of the German universities which would be in accord with his attainments as scientific investigator. Weigert's pupils include the foremost names in histology and pathology, and the publication here noted constitutes an eloquent, though perhaps an incomplete tribute, to one of the masters of modern medical investigation.

A Manual of Pathology. By Guthrie McConnell, M.D., Pathologist to the St. Louis Skin and Cancer Hospital and to St. Luke's Hospital; Bacteriologist to the Missouri State Board of Health; formerly Assistant Pathologist to the Philadelphia City Hospital. Illustrated. Philadelphia and London: W. B. Saunders Company, 1906.

In the preface the author states that the object of the volume is to enable the student to acquire the salient points of the subject. As far as it goes, the work fulfills its purpose admirably. It is well arranged, fairly well written, and the illustrations are very good, especially those on the various tumor formations. The classifications of the animal and vegetable parasites are well selected. The chapter on "Infection and Immunity" barely touches the salient points, and that is all. It will take considerable more reading on the student's part to understand the theories of immunity. While the book is very good in its way there is little real need for such a volume.

How to Suppress a Malpractice Suit, and other Medical Miscellanies. By Thomas Hall Shastid, A.M., M.D., LL.B. Marion, Ill.: Marion Publishing Company, 1906.

The author of this book wants to fight fire with fire. His theory is that most malpractice suits are inspired by some envious rival of the accused physician, and his remedy is to collect all the facts possible reflecting on the character of this rival and use them to discredit him. This is small business. If the defendant in a malpractice suit is not sufficiently sure of his own integrity and honesty of purpose, he will gain little by besmirching the character of witnesses for the prosecution.

Biographic Clinics. Volume V. Essays Concerning the Influence of Visual Function, Pathologic and Physiologic, upon the Health of Patients. By George M. Gould, M.D., Editor of *American Medicine*, Author of "An Illustrated Dictionary of Medicine," "The Practitioner's Medical Dictionary," etc., "Borderland Studies," "The Meaning and the Method of Life," etc. Philadelphia: P. Blakiston's Son and Company, 1907.

In this volume there are no "biographic clinics," strictly speaking, the cases reported being those of actual patients who "had suffered many things of many physicians" because these same physicians did not recognize the fact that the ills from which their patients suffered were not organic diseases, at least not in their origin, but were simply ocular reflexes. Many of these histories are pathetic in the extreme, and they teach one lesson at least, which is that sometimes, if not always or even often, very grave disturbances may arise from eyestrain. An eye examination is not a serious matter, surely, and it seems but fair that patients should be given this chance after other measures, addressed more directly to the organs apparently at fault, have been tried without avail. We cannot doubt the correctness of the narrations in this interesting book, even if we may be tempted to regard them as exceptional. The titles of some of these chapters will serve to indicate the nature of the histories recorded. One is: "A Case of Hyperchlorhydria, Indigestion, Constipation, etc., as Treated by One Gastrologist, Three General Physicians, One 'Mechano-Neuralist,' One Hospital, One Professor of Medicine, and One Refractionist." Another is: "A Case of 'Neurasthenia' as Treated by Two General Physicians, One Homeopath, One Quack, One Osteopath, One Pregnancy, Three Ophthalmic Surgeons, Two Gynecologists, One Diagnostician, One Neurologist, One Resident Sanitarium Physician, and One Refractionist." Still another is: "One Patient's Experience with Two General Physicians, One Neurologist, One Leading Physician, One Gastrologist, Two Ophthalmic Surgeons, One Diagnostician, and One Refractionist." "A Life and Career Blighted by Ignored Eyestrain," "Thirty-five Years of Treatment by Seventeen Physicians for Strabismus, Tinnitus, Headache, Indigestion, Eyestrain, etc," are two other titles. There are twenty-two essays and case histories in the book, all of which are worth reading and digesting. Whether the reader will be converted against his will to the eyestrain theory is doubtful, but he will be interested at all events, as everyone must be by anything this gifted and polemic writer publishes.

Medical Diagnosis. A Manual for Students and Practitioners. By Charles Lyman Greene, M.D., Professor of the Theory and Practice of Medicine in the University of Minnesota; Attending Physician, St. Luke's Hospital, the City Hospital, and the St. Paul Free Dispensary; Member of the Association of American Physicians, the American Medical Association, American Association for the Advancement of Science; Author of "The Examination for Life Insurance and Its Associated Clinical Methods." Philadelphia: P. Blakiston's Son and Company, 1907.

This work on diagnosis differs from others of the kind in several particulars. The book itself is of a very handy size, much smaller than most medical books, light in weight, bound in flexible morocco, and with gilt edges. The paper is thin and tough, so that the nearly seven hundred pages make a book no thicker than one of three hundred pages of ordinary paper. The type is small but distinct, and the illustrations, which are also small but numerous, are for the most part excellent in design and execution; there are seven colored plates, and some of the pictures in the text are also colored.

The work itself is of the most practical character, the language is clear and concise, there is nothing superfluous in the description of the symptoms and the diagnostic methods, and of the latter only those are referred to which have been found of value and are retained in daily use. The arrangement of the text with running page heads and marginal notes facilitates ready reference to a remarkable degree, and this is aided further by an analytical table of contents and a very complex index. After introductory sections on the outward signs of disease, the diagnostic significance of age, sex, social status, etc., and the aid to diagnosis afforded by the previous history, the diseases of special organs and parts of the body are considered; then follow the symptoms of diseases associated with changes in the blood and ductless glands, infectious diseases, intoxications, parasitic diseases, the group of rheumatic affections including gout, the nervous system, and the symptoms and treatment of acute poisons; an excellent summary of malingering and the means of detecting it is also included. The chapter on the physical diagnosis of valvular affections is particularly worthy of commendation.

Society Reports.

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Third Annual Meeting, Held at Washington, D. C., May 6, 7 and 8, 1907.

(Special Report to the MEDICAL RECORD.)

(*Continued from Page 799.*)

SECTION ON TUBERCULOSIS IN CHILDREN.

DR. THOMAS MORGAN ROTCH OF BOSTON, CHAIRMAN.

Address of the Chairman.—Dr. THOMAS MORGAN ROTCH of Boston made this address, choosing as the subject of his remarks, "The Living Pathology of Tuberculosis of the Bones in Early Life." He said that in order to diagnosticate tuberculous conditions as such, and to enable them to differentiate tuberculous from nontuberculous conditions, it was of the utmost importance that they should recognize the normal living anatomy of the bones at different periods of development, as portrayed by the Röntgen ray. This was especially necessary in the early stages of tuberculous disease where the pathological changes were often slight and obscure, and yet where an early diagnosis was extremely valuable; not only often enabling them to arrest the disease by treatment, but to determine whether the condition was merely a slight anomaly of healthy bone, or some nontuberculous affection. In both these latter conditions they could often decide that the case was not tuberculous and, therefore, not fit to be sent to tuberculosis hospitals or homes for two reasons. First, because they had none too much accommodation for tuberculous cases who had the prior right to be looked after; and second, because they should not ignorantly expose a nontuberculous patient to tuberculous infection. It was also important that the treatment in tuberculosis should be begun very early, so as to protect the ear and other organs from resulting infection. There was no diagnostic means so valuable for the detection of tuberculosis of the bones as the Röntgen ray in the hands of an expert in its technique. Over and over again it became a most important factor in the chain of evidence which might lead, unless refuted by the ray, to stamping an individual as syphilitic, and thus perhaps ruining his social life. He said that one should witness the possible differentiation of the tuberculous bone process from the periosteal lesion of syphilis, and the special lesions represented by dactylitis. Again the importance of differentiating by the ray a nontuberculous from a tuberculous arthritis, and a tuberculous hip from an osteomyelitis, or an acute eczema. The moral to be drawn from what had been said was that in the past, and very often in the present, many groups of clinical symptoms were taken for granted from the very first to be tuberculous in origin when they were by no means really so. The Röntgen ray made it evident that tuberculous conditions should be treated for tuberculosis, and that nontuberculous conditions should not be so treated, but treated according to what was indicated by their special infecting organisms. Dr. Rotch then cited cases, illustrating them with Röntgen ray pictures, showing not only the importance in diagnosis, but made the treatment conspicuously obvious.

Recent Advances in the Knowledge of Tuberculosis of Early Life.—Dr. CHARLES HUNTER DUNN of Boston read this paper. He said that important conclusions, based on the immense number of autopsies, had been drawn as to the frequency of tuberculosis in early life, and the most striking fact brought out in the autopsy statistics was that the frequency of occurrence of tuberculosis increased regularly with the age. It was rare in the first three months of life, and increased steadily throughout childhood, not only from year to year, but also, in the first two years, from month to month. This fact was of great importance in connection with the question of source and mode of infection. The same statistics showed that tuberculosis as the cause of death in those cases in which it was found at autopsy decreased with advancing age. Tuberculosis in infancy and childhood was essentially a disease of the lymphatics. Tuberculous adenitis represented the chronic tuberculosis of childhood, as phthisis represented the chronic tuberculosis of the adult. They knew that in children the bacilli did not usually cause demonstrable primary lesions of the skin or mucous membranes, but localized themselves in the lymph nodes. Here they set up a chronic process which authorities agreed to be a reaction of defense, directed toward the prevention of a further extension of the virus. In proportion to the completeness of this protective reaction, the bacilli were either prevented from multiplying, and thus might remain indefinitely latent, or they multiplied, though prevented from spreading. In the former case, there were no clinical manifestations; in the latter, there was faulty nutrition, loss of weight, and occasionally fever. A metastasis of chronic tuberculosis was not the usual method in which further spreading took place. The usual method was the acute tuberculosis of early life. It was now generally recognized that the only source of tuberculous infection was the tuberculous man or animal. There were four theories that had been held as the source of the infection: First, the congenital theory, that tuberculosis was always intrauterine in origin, due to placental infection; second, that infection took place from the inhalation of dried tuberculous sputum; third, that the source of infection was the fine moist drops expelled in coughing; fourth, that the source of infection was the milk of tuberculous animals. It was now known that the bovine type could produce tuberculosis in man. In Japan, where there were no cattle, and where milk was never used as an infant food, tuberculosis was just as common, in just the same forms, as in milk-drinking countries. The whole history of tuberculosis in early life was against the idea of any one exclusive source of infection. The chief factor in tuberculous infection was the surroundings of the infant. It was probable that in infancy the commonest portals of entry were the lungs, the tonsils and nasopharynx, and the intestine. Corresponding to these three portals of entry, they found primary involvement of the bronchial, cervical, and mesenteric lymph nodes. Dr. Dunn then called attention to some theoretical considerations, and especially those recently advanced by Dr. Theobald Smith. As to the diagnosis of tuberculosis in early life, much work had been done with a view to determining the exact diagnostic value of the tuberculin reaction, and Schick believed that a local reaction was less apt to fail than the general constitutional reaction, and he concluded that no known case where tuberculosis had been excluded with certainty had given a local reaction, and that this reaction was often the only positive sign. As to serum diagnosis, final conclusions as to its value could not yet be drawn. D'Espine believed that he had found a reliable method of diagnosticating enlargement of the bronchial lymph nodes, by auscultating the voice. The most important diagnostic method, however, which they now had at their disposal was due to the recent perfection of radioscopic diagnosis. He said that there had been much discussion recently as to the possibility of recovery from tuberculous meningitis. In the literature of the last twelve years he found only three cases of recovery in which the diagnosis was satisfactorily established. The central problem had been the conferring of artificial immunity; this was so complicated

that, as far as human beings were concerned, but little positive and practical value had been accomplished. The human being was undoubtedly in a fairly good state of general resistance toward tuberculosis, and there was much hope that a method would be devised by which, by the creation of local foci under the control of the observer, general immunity might be attained.

The Present Status of the Transmissibility of Bovine Tuberculosis, as Illustrated by Infants and Young Children.—Dr. HENRY LARNED KIETH SHAW of Albany presented this communication. He said that Koch in 1901 called the attention of the medical profession to the question of the intercommunicability of bovine and human tuberculosis. Koch was the first to authoritatively state that tuberculous cattle were not the source of infection to human beings. Behring took the opposite view and claimed that all tuberculosis was of bovine origin. No attempt was made in Dr. Shaw's paper to review or analyze the vast amount of literature that was accumulating on this subject. Ravenel, in this country, Kossel in Germany, and the Royal Commission in England, had all produced bovine tuberculosis from the human bacillus. It was experimentally shown that the human bacillus was not very virulent to cattle; on the other hand, the bovine bacillus was very virulent to cows and swine. The question of greatest concern was whether the bovine bacillus was transmissible to man, and, if so, to what extent. This was a question that could not be demonstrated experimentally, but must be judged from inferences. Do bovine bacilli occur in milk and, if so, are they pathogenic for children? It was generally believed that the udders must be affected before bacilli were found in the milk. It was difficult to state the exact frequency of tuberculosis in cattle. The statistics showed that tuberculosis in cattle in the United States was far from an uncommon occurrence. If bovine tuberculosis was transmissible to children, it must be through the milk, and if all milk containing tubercle bacilli was capable of producing tuberculosis, very few would escape. In view of the very confusing literature, and wishing to establish a scientific clinical justification for the transmission theory, Dr. Shaw addressed a circular letter with questions bearing on this point to the members of the American Pediatric Society, to teachers of pediatrics not members of the society, and to several prominent pathologists who had contributed to this subject. Seventy-nine letters were sent out, and 67 answers received. The first question was: "Do you believe that bovine tuberculosis is transmissible to man?" Five replied in the negative, 25 would express no opinion, the remaining 37 answering "Yes," but 10 of these qualified their answers. The second question was: "Have you in your personal experience seen cases which you believed to be such?" There were only 9 affirmative answers to this question. The remaining twelve questions pertained to the clinical, pathological, and bacteriological points. Dr. Shaw gave a personal experience to show the importance of making a thorough examination of all the factors entering in the study of a clinical case. There could be little doubt in the mind of an unbiased observer after a careful study of the literature that infection took place both through the air and the food. Statistics from all sources showed that tuberculosis was relatively rare in the first six months of life, and that the greatest number of cases occurred between the second and sixth year. If tuberculous milk was such a great source of danger, the greater number of cases would appear before the second year.

Dr. THEOBALD SMITH of Boston, Dr. MAZYCK P. RAVENEL of Philadelphia, Dr. ALFRED MEYER of New York, and Dr. HESS of New York discussed these papers, and Dr. DUNN and Dr. SHAW closed the discussion.

Are Tuberculous Infants and Children in the First Five Years of Life Liable to be Sources of Infection?—Dr. SAMUEL S. ADAMS of Washington read this paper. He said that the answer to this question must of necessity involve theoretical reasoning rather than practical deductions, because data bearing directly upon this phase of the problem of tuberculosis were not to be found. As to the frequency of tuberculosis in young children, the statistics of the numerous clinicians precluded the possibility of reaching a definite percentage. In the Children's Hospital of the District of Columbia during the past twelve years, 2.2 per cent. of all patients admitted to the baby ward were tuberculous; the percentage of deaths from tuberculosis being 5.4 per cent. of the mortality of all causes. Of the pulmonary type, 0.88 per cent. were admitted, of which 50 per cent. died; of general tuberculosis, 0.66 per cent. were admitted and 83 per cent. died, and of the tuberculous meningitis 0.66 per cent. were admitted, and all died. The statistics of this institution, excluding infants under eighteen months, would show the frequency of tuberculosis approximating the percentage of cases examined by Müller of Munich, in which 40 per cent. were tuberculous. On the other hand, the records of the Washington Hospital for Foundlings gave a percentage less than that of either the New York Infant Asylum (8 per cent.) or the New York Babies' Hospital (14 per cent.). The large number of cases in the first named Washington institution was due to the admission of negroes, in whom it was the exception not to find tuberculosis at necropsy, whatever the immediate cause of death. Its frequency in the Washington Hospitals for Foundlings, when compared with similar institutions in other cities, might be attributed to racial and social influences. Sufficient evidence was at hand to establish the fact that infants and young children were more frequently affected by tuberculosis than was generally supposed, and that the organs involved in the greatest number were the lungs, as in the adults, but this did not prove that they were the sources of infection. It was generally conceded that the respiratory and gastrointestinal tracts were the avenues of entrance for the infection; but it was also admitted that as long as the tubercle bacillus remained with the host it was not dangerous to others. If they admitted that in 90 per cent. of tuberculous children under five years dying of the disease the respiratory tract was the portal of entry, and the lungs, pleura, and bronchial lymph nodes were the seat of disease, could they assert that such subjects did infect others? No one would deny that the youth or adult with pulmonary tuberculosis might infect others by his sputum, which contained the tubercle bacilli; but did the young child do this? In many cases of pulmonary tuberculosis, even in the worst forms, cough was absent and there was no expectoration. That being the general rule, how might such a child become the source of infection? It was true that the young child did not expectorate; but it was equally true that the exudate passed from the lung to the pharynx and was swallowed. Under such conditions tubercle bacilli might be found in the saliva, the vomited matter, and in the stools. If in the saliva, the opportunity for dissemination was offered. Tuberculosis of the mesenteric lymph nodes, the intestines, and peritoneum was next in frequency. So long as the tuberculous process was confined to the peritoneal cavity, there would seem to be little likelihood of the child being a source of infection other than auto. In tuberculosis of the intestines, especially with ulcerations, tubercle bacilli were found in the stools. If, then, the stools of the child having pulmonary, mesenteric, peritoneal, or intestinal tuberculosis did contain tubercle bacilli, they were as liable to spread this disease as were the stools of a patient with typhoid. Dr. Adams closed his paper by saying that we might assume that the young child affected with tuberculosis of the upper air passages, the lungs, or the intestinal tract, from which the tubercle bacillus had egress through the mouth, nose, or anus, was

a source of infection, and, reasoning from analogy, should be subjected to the same restrictions applicable to the adult similarly affected. In those cases, however, in which the tubercle spent its force in the cranial or peritoneal cavities, and in which there was apparently no direct exit for the microorganism, more or less uncertainty confronted them.

A Committee on Bovine Tuberculosis.—Dr. HENRY LARNED KEITH SHAW of Albany said that in view of the practical bearing of this subject from a sanitary, hygienic, and dietetic point of view, and the evident confusion and lack of positive knowledge, he earnestly urged that this Section take up a further and systematic study of bovine tuberculosis and its transmission through milk. A committee, to consist of a pathologist, bacteriologist, veterinarian, and two medical men (clinicians), could be formed to make a report at each meeting of the work being done in different countries, and to urge and see that a differential diagnobacteriological examination be made of all suspected cases. Therefore he offered the following motion:

"That the Chairman of the Section of Tuberculosis in Children, National Association for the Study and Prevention of Tuberculosis, appoint a committee to study this question of the transmissibility of bovine tuberculosis, such committee to report at each meeting of the Society." This was duly seconded and carried.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twenty-second Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

FRANCIS P. KINNICUTT, M.D., NEW YORK, PRESIDENT, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 793.*)

Wednesday, May 8—Second Day.

Experimental Fibrinous Pleurisy.—Dr. EUGENE L. OPIE of New York read this paper, giving the results of his experiments on dogs. Serofibrinous pleurisy was produced by a sterile inflammatory irritant, such as turpentine, injected into the pleural cavity of the dog. Accumulation of fluid reached a maximum at the end of three days, and fluid had completely disappeared at the end of six days. Resolution of fibrin began (first stage) while fluid was present, and was completed (second stage) after the disappearance of the fluid. In the first stage the fibrin of the exudate digested itself in the presence of weak alkali, but in the second stage it had completely lost this power, and digested itself only in the presence of weak acid. It was possible that carbon dioxide in the body, acting as an acid, produced resolution of the exudate by the enzyme. By aspiration of fluid and by other means the characters of the exudate might be modified.

On Certain Acoustic Limitations of the Stethoscope and their Clinical Significance.—Dr. LEWIS A. CONNOR of New York City gave, in this communication, a summary of his findings in a series of heart and lung cases subjected to auscultation by means of the ear and of the stethoscope. Certain types of sounds in both lungs and heart could be more clearly heard with the naked ear than through the stethoscope. He cited three cases of aortic insufficiency in which a murmur was distinctly heard with the naked ear, yet neither he nor anyone else could hear it through the stethoscope. He had found again and again in lung cases that no bronchial breathing could be heard with the stethoscope, whereas with the ear a high-pitched, blowing sound could be heard twenty-four hours before audible with the stethoscope. He discussed the theoretic explanation of this peculiarity and its practical bearing, and emphasized the importance of medical students being taught to use the naked ear for purposes of auscultation.

Dr. SOLOMON SOLIS-COHEN of Philadelphia emphasized the point made by Dr. Connor with reference to teaching medical students to use the naked ear. As a teacher of medicine, he came in contact with students at the bedside who have been using the stethoscope only, and he found it very difficult to make them hear what he heard. He considered the sole use of the stethoscope that of localizing sounds previously heard with the naked ear.

Dr. E. G. JANEWAY of New York City said that in pneumonia certain sounds could be heard with the ear which could not be heard with the stethoscope.

Dr. A. JACOBI of New York City suggested that not infrequently over the area covered many sounds could be heard with a large stethoscope which could not be heard with a small one.

Dr. Connor in closing the discussion said that all his cases at the time the diagnosis was made were complicated cases, other signs were uncertain, and the diagnosis rested on the findings of the ear; the diagnosis later, however, became clear, and sounds could be recognized with the stethoscope.

Some Points Regarding Tuberculosis in Infancy.—Dr. L. EMMETT HOLT of New York City gave, in this paper, interesting data relative to the great frequency of pulmonary tuberculosis in children, the sources of infection, and the methods of obtaining sputum for examination from infants. He gave contagion in the home as the most frequent cause, the disease, as a rule, being contracted by infants living in infected households. The early symptoms were usually indefinite. He cited a record of thirty-six cases of tubercular meningitis in which the bacilli were found in the fluid by lumbar puncture. The proportion of cases in which the bacilli were also found in the sputum was large, even though no pulmonary signs or symptoms were present.

Dr. GEORGE M. KOBER of Washington, D. C., asked if any investigation had been made to recover the bacilli in the feces. In over 4 per cent. of the cases he had examined thus far bacilli had been found in the feces.

Dr. RICHARD C. CABOT of Boston, Mass., emphasized the importance of following up the children of tuberculous parents, as had been done at the Massachusetts General Hospital. Twenty-six out of a hundred children whose parents had been admitted to the hospital with a diagnosis of tuberculosis had been found to have the disease in one form or another, though not complaining of the disease, and going regularly to school. Such children were taken to the hospital and put under treatment.

Dr. HOLT, in closing the discussion, said it was surprising how much fluid could be withdrawn in these cases. It varies from one-half to two and even three ounces, the average amount withdrawn being one and a half ounces. He had made no study of the feces. Judging from the large number of bacilli swallowed, they should be present in the feces in large numbers.

A Study of Normal Living Anatomy in the First Twelve Years of Life.—Dr. THOMAS MORGAN ROTCH of Boston, Mass., emphasized the necessity of having a series of Roentgen rays taken which would show the development of the different parts of the body, organs as well as bones, from premature birth up to adolescence. He drew especial attention to the importance of observing the changes which take place in the zone of proliferation and in the development of the epiphyses. By means of this series of Roentgen ray pictures, which he intended to put into book form later, a physician or surgeon could, after having a radiograph taken of the especial disease case, compare the plate with that of a child of the same age and supposedly average anatomical conditions. The radiograph should be taken upon a standard basis, that is, the part being taken should be at a standard distance from the tube, it should be taken at a standard angle, and if the plate used be of natural size it should be

so stated; if enlarged, it should be stated how much enlarged; if reduced, how much reduced. A series of children of the same age should be taken before determining what the normal average picture at that age would be. He then exhibited a series of radiographs taken by Dr. A. W. George, Roentgenologist to the Children's Hospital, Boston. Of especial interest were the radiographs of twin premature babies at seven and a half months. He also showed radiographs of the stomach at various ages, emphasizing the value of such rays in cases of pyloric stenosis, where both diagnosis and treatment were somewhat uncertain. This had been accomplished by the introduction of bismuth into the stomach, and also by dilating the stomach with gas, the idea being that this should be done before resorting to exploratory laparotomy. He also showed how by this means the relations of the pericardium to the heart could be seen, and whether the pericardium should be tapped. The subject was of especial interest as something new and something which would be another instrument of precision in the hands of physicians and surgeons for diagnosis and treatment.

The Life-Saving Value of Diuresis. Dr. S. J. Meltzer of New York City reported a series of experiments on animals instituted for the purpose of determining the value of diuresis as a life saving measure. Experiments were made with subcutaneous injections of magnesium salts, seven different species of animals being employed for the purpose. It was found that one and a half grams per kilo would produce profound anesthesia, with complete relaxation of the entire musculature of the animal, but the animal would recover. If one and three-quarter grams per kilo be injected the animal would die of paralysis within an hour. It was found, however, that if the animal urinated between the anesthetic and the fetal stage recovery would ensue. Magnesium was eliminated through the urine in quantity varying between anesthetic and toxic doses. It was eliminated largely through the kidneys, but this assumption could not be accepted without further proof, as a number of alkali earths were eliminated through the gastrointestinal canal. Alkali earths were eliminated through the gastrointestinal canal and alkali metals through the kidneys. The degree of toxicity of magnesium salts, especially in rabbits, was studied, and it was perfectly evident that nephrectomy increased the toxicity, eight-tenths of a gram producing deep anesthesia in a nephrectomized animal when administered subcutaneously. Experiments with artificially produced nephritis gave similar results.

The Hemorrhagic Diathesis in Bright's Disease.—Dr. David Riesman of Philadelphia reported two cases of uncontrollable bleeding in Bright's disease. He said the hemorrhagic diathesis occurring in the course of Bright's disease might take the form of spontaneous bleeding from the mucous membranes—nose, mouth, uterus, intestine—or there may be bleeding into the skin, a true purpura. The condition was met with in all forms of chronic nephritis, perhaps more often when there was an associated arteriosclerosis; the latter, however, was not a necessary factor. The cause was to be found in toxemia, as well as, in some cases, in an altered state of the vessel walls.

A Case of Secondary Carcinoma with Recurrences in Unusual Sites.—Dr. George L. Peabody of New York City, in this paper, detailed the case of a woman forty-three years old, who, four years after removal of the right breast for carcinoma, developed pains especially marked in the lower extremities, small of the back, and shoulders. There were no joint pains and no swellings, except that the thyroid had always been large. The pains were severe and prostration became intense. The urine was greatly increased in amount, often over 200 ounces. The specific gravity was low and it occasionally showed many patches of pigment. Her chest and abdomen showed many patches of pigment. Electric reactions normal. No treatment relieved her pains; she slept but little, and gradually became mildly delirious. Lumbar puncture gave normal fluid. About a week before death she developed partial ptosis of the right eye, partial paralysis of the muscles of the right side of the face, weakness of the right palate muscles, and partial deafness of the right ear. Diplopia in part of field of vision. Pain in thighs and legs persisted, and pain in lumbosacral region on attempting to sit upright, and on pressure. No alteration in sensation otherwise. Eyegrounds normal. Urine and feces became involuntary. Muscles of deglutition gradually became impaired; water regurgitated through the nose. She died three weeks after coming under observation of edema of the lungs. Autopsy showed metastatic carcinoma of the thyroid, of one suprarenal gland, of one lung, of wall of an old cyst in cerebellum numerous small metastatic growths in pia and medulla, without lesion of pons or medulla. Diffused infiltration of perineural lymph sheaths of one trunk nerve of cauda equina, with carcinoma, and in one place the nerve trunk itself was similarly invaded. Pia covering cord showed small metastatic growths. New growths in lung showed several large vessels completely filled with carcinomatous tissue, and these carcinomatous thrombi suggested an explanation for secondary metastases.

Drs. Peabody, Meltzer, and Solis-Cohen discussed this paper, and the reader closed the discussion.

Experimental Observations Upon the Action of Intestinal Antiseptics.—Dr. J. Dutton Steele of Philadelphia read this paper, which discussed the difficulty of finding an index for the amount and character of bacterial activity in the intestine; the method of estimating the amount of bacteria in the feces by weight (Strasburger); the fact that scientific investigation of intestinal antiseptics has until recently been insufficient, leading to somewhat contradictory results, and the writer's experience with bismuth, salicylate, and beta naphthol, using the total amount of fecal bacteria as an indicator of their efficiency.

Dr. Lewis A. Connor of New York City called attention to the fact that it was as necessary to preserve the bacteria, which are normal and useful, as to destroy those which are harmful. He thought that in giving an intestinal antiseptic one was going blindly, and that by giving attention to diet and other measures one would be working in a much more hopeful direction.

Observations Regarding the Hygiene of Medical Cases, Particularly in Hospital Wards.—Dr. D. L. Edsall of Philadelphia gave a collective review of a number of groups of ward infections of various sorts. Part of these had been previously recorded, and part had not been published. He gave some suggestions as to the influence of superinduced gastrointestinal infections upon the cause of typhoid fever in particular, with recommendations regarding some points in ward hygiene, especially regarding ward nursing.

Dr. Victor C. Vaughan of Ann Arbor, Mich., called attention to the great epidemic of typhoid fever during the Spanish war, when both the laity and the medical profession in the United States got the impression that it was due to the fly, when in reality over 60 per cent. of the cases were due to contact infection.

Dr. George M. Kober of Washington, D. C., called attention to the fact that large numbers of cases of typhoid fever in nurses may be accounted for to some extent by the fact that they are as a rule at a susceptible age. He called attention, also, to the fact that the great epidemics of typhoid fever are reported by England and America, not by Germany, France, and Italy, noting the significant fact that the first two nations are in the habit of taking raw milk. Ten per cent. of the cases in the city had been traced to the milk supply. He emphasized the importance of pasteurization of the milk.

Dr. William H. Park of New York City cited several ward epidemics traceable to careless methods on the part of the nurse.

Dr. E. G. Janeway of New York City thought physicians should take better care of the nurses. As it is, they are

weakened by overwork and are very susceptible. They should be given more rest.

Dr. A. C. Abbott of Philadelphia emphasized the untrustworthiness of isolation, epidemics not infrequently following the release from isolation of a person apparently well. He cited one or two such instances.

Dr. W. P. Northrup of New York City cited the case of two roommates, teachers, who came down with typhoid fever. Investigation revealed the fact that they drank only distilled water, drank no milk, and ate only cooked food. The source of infection was traced to the glass jar in which the distilled water was kept.

Dr. Solomon Solis-Cohen advocated the more complete segregation of infectious cases in hospitals. The present imperfect system leads to many ward epidemics.

Dr. Edsall in closing the discussion agreed with the other speakers concerning the importance of isolation. Satisfactory isolation, however, was impossible with the present hospital facilities. The proper precautions would greatly reduce the number of epidemics.

Antitoxin and Post-Diphtheritic Paralysis.—Drs. M. J. Rosenau and J. F. Anderson of Washington, D. C., had carried on a series of experiments on guinea-pigs which fully justified the drawing of conclusions in respect to man. Dr. Rosenau, who read the paper, said that all the pigs received the same dose of toxin and antitoxin mixture, which was so nicely adjusted that none of them died. Those given 250 units of antitoxin twenty-four hours after infection recovered, whereas those given forty-eight hours after infection developed paralysis and died later. Those receiving one thousand units forty-eight hours after infection rapidly recovered. The pigs that received antitoxin in repeated doses daily told a similar but better story. Those that received 250 units twenty-four hours after infection and in repeated doses rapidly recovered; of those that received it forty-eight hours after infection two lived and one died. If antitoxin is given just before the symptoms begin it has no effect upon the paralysis or in saving life. The experiments emphasized the importance of giving the remedy early, and of giving large doses when the case is seen late.

Effects of Egg-White and Its Split Products Upon Animals; A Study of Susceptibility and Immunity.—Dr. Victor C. Vaughan of Ann Arbor, Mich., read this paper, which outlined the work done by himself and Dr. May Wheeler. For a number of years, he said, they had been studying the products obtained by splitting up various proteid molecules. The proteids with which they worked were bacterial, vegetable, and animal. All of these, they found, may be split up into poisonous and nonpoisonous portions. We have ascertained that the nonpoisonous products obtained by the cleavage of the proteids of the colon bacillus and of the typhoid bacillus induced specific immunity to the microorganisms of these diseases. Some two years ago we split egg-white into poisonous and nonpoisonous portions. The experiments of Drs. Rosenau and Anderson, on the susceptibility of animals to second injections of blood serum, led Drs. Vaughan and Wheeler to try the effect of the nonpoisonous portion of egg-white upon animals. They found that this part of egg-white sensitizes the animal to the unbroken egg-white, and that the sensitization thus induced corresponded in all particulars with that produced by the injection of unbroken egg-white. An attempt would be made to explain the sensitizing effect of the nonpoisonous portion of egg-white, and to show that this was along the same line as the immunity induced to the typhoid and colon bacilli by the nonpoisonous portions obtained from the cellular substance of these organisms. The claim would be made that when egg-white, or the nonpoisonous part of egg-white, is injected into a fresh animal certain cells of the body are so influenced that they elaborate a new ferment, which, in the form of zymogen, remains in the cell until activated by the second injection, when it is set free and splits up the egg-white in a manner similar to that which they had used in the laboratory, and that the effect induced is the same as that caused by the poisonous portion of egg-white, as they had split it up in the retort. Similar phenomena occurred when animals were immunized or sensitized with the nonpoisonous portion of the typhoid or colon bacillus, and subsequently inoculated with the living organism.

A Symposium on the Opsonins in Medicine.—The remainder of the session was devoted to this subject, the following papers being read:

A Review of the Experimental Basis of the Opsonic Phenomena.—Dr. E. L. Opie of New York City opened the symposium with this paper, giving as the experimental basis for the existence of opsonins the following: (1) The normal blood serum so modifies bacteria that they are readily ingested by phagocytes. (2) The power of the blood serum to promote phagocytosis is increased by immunization. (3) Nonvirulent bacteria are more readily prepared for phagocytosis than virulent bacteria. The properties of the opsonins and their relation to other bodies concerned in the processes of immunization are not clearly understood. The opsonic power of normal blood serum is subject to considerable variation, and this variation materially affects estimation of the so-called opsonic index.

The Opsonins in Tuberculosis.—Dr. Edward R. Baldwin of Saranac Lake, New York, reviewed the experiments on immunized animals. The opsonic function was less marked in immunized rabbit serum than in controls after test inoculations though at site of tubercles, phagocytosis was much stronger, and agglutination power of the serum higher. Of this he gave a provisional explanation. He called attention to the difficulties in determining the relation between the agglutinating and the opsonic functions, and the apparent independence of each. "Aggressin" from fatally poisoned guinea-pigs retained opsonic functions; virulent bacilli "opsonified" by immunized cow serum retained virulence. There was an apparent absence of bacteriolysis in test-tube, but a possible connection with it in the animal. Apropos of von Behring's statements application to the vaccine therapy was suggested. The paper closed with some remarks on the technique of the opsonic test and its application in pulmonary tuberculosis.

The Opsonic Index in Certain Acute Infectious Diseases.—Dr. Ludwig Hektoen of Chicago presented this paper, in which he discussed the course of the opsonic index in typhoid fever, pneumonia, diphtheria, and erysipelas. He presented a series of charts illustrating the streptococcoopsonic index in scarlet fever, with and without complications, and called attention to the effect of suppurative scarlatinal otitis on the opsonins for the bacteria concerned.

A Summary of the Studies on Opsonins Carried Out at the Rockefeller Institute.—Dr. E. H. Schorer of New York City read this paper. The opsonic index in cases of erysipelas was constantly neither nigher nor lower than normal. Vaccines were prepared from streptococci isolated from wound infections and from cases of erysipelas. Fifty cases of erysipelas were inoculated with such vaccines, the opsonic index being determined at intervals by use of the same microorganisms. The inoculation of vaccine was not followed by a constant modification of the opsonic index or of the course of the disease.

A Summary of the Work on Opsonins at the Johns Hopkins Hospital.—By Drs. L. F. Barker and Rufus I. Cole of Baltimore, Md. The paper epitomized the work done during the past year in the medical and surgical wards of the Johns Hopkins Hospital, and in the biological division of the Clinical Laboratory. The report included the results of the determination of the opsonic index for diagnostic purposes and as a guide to vaccine therapy. It also dealt with the results of investigations concerning the reliability of the methods now in vogue, the specificity of opsonins, the possibility of the production of sera of high concentration in opsonins, etc.

A Summary of the Studies on Opsonins Carried Out Under the Auspices of the Commission for the Investigation of Respiratory Diseases of the New York Board of Health.—By Drs. HERMANN M. BIGGS, WM. H. PARK, and NATHANIEL B. POTTER of New York City. The results of these studies were presented in two papers, one read by Dr. Park and the other by Dr. Potter, the latter being illustrated with lantern slides. From all the work done it was concluded that the opsonic index must be considered an approximate, and not a real index of the amount of opsonins in the blood in any given test. The errors were inherent in the method, and probably could not be eliminated by any other method. It was found in the treatment of a number of cases by vaccine that, as a rule, the index had not been a sufficient guide to the treatment by the injections. In some of the cases, especially those due to local staphylococcus infections, good results had been obtained by vaccines, while in cases of mixed infection and of inflammation of mucous membranes the results on the whole had been satisfactory. In tuberculosis the results in those treated under the guidance of the opsonic index had not differed from those treated in other ways.

Dr. CHARLES E. NORTH of New York City presented a number of charts showing the variation in the findings of twelve laboratories working simultaneously with the same organism according to the Wright-Douglass method.

Dr. THOMAS MORGAN ROTCH of Boston presented the results of his clinical work in his wards at the Children's Hospital in Boston. He had treated a series of cases of cerebrospinal meningitis in children, and had studied the opsonic index in connection therewith. Some of the cases were acute and some subacute. The dose of the meningococcus vaccine given was one hundred and twenty million. He explained that he had at the head of the bed a chart showing the temperature, pulse, and respiration, and also the opsonic index. In connection with each chart he gave the age, the duration of the disease, the character of the especial case, whether acute, chronic, mild or severe, also the effect on the opsonic index when spinal puncture was made, when inoculation was given, and when antitoxin was given. There seemed to be interesting relations between the use of antitoxin and the meningococcus vaccine. In cases where the meningococcus vaccine did not raise the index antitoxin was found to do so. Two or three years ago he had treated in his wards twenty-five cases of cerebrospinal meningitis in children with antitoxin, with some interesting results, but on the whole they were not satisfactory from a curative sense.

Dr. Ross of Montreal, Canada, who had worked with Wright for three years, spoke very enthusiastically of the work and of the clinical value of the opsonic theory, but said he would welcome some easier method which would enable him to obtain the same results.

Drs. BARKER, WEBB, and others took part in the discussion, which was closed by the readers of the various papers.

(To be continued.)

AMERICAN SURGICAL ASSOCIATION

Twenty-eighth Annual Meeting, Held in Washington D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the MEDICAL RECORD.)

(Continued from page 797.)

Wednesday, May 8—Second Day.

Ancient Egyptian Surgical Instruments.—Dr. M. SOLIS COHEN of Philadelphia demonstrated these instruments, which were said to have been found in the tomb of a physician east of the Nile, near Thebes. The instruments, made of bronze, were probably the earliest surgical instruments existing in the world, the date of their manufacture being somewhat more recent than 2,000 years B.C. Their use had been conjectured as possibly for cataract.

End Results Following Operations for Carcinoma of the Breast.—This was the title of all the papers read at the session. Dr. WM. S. HALSTED of Baltimore read the first paper of the series. He said that statistics could be varied by selecting the cases and by classifying the cases according to different standards. All statistics, he thought, should exclude the totally inadequate operations that were recognized by all. Excluding the incomplete operations done at Johns Hopkins Hospital, there had been 89 cases, 43 per cent. of which were free from recurrence at the end of three years. As to the point of recurrence, bone metastases in forearm and lower leg had not been recorded, and subcutaneous recurrences had been limited to an area still slightly nearer the primary growth, extending to mid-thigh and to mid-arm, hence he did not consider blood metastases as probable, but the spread as due to the lymphatics by way of the fascial planes. In support of this were the bone lesions in the femur, most often at the great trochanter, and in the humerus at the insertion of the deltoid. Similar lymphatic spread could account for lesions in brain and liver. Of the cases that at the time of operation had had no glandular involvement there were 64, of which 70 per cent. had remained cured. Of 110 cases with axillary gland involvement 25 per cent. remained cured. Of 101 cases with cervical gland involvement only 7 per cent. remained cured. To confirm the diagnosis of a cure he would insist on a negative autopsy at the expiration of five years. He removed the glands of the neck in most of the cases with the exception of adenocarcinoma. He expected to recognize cancer cysts by their containing blood-stained fluid, their having very thin walls, and the presence of papillomata; but he had failed in this in the first few cases and had had to do an early secondary operation after the pathologists' report. He considered the extension most rapid beneath the skin, and so did an extensive removal of skin and neighboring muscle planes. He presented the following table of results:

Cancer cysts	6 cases,	2 cured,	33.3	per cent
Adenocarcinoma	32 "	24 "	75	"
Medullary carcinoma	25 "	12 "	48	"
Circumscribed scirrhus...	28 "	13 "	46.4	"
Small infiltrating scirrhus.	80 "	30 "	35.5	"
Large infiltrating scirrhus.	39 "	8 "	20.5	"

Dr. J. C. WARREN of Boston read the next paper. He gave the statistics of the Massachusetts General Hospital, which represented the work of numerous surgeons. The work of collaborating the material had been done by Drs. Greenough, Simms, and Barney, who had seen and examined the cases, at their houses if necessary, to determine the late results of the operations. The statistics were for a continuous series of cases operated on at the hospital in the ten years ending three years ago. Of these there had been 376 patients with 416 operations; 64 were alive and well from three to thirteen years after the operation. Seven had died of some other disease after the lapse of three years, making a total of 71 cases, 20.9 per cent., that had been cured without recurrence for three or more years. All but one of these had good use of the arm. There had been a swelling of the arm in some of the cases for a shorter or longer period. Of the unfavorable conditions at the time of operation he mentioned adherence of the tumor to the skin or to the chest wall and involvement of axillary and cervical glands. Of all the cases in which the cervical glands were felt, only two had survived, and in those two the glands that were felt and removed had not been cancerous. In none of the cases, where both breasts were involved, had the patient survived. Of the different types of cancer the medullary seemed to have had the greatest malignancy and the adenocarcinoma to have been relatively benign. The type of cancer and the extent of involvement were the most significant factors to be considered in the prognosis. Of 100 cases where the complete

operation had been done, removing glands in the axilla and neck, 60 had been cured. The removal of a large area of skin had given better results than removal of small areas. In the incomplete operations 25 per cent. were free from recurrence. This apparently better result from the incomplete operation than from the complete operation was due to the extent of the lesion and the character of the tumor chosen for the incomplete operations. Of the cases in which merely palliative operations had been done, not expecting a cure, four were cured. Perhaps these patients had been able to combat successfully with the small amount of tissue that had been left. Recurrences in the scar had occurred in 48 per cent. of the cases. There had been four cases of late recurrence; two in the scar, one at eight years, and one at eight and a half years; there had been a metastasis in the spine at seven years, and another recurrence at six years. Eighty-eight cases that had passed the three-year limit had died later.

Dr. A. T. Cabot of Boston read the next paper. In this he discussed his own private cases. He had made no selection of cases except to exclude one woman who had a bad heart and an adherent cancer. Of these forty-two cases nine were free from recurrence from four to nineteen years. Five others are living, but had had recurrences which were removed more than three years ago. Of the nine cases that were well three had been adenocarcinoma, three small scirrhus, one Paget's disease, one medullary cancer, and in one the diagnosis had been lost. Of these, in six there had been no cancer in the lymph glands removed, and in the other three only slight involvement. He used *x*-ray treatment to check growth in the inoperable cases. Recently he had begun to give *x*-ray treatment in all cases immediately after operation, but none of these cases were included in the report, because they were all too recent.

Dr. J. C. Munro of Boston said that he wished to make merely a preliminary report on 105 cases, 27 per cent. of which had remained free from recurrence for from three to fifteen years. The longest were cases in which he had removed axillary glands and fascia, but not muscle. Of the recurrences four-fifths had been inside of two years.

Dr. Willy Meyer of New York reported eighty-seven personal cases operated on since 1894. Of these thirty per cent. had been well from five to twelve years. He did not consider the neck operation desirable as a routine unless the glands were found involved. During the operation sometimes the subscapular nerves could be sacrificed to advantage, and also the axillary vein removed. Edema of the arm was rare, and usually due to the cicatrix. Neuralgia was present in some of the cases. All had full use of the arm. In cases where the primary tumor involved the upper quadrants involvement of the neck glands were more likely. He did the radical operation on all cases except where metastases were present, taking out breast, axilla, and all tissues en masse.

Dr. L. S. Pilcher of Brooklyn spoke especially of the cases in which the neck had been involved and its glands removed with the breast and axilla. The main opposition was the argument that in such cases the mediastinum was also probably involved. He recognized the fact that all such cases were well advanced, but knew that some could be saved. He had had one case that seven years after operation had died of heart trouble, and two other cases alive and well, one seven and one nine years after operation. Of eleven cases, nine had been free six months or more. In four cases the neck glands had been felt before cutting the skin; in eleven others only after the skin incision. The point of suspicion in the neck is in the subclavian triangle around the jugular vein. He considered no operation complete without exploration of the base of the neck.

Dr. A. Vander Veer of Albany, reporting his personal cases and hospital cases over a period of forty years, spoke of the marked improvement in the results of the operation since his first cases. He had operated on 103 patients, of whom thirteen were well. The longest period after operation in which he had seen recurrence was twelve years. He cleaned out, now, the axilla in all cases, but tried to save the nerves. He had had three cases with lumps in the breast for from six to twenty years, after which they had developed adenocarcinoma of very rapid development. He had had ten cases of traumatic history, and one case of worry and fear that cancer would appear until found a year later. After that the patient had worried about the other breast, and the development of a cancer there had followed a year later, and after that had been promptly removed by death from metastases.

Dr. A. J. Ochsner of Chicago had been able to trace to a final report 101 of his 164 cases. Of these 57 were living, and all but two well. All were operated on more than a year ago, 39 living more than three years after operation; 25 more than five years, and 5 more than ten years. Of the 57 living cases 10 had stiffness of the arm. All of his cases in the past six years had had *x*-ray treatment. One woman operated on in 1801 had a recurrence in the scar within six months. This had disappeared under the *x*-ray, and the woman was still alive and well five years after. One case of recurrence where the *x*-ray had no effect had been cured by a paste. Another case of cancer had been cured by some patent medicine given hypodermically. One case of cancer of the neck and axilla had been cured by the *x*-ray. An isolated node appearing later had been excised and followed by the *x*-ray, and the patient was alive five years later.

Dr. N. Jacobson of Syracuse spoke of the marked variations in virulence even in tumors of the same type. In one case of scirrhus cancer, which is usually so slow in development, a mass the size of a hen's egg, with axillary involvement, had appeared within ten days. There had been recurrences inside of a month, and the patient died of metastases inside of six months. In another case of scirrhus cancer the operation was done with a wide excision two days after the cancer was first noticed. Three months later there were recurrences over all the chest wall and back, and the patient died in a few months. He seemed to think that there was a special predisposition to cancer in some persons with recurrence in various organs. He had had one case with cancer in uterus, breast, and stomach. He had had three cancers of the breast in men, all with recurrences and death.

Dr. J. C. Oliver reported thirty-five personal cases, all operated more than three years ago. He had had two cases with a radical operation done on one breast and a simple operation done later on the other breast; both patients were alive and well, one five and the other seven years after the operation. He had had one case with fatal recurrence after fourteen years. He had had two rapid, malignant cases recurring in tumors that had been in the breast, one for ten years and one for twenty years. He considered supraclavicular recurrence less frequent than involvement of the opposite breast. Tumors in the central portion and lower quadrants gave the most recoveries. He hoped to learn more of the prophylaxis and nature of cancer in the future.

Very Late Recurrences after Operation for Cancer of the Breast.—Dr. J. Ransohoff of Cincinnati read this paper. He said that twenty per cent. of the cases that passed the three years limit for cure died of recurrence, and he would rather put the limit of recurrence at five or seven years. He considered the improved end results after such operations to be due to the increasing intelligence of the people. He had been able to collect reports of cases living 22, 26, and 20 years after operation and that after an incomplete operation. He considered one great danger of the operation from excessive manipulation of the tumor. He said that local recurrence took place in fifty-eight per cent. of the cases. That recurrence appeared during the

first year in sixty-two per cent. of the cases; that recurrence occurred principally in the scar or neighboring skin, but that after three years this local recurrence was less frequent. He had found reports of sixty-two cases with recurrences after six years, the latest at the end of nineteen years. In several cases there had been distant, but no local recurrence. In one case after twenty-one years there had been a recurrence in the scar. The later appearances in these remote organs were probably primary cancers. In some of the cases with the longest interval before the recurrence there had been no axillary involvement at the time of operation. A possible explanation of the long interval would lie in cell deposits that have remained dormant just as retrograde processes were known to follow giant cell action upon some condition. Or again that the scar tissue was especially subject to disease and degenerated anew in the site of the former operation.

The Law of Accelerating Risk Clinically Tested in Breast Cancer; End Results Compared with the Predictions.—Dr. E. W. Andrews of Chicago read a paper explanatory of the theory that cancers follow the law of squares in their rate of development, the cancer growing incessantly with no acquired resistance to combat it and no retrogression. On the contrary, the vigorous people seemed to show more susceptibility to cancer. Cancer seemed to grow at an accelerating rate, so that in a short time the danger from the growth became extreme. He charted the time required for the cancer to double in size, and when the size had doubled the risk had quadrupled. He reported one case in which the mass had doubled in a week, and five months later, in spite of operation, the patient died from cancer of both breasts. This was an exceedingly rapid growth and probably no operation could have saved the patient.

(*To be continued.*)

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-fourth Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the Medical Record)

The President, Dr. Thomas Darlington of New York, in the Chair.

Tuesday, May 7—First Day.

President's Address.—Dr. Darlington warned against the possible tendency of the Association to focus too large a share of attention upon pulmonary tuberculosis, worthy and important as the subject was, and presented suggestions for future achievement in other lines of work. The results of the Association toward the elimination of tuberculosis were dwelt upon, and attention called to the need of more work along the line of the mode of infection of pulmonary tuberculosis. Particular emphasis was placed upon the question of intestinal infection caused by the ingestion of contaminated food. In referring to the potential possibilities of the Association in research work, attention was called to the increased mortality from heart and kidney diseases. Charts were exhibited showing most graphically this increase in New York City. Figures were given showing the death rates in a number of cities of the United States, the most marked increase being in Boston, where the rate from heart disease was 11.71 in 1880 and 18.17 per 10,000 population in 1905. New Orleans gave the greatest increase in the mortality due to Bright's disease, the rate being 5.21 per 10,000 population in 1881 and 17.30 in 1905. Using the complete tables as a basis, it was shown that the death rate from these diseases in Boston, New York, and Chicago had nearly doubled in the twenty-five-year period, while the general death rate had shown a decided decrease. A study of the causative factors of this alarming increase naturally suggested the part played by the nervous activity of the modern city business man and the equally strenuous social whirl of the city woman. The doctrine of the restful life, of individual self poise and mental and physical well being was advocated. The relation of influenza to the causation of cardiac difficulties was mentioned as an almost untilled field for investigation. Pneumonia among infectious diseases also demanded attention. While the hope of its specific medication seemed to lie in the field of serum therapy, it was suggested that the profession was probably too quiescent in its attitude toward general prophylaxis and the methods tending to eradicate the disease. The question of climate in relation to the prevalence of disease should receive more attention than it has heretofore. Reference was made to the fact that the Esquimaux brought by Commander Peary from the Arctic regions in 1898 practically all succumbed to pneumonia soon after reaching New York, while the disease is unknown in their home climate. An investigation of the causes of the acute respiratory diseases was urged as a subject well worthy the attention of the Association.

The Search for a Suitable Climate.—Dr. Samuel A. Fisk of Brimfield, Mass., read this paper, giving his personal experience as a basis of judgment. As a young man of twenty-four, broken down with consumption, but with a tendency to repair, he had gone to Colorado. He had found it preeminently a place of outdoor life, flooded with sunshine, abounding in a dry, pure air, with ideal temperature and a dry soil. The comparative advantages of Minnesota, Colorado, Nassau, Southern California; the hills of New England, of New York, Arizona, New Mexico, and life on shipboard, were considered, and Colorado was given decided preference as a place of residence for one presenting the conditions manifested by the author in his early life.

Dr. Delancey Rochester of Buffalo would send tuberculous patients to Colorado or North Carolina. His choice as a substitute for these localities would be the Adirondack Mountains, and his last resort the employment of home treatment.

Dr. W. Jarvis Barlow of Los Angeles said that the fogs mentioned by Dr. Fisk as peculiar to Southern California were to be found only near the coast. An advantage of the fogs was their tendency to make the weather cooler. Persons with kidney and heart troubles, he thought, did better in Southern California than did those with pulmonary affections.

Dr. Charles Denison of Denver called attention to the great value of the personality of the author bearing upon the paper forming an authoritative statement from the membership of the Association of the value of the climate of Colorado.

Dr. F. I. Knight of Boston expressed his appreciation of the beautiful manner in which Mrs. Fisk had read the Doctor's paper.

Dr. J. Edward Stubbert of New York City was particularly interested in the paper, in that his own experience in the development of tuberculosis had been somewhat similar to that of Dr. Fisk. In contrast to Dr. Fisk, however, he had taken short trips into various climates, but had not been to Colorado. He had been to sea in the tropics and returned with the disease apparently cured, but it had redeveloped. He had then gone to China and lived in a climate where the sun shone for five minutes in twenty-eight days. He had subsequently entirely recovered. The application of the same rule in the treatment of many of his cases of tuberculosis had given good results. He would send patients south on a sea trip in preference to the North Atlantic, because of their ability to live on deck in the open.

Dr. William C. Rives spoke of the invigorating effect of climates of high altitude upon persons of ordinary health, arguing that tuberculosis, preeminently a disease of malnutrition, therefore should be benefited by the appropriate climate.

Dr. Vincent Y. Bowditch agreed with Dr. Fisk in his opinion of the climate of Colorado for tuberculous cases. For the vast number of patients who cannot possibly go away he advocated the home treatment. Every case should be judged upon its own merits.

Dr. R. H. Babcock of Chicago thought that Dr. Stubbert's recovery was not because, but in spite of the short trips he had taken. Regarding climate, Dr. Babcock believes that patients can recover at home, but that recovery is much more easily accomplished in a proper climate.

Dr. James A. Hart agreed in the opinion of Colorado being a favorable climate for tuberculous cases.

Dr. Fisk, in closing, said that he did not wish to take issue with Dr. Barlow, except to say that when in Southern California in 1902 his clothes, if hung by a window at night, were too damp for wearing the next morning.

Leishman-Donovan Disease or Assam Fever.—Dr. Judson Daland of Philadelphia read this paper, referring to the synonyms commonly employed for this disease and making mention of the geographical distribution of kala azar. The cause and relationship of the Leishman-Donovan body to the disease was established. The author holds the opinion that already sufficient evidence exists to justify the belief that the alternate host is the bedbug. That the disease is a house infection, probably carried by a biting insect, has long been the opinion of Major Leonard Rogers. Captain Patton of Madras had been able to demonstrate the life cycle of the parasite in bedbugs fed upon blood from a case of Assam fever. In the opinion of the author kala azar was transmitted from the sick to the well by the bedbug. Diagnosis, differential diagnosis, and the complications of the disease were discussed, special stress being laid upon the method of securing the blood for the detection of this parasite by splenopuncture. Long-continued, irregular, alternating, intermittent or remittent fever, enlarged painful spleen, enlarged liver, progressive loss of flesh, strength and color, leucopenia with mononuclear increase, and pigmentation of the palms of the hands and soles of the feet were mentioned as being highly diagnostic, especially in the absence of the malarial parasite from the peripheral blood. The only treatment of value was said to be the prophylactic, and but moderate benefit was to be expected from the use of from 60 to 90 grains of quinine each twenty-four hours.

Dr. Frank Fremont-Smith inquired whether the disease occurred in the Southern States.

Dr. Daland said that until within a few years ago the disease was supposedly confined to Assam and the region of Madras, but that recently in Egypt and Arabia the identification of the disease has made it seem not impossible to find it in our Southern States or in the West Indies

(To be continued.)

Treatment of La Grippe in Children.—Laumonier calls attention to the important influence of grippal infection on the functions of the organism of a child during the period of convalescence. At this time the patient is a prey to general asthenia. The tissues offer a good soil for grave infections and the natural forces of the organism should be fortified in order to prevent such dangers. The body cavities, especially the nose, should be cleansed with weak boracic acid solution. The child should be kept in bed in a large, well-aired, and sunny room until convalescence is fully established. A very light diet should be given. Drugs should be suited to the special indications for them. Great care should be taken of children who have been exposed to this infection. The nose, mouth, and throat should be kept clean and all clothing or other objects that have come in contact with the patient should be thoroughly disinfected. Every child suffering with grippe should be isolated from the rest of the household. The convalescent patient should be sent to the country. A month's time will generally be sufficient for restoring the health.—*Française de Médicine et de Chirurgie*

THE ANTRUM OF HIGHMORE AS AN ETIOLOGICAL FACTOR IN THE PRODUCTION OF HAY-FEVER (SO-CALLED).*

B. JACOB E. SCHADLE, M.D.

ST. PAUL, MINNESOTA

THE following paper is presented for the purpose of drawing special attention to a certain phase of a familiarly known disease, the cause and treatment of which have always been perplexing to understand. According to recent experiments, the disease appears to be based on anatomical deviations in its pathological aspects. These anatomical malformations act both as predisposing and contributory local factors. In accordance with this view, clinical investigations demonstrate that the antrum of Highmore holds an important position in the etiology of hay-fever and in some of the commoner forms of catarrhal and nervous disturbances of the nose. A series of a large number of cases coming under this class of affections, I have studied during the past number of years with considerable interest. The results of my observations have been of such a character as to corroborate the theory. To discuss empyema of the antrum in this connection is not the province of this report. In the first place the design is to deal with nonsuppurative processes. While of the pus-producing conditions of the antrum much has been said in recent years, and medical literature abounds in valuable contributions on the subject, reference will be made to suppurative maxillary sinusitis only for the purpose of illustrating pathological and symptomatic relationships.

It is my belief that the nervous catarrhal manifestations of the nose, in their relation to the presence of a catarrhal maxillary sinusitis, are of sufficient importance to merit attention and suggest further investigation. Is it not logical to associate disturbances of the maxillary sinus with the various forms of nervous coryza, when it is remembered that an intimate anatomical and physiological relationship exists between this cavity and the nasal passages in their nerve supply and mucous membrane connections?

In order to show the ground for believing that the antrum forms an etiological factor in the causation of hay-fever, I will quote in this connection the history of my first case treated in the manner herein described: F. N. D., aged forty-three years, lawyer, suffered from hay-fever for a period of twenty-five years. Nine months before his first attack, he sustained an injury to the nose from a blow received on the right side over the region of the maxillary sinus. This injury was followed by stenosis of the left nostril, which at the time of my examination twelve years ago, when he first consulted me on account of hay-fever, was found to be obstructed by the presence of a deviation and exostosis of the septum. The patient contended that the hay-fever resulted from the traumatism, as prior to the infliction of the injury he experienced none of the symptoms peculiar to the disease. This occurred early in the spring, and the attack of hay-fever came on in the autumn of the same year. At the time of our first interview (twelve years ago) his suffering was intense and the symptoms of the disease were pronounced, chief among which was an orbital cellulitis of a serious character. With a view to lessening the severity of the symptoms, I suggested correction of the septal deformity as soon as the urgent symptoms had sufficiently subsided to warrant operative interference. Removal of the exostosis and correction of the deviation improved his respiration and general condition; but he still continued to suffer thereafter more or less severely from the disease during subsequent years. It was a common occurrence for him to be incapacitated for work from six to eight weeks out of the year, and he was left at the end of each season in a state of general physical debility. In the latter part of December, 1903, he began to complain of facial neuralgia and severe pain over the right superior maxillary bone. He consulted me in reference to this trouble, and I found that the antral cavity was very much disturbed, as was evidenced by the presence of offensive discharges in the right nostril. The antrum was cleansed by irrigation through the opening communicating with the nose. A warm normal salt solution was used. The contents of the sinus as they appeared in the drainage basin, were found to be most offensive, the discharge consisting of inspissated mucopurulent material which had undergone fermentation and decomposition. A number of similar irrigations at different intervals succeeded in affording complete relief both as to maxillary pain or tenderness and the condition of the sinus itself. Of considerable interest was the fact that the opening of the antrum in this case was extremly abnormal, as it was possible to introduce a large-sized Eustachian catheter. This unusual openin[illegible] without doubt, by virtue of its admitting readily into the sinus particles of extraneous irritating or infective substances, contributed in no small degree toward creating the disturbance of which he was suffering at the time. Having known the man so well as a hay-fever victim in previous years, it occurred to me that, perhaps, the diseased antrum and its abnormal opening formed the basic lesion of his autumnal catarrh. The suspicion that this might be so, ended in a mutual understanding that when the next hay-fever season arrived, I should treat the antrum for experimental purposes. About the middle of August (1904) he was seized with the usual symptoms of the disease, but he did not visit me until two weeks

*Read at Denver, Colorado, February 16, 1907, before the Western Section of the American Laryngological, Rhinological, and Otological Society.

later, when he recalled our mutual arrangement. During these two weeks he had suffered about the same as on former occasions, and on the day of his visit the symptoms were well marked. I washed out the antrum with a very warm solution of boric acid, the return fluid from the cavity containing quantities of retained and decomposed secretions; the syringing of the sinus was continued at each sitting until the solution appeared clear in the catchbasin. These irrigations were followed by injections of a warm 5 per cent. solution of mentholated oil into the antrum. The next day the symptoms had materially abated and I again treated him as on the day previous. He did not return until two weeks later, when he presented himself more for the purpose of making a report than to be treated. He said after the second treatment all the symptoms, both local and general, disappeared. In 1905, he gave the method a thorough trial. During the season, beginning August 15, he was treated on five different occasions every other day and thereafter once a week, which treatment had the desired effect, and his suffering as compared with other years was minimized to such a degree as to render him absolutely comfortable. As the mentholated oil was rather pungent and painful, it was abandoned, and in lieu thereof thymol iodide was substituted and used in the form of an insufflation into the maxillary sinus after it was cleansed with the boric acid solution, thereby rendering the treatment more tolerable and efficacious. The past year (1906) for experimental purposes, the patient permitted me to apply the treatment occasionally, with a view of seeing whether or not the hay-fever season could be passed without the appearance of any of the symptoms. Once or twice a month during the year this was done, and it is satisfactory to state that last season (1906) the patient remained unaffected with but one exception; namely, one day he was making researches among old, stored-away, dusty legal books and pamphlets, when exposure to the dust brought on an array of nasal symptoms simulating those of hay-fever, whereupon the patient immediately came to my office for relief, and the antral cavity was subjected to the same procedure as before, with the gratifying result of at once eradicating the trouble. Further experimentation will be required to solve the problem of immunity not only as concerns this case, but also others in which similar results were obtained. Just now it is too early to consider the question. It will be noted, however, that I have spoken of the right antrum only: the left side having received no attention. The patient's suspicion that the trauma twenty-five years ago brought on the hay-fever may have some foundation: the injury of the nose and maxillary bone evidently had the effect of impairing the integrity of the sinus and of the ostium as well, and the history of the case and the results of treatment in a way strongly confirm this view. The patient speaks of the treatment as follows: "The result of these treatments has been surprising and most gratifying. I have passed through the hay-fever season without any annoyance whatever. I have lost not a moment's sleep. I have not been incapacitated for business in any way. I have attended the theater, taken long drives in the country, and long walks in the woods and fields, things not to be thought of in seasons past. In fact, I have escaped all annoyance and distress incident to hay-fever, and feel that hereafter I shall be at once relieved and need no longer dread the hay-fever seasons."

We have presented in this instance an example furnishing facts as related to hay-fever, that are worthy of recognition and serious reflection with regard to the etiology of the disease. The history of the case and the results of treatment almost conclusively demonstrate that the antrum was primarily at fault and formed, as it were, the basic lesion.

The Ostium Maxillare.—The pivotal point of the antral theory of hay-fever is the ostium maxillare. The anatomic condition and location of the orifice of the antrum determine the etiological and pathological features of the part played by the maxillary sinus in the production of hay-fever phenomena. Generally speaking, the antrum of Highmore is practically a sterile cavity, particularly, so long as it remains uninvaded by active pathogenic germs, but when irritation or infection is present, it will be seen by investigation that a supplementary or a malformed opening of the antrum exists, and fundamentally contributes to the sources of irritation or infection of the sinus.

Bacteriologists may say the antrum is not sterile, for the reason that various bacteria are always present in the nasal passages with which the sinus communicates. In the main this is true, but are they not inactive germs? When it is taken into account that the ostium maxillare in a strictly normal sense is of definite construction, and by virtue of its location has but one function, namely, that of supplying air to the antrum and guarding its integrity against the entrance of infective or irritating agents, it is altogether natural to consider it sterile, in spite of the presence of nonactive bacteria. As soon, however, as the ostium deviates in size and course from what nature designed it to be, then the antral cavity may at any time become subject to the action of morbific influences. Reasoning from analogy it can be argued that, if the middle ear or cavum tympanum is practically sterile, in the absence of germ activity, despite its communication through the Eustachian tube with the nasopharynx, the maxillary sinus for like reason is entitled to the same consideration. Therefore it would seem that the ostium maxillare bears the same relation to the maxillary sinus as does the Eustachian tube to the cavum tympanum, and consequently to maintain normal integrity of the respective cavities, no alteration of the tubes or ducts should exist.

The normal opening of the antrum is intricately located with reference to anatomical landmarks which are not constant and often make exploratory procedures difficult or impossible. Situated in the middle meatus underneath the middle turbinated body and at the posterior end of the hiatus semilunaris, between the uncinate process and the bulla ethmoidalis, the opening of the antrum is more or less concealed. We can readily understand how undue development of the bulla and of the uncinate process may contract the semilunar hiatus and increase the amount of concealment, thus rendering the ostium absolutely inaccessible. It has been shown by Hajek that the opening of the antrum is not constant as to size in all individuals. The normal ostium is about 2 mm. by 3 mm., and leads to the maxillary sinus in a direction downward, sharply forward and outward. It would seem that the obscure location of the ostium and its tortuous direction, so to speak, indicate nature's design with regard to the function of the opening. In my opinion it has but one function and that is to supply the antrum, a pneumatic cavity, with air. In a perfectly normal state, it is very doubtful whether it was ever intended to serve the purpose of a drainage canal; its very location favors this opinion when viewed from

a physiological standpoint. The opening exists at the extreme upper part of the nasoantral wall in the region of the middle meatus of the nose where the inspired current of air reaches the channel and antral orifice in full volume, and thereby ventilates the antrum. This physiological principle furnishes abundant reason for the location of the ostium, and it is only on abnormal or pathological grounds that the orifice can be safely regarded as a drainage canal. The question is sometimes asked: How is it possible to wash out or irrigate the antrum through the normal opening? It is not possible to do so. It is practicable only when the opening is abnormally large or when there exists a supplementary communication between the nose and the antrum. When the opening of the antrum deviates from its normal dimensions (2 mm. by 3 mm.) and departs from its natural course, it no longer sustains its primary relation, but becomes an avenue of communication, fraught with morbid influences productive of antral disturbances.

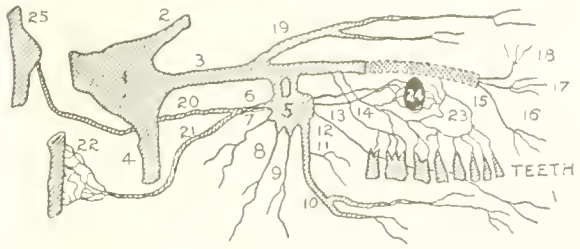
In certain instances on dissection the opening has been found to measure in its anteroposterior diameter as much as 18 mm. (Turner). Where so great a change, or even less, in the diameter of the ostium takes place, it may be concluded that the course of the duct is also changed and proceeds more directly toward the antrum than otherwise. This variation undoubtedly is due to anatomical defects, or, in cases of sclerosis of the nose, to atrophic changes of the tissues.

There frequently exists a supplementary or accessory opening of the antrum, and, according to Zuckerkandl, it may be present in 10 per cent. of cases. Logan Turner found it to be present four times out of nine dissections, while Douglas says it occurs in 50 per cent. of cases and clinical observations confirm the statement of the last-named authority. These statistics are important and shed considerable light on the antral theory of hay-fever and catarrhal maxillary sinusitis.

The location of accessory ostia is usually above the inferior turbinated body at the junction of the middle with the posterior third of the bone on a line without and below the posterior end of the semilunar canal. They occur in the membranous portion of the nasoantral wall and range in size from the head of a pin to 8 mm., and sometimes more than one exists on the same side; but whether these accessory openings are formed during the developmental period of the antrum or whether they are mainly due to disease or trauma, is not fully understood.

Taking into consideration their varying dimensions and the frequency with which they occur in a given series of cases, the supplementary openings of the antrum form a conspicuous part played by the maxillary sinus in the production of the disease under consideration. Further than this, they occupy a favorable position in the middle meatus for the accomplishment of exploratory and therapeutic ends. In the presence of these anatomical nasoantral irregularities, so far as they pertain to the orifice of the antrum, it is not difficult to comprehend the *modus operandi* of the various extraneous exciting agents peculiar to the induction of hay-fever, and for the same reason it is not hard to understand how a catarrhal maxillary sinusitis produces hypersecretion of the cavity and in turn provokes nasal irritation and nervous coryza.

A comparative study shows that as to size the antrum varies in different individuals. It is lined by mucous membrane consisting of ciliated epithelium and a rich distribution of muciperous glands, and it is, in part at least, analogous to that of the nasal fossæ.



1. Gasserian ganglion. 2. Ophthalmic division. 3 Superior maxillary division. 4. Inferior maxillary division. 5. Meckel's ganglion. 6. Vidian nerve. 7. Pharyngeal nerve. 8. Posterior palatine 9 Middle palatine 10. Anterior palatine 11. Inferior nasal. 12. Nasopalatine. 13 Superior nasal. 14. Posterior dental 15. Anterior dental. 16. Labial. 17. Nasal, and 18, Palpebral, on external aspect. 19. Orbital. 20. Large petrosal. 21. Carotid 22. Carotid plexus of sympathetic. 23 Anastomoses of anterior, posterior, and superior nasal branches to supply antrum 24. Ganglion of Bochdalek. 25. Facial nerve with geniculate ganglion

Nerve Connections.—The antral mucosa receives numerous sensitive nervous filaments given off by the superior maxillary division of the trigeminus, and it is also abundantly supplied by secretory nervous fibers. The anterior dental, the posterior dental, and the superior nasal from Meckel's ganglion, form the nervous supply of the antrum (Gray). Sympathetic fibers come from the Vidian, composed of the great petrosal and carotid. The carotid forms a connection between the carotid plexus of the sympathetic and Meckel's ganglion. Nervous filaments are given off from the lower border of the posterior dental which forms a minute plexus on the outer wall of the superior maxillary bone immediately above the alveoli. From this plexus, filaments are distributed to pulps of molar and second bicuspid teeth, *the lining membrane of the antrum* and a corresponding portion of the gums. The anterior dental is given off just before its exit from the infraorbital foramen; it enters a special canal in the anterior wall of the antrum and anastosmoses with the posterior dental and superior nasal branches. From this nerve some filaments are distributed to the incisor, canine, and first bicuspid; others are lost upon the lining membrane covering the fore part of the inferior meatus. In this situation it forms a connection with a nasal branch from Meckel's ganglion called the ganglion of Bochdalek. From Meckel's ganglion are branches (descending or palatine) supplying the lining membrane of the nose. It has three sets of fibers: motor, sensory, and sympathetic. Internal branches are distributed to the septum, and outer wall of the nasal fossa; one branch (posterior) is distributed to the outer wall of the antrum and forms a communication with the anterior dental in the ganglion of Bochdalek.

From this we see the antrum to be abundantly supplied with nerves. The posterior dental, anterior dental, and the branches from Meckel's ganglion give motor, sensory, and sympathetic fibers not less to the antrum than to the meati of the nose. Irritation of these fibers in the antrum is not only capable of producing the sensory and sympathetic disturbances seen in hay-fever, but neglect to relieve the antrum from sources of irritation and disease explains the discouraging failure to cure the condition by operative and other therapy upon the nasal cavities. Moreover, the continued irritation of these sensory and sympathetic fibers is capable of establishing in those of unstable nervous organization that distressing chain of neurasthenic symptoms which are the secondary and coincident con-

ditions in most cases, for under emotional and morbific influences a reciprocal relationship between the sympathetic and central nervous system exists. In hay-fever the sensitive nerve endings present in the antral and rhinal cavities are kept in a state of excitation as a result of local irritation.

Pathological Connections.—The maxillary sinus, apart from its orifice, is a closed cavity where warmth and moisture have ample chance to engender fermentation and generate bacterial products. Its mucous membrane is continuous with that of the nasal passages through the ostium maxillary. This arrangement, under abnormal anatomical conditions, with regard to the nasoantral orifice, forms the pathological connection between the antrum and the nose, and shows how readily an inflammation of the antrum can reflect itself to the nose by extension or by irritation consequent to its discharging contents. In hay-fever, the secretions arising from inflammation of the antrum are the source of the vasomotor nasal disturbances and the associated reflex symptoms, which are relatively augmented or diminished in proportion to the quantity and irritative properties of those discharges.

The query arises, how does the antrum get rid of its fluid contents when hypersecretion in the cavity obtains? In the first place, gravity performs an important part in the function. Various positions or movements of the head favor the exit of the secretions. In the second place, it is demonstrable that the act of respiration or of blowing the nose drains the cavity by a process of suction. The peculiarly favorable position of the accessory or malformed ostium, as it is related to the middle meatus and the middle and upper turbinated bodies, makes drainage possible in the manner described. I have frequently observed that after washing out the sinus for therapeutic purposes, the fluid was thoroughly evacuated by the time the patient had finished blowing the nose, as was illustrated by the use of the air bag, and insufflation of medicinal powders.

With regard to the so-called extraneous exciting causes of hay-fever, such as pollen from weeds, grasses, and flowers, odoriferous emanations, dust, certain drugs, etc., etc., how are they related to the antral theory of the disease? Is it not possible, and is it not a fact, that these external excitants, after reaching the nasal passages, enter the antral cavity and through their action induce hyperemia and catarrhal inflammation productive of hypersecretion and, in cases of chronic preexisting antral disease, intensify the activity of the lesion?

I am of the opinion that when the communication between the nose and antrum is absolutely anatomically normal as to size and situation, disturbances of the character mentioned are not likely to take place in the absence of alveolar or dental irritation, but in instances in which the ostium is abnormally large, or in which there is an accessory opening, an avenue is created for the favorable entrance into the cavity of extraneous irritative or infective substances by air in motion or the act of respiration. Thus we can readily see how these foreign substances can enter and lodge in the antrum, induce irritation and infection, and give rise to inflammation which usually is secretory in character. Fundamentally speaking, the whole theory rests on anatomical abnormalities.

In 1904 Emanuel Fink, Hamburg, Germany, in a contribution, drew attention to the antrum of Highmore as furnishing the probable source of the disease, and successfully treated it in accordance with these views. In support of the antral theory, Fink quotes Helmholtz, who himself was a sufferer from the disorder, and ascribed the affection to the influences of certain vibrios contained in the secretion of the nose, thrown off by violent attacks of sneezing, while, on the other hand, Helmholtz contended that a secretion which passed from the nasal passages, drop by drop, did not present the vibrios; they were lodged in the variously hidden recesses of the sinuses of the nose. It is maintained that even if the vibrios could not be regarded as a specific form of disease, Helmholtz's observations would prove that the secretion must come from the sinuses, especially from the antrum of Highmore. Sneezing, a constant accompaniment of hay-fever, is, according to Sandmann, the result of irritation of the ethmoidalis nerve. This irritation may be caused either directly through the agents contained in the inspired air, or indirectly through the secretion flowing from the antrum. Concerning asthma, it has been shown by reliable authority (Francois, France, and Lazarus), that through excitement of the nasal mucous membrane, spasm of the bronchial muscles can be produced reflexly. Recent physiological researches show that the mucous membrane of the antrum of Highmore when disturbed stands in the same relation to bronchial spasm as does that of the nasal passages.

It is no longer questioned that a number of respiratory, as well as associated diseases, are both directly and indirectly due to sinus affections; for instance, the source of nasal polypi, headache, ophthalmic disorders, chronic rhinitis (atrophic in particular), mental derangements, trifacial neuralgia, odontalgia, bronchial asthma, etc., etc., is often capable of such demonstration by operative and other measures.

Neurasthenic Aspects.—Earlier as well as more modern writers maintain that hay-fever is a neurosis and in display of symptoms perhaps it may be true, as the nervous characteristics of the disease largely form the symptomatology, and, in fact, it is this feature of the affection that gives rise to the troublesome complications with which the physician is called upon to contend. Do the nervous manifestations constitute the disease, *per se*, without the existence of a primary lesion? It is hardly logical to assume such a position, when it is known that pathological states involving other organs of the body are often responsible for the presence of neurasthenic symptoms.

When the late Dr. George M. Beard introduced into our medical nomenclature the term neurasthenia, he did not intend that the use of the name should be applied to diseased processes inducing a group of peculiar nervous symptoms hitherto misunderstood, for the purpose of disguising erroneous diagnoses or concealing sins of omission and commission. He maintained that these neurotic symptoms sprang from definite, tangible causes, and that by grouping them together under one general designation he thereby would give them a special significance; for instance, when they accompanied a gastric disease, it was termed "gastric neurasthenia," and when associated with a disturbance or abuse of the sexual organs, "sexual neurasthenia," and so on. Therefore, with the same propriety, the neurotic phenomena attending nasal nervous catarrh, due to sinus origin, may be called *sinus* neurasthenia. There has always been a tendency to emphasize the importance of the nervous symptoms of hay-fever; this is exemplified by the many different forms of treatment adopted with a view to meet

symptom emergencies only, while its organic phase is lost sight of or not inquired into.

There are those also who contend that the nervous features are partly imaginary. Few ailments of the body can justly be ascribed to the power of the imagination alone. Under extraordinary circumstances, perhaps, such a belief is tenable, especially when hysteria is present, but it is not infrequent, however, that on closer scrutiny of existing conditions as to origin, a hidden morbid state, regardless of its location, is often found in given cases to be at the bottom of the hysteria.

In hay-fever subjects where a nervous state of the individual predominates, causal factors ought always to be considered, because if the neurasthenia is a secondary factor, and simply constitutes a reflection of disturbed nervous harmony or equilibrium, induced by distinct lesions acting directly or indirectly on an unstable central nervous system, the solution of the problem becomes easier. It is also true that certain basic conditions of disease are capable of creating in patients of nervous instability, a special susceptibility to exciting causes. These persons are those of idiosyncratic temperament, so-called. I believe this to be the case in hay-fever, the phenomena of which are ascribed by some authors to a special idiosyncrasy. In other words, the idiosyncrasy is the result of morbid central evolutionary processes, in which the sympathetic and vasomotor nervous systems play a conspicuous part in establishing the hay-fever predisposition. External excitants are only contributory factors and hold a subordinate position in etiology, and excite into action a lesion over which they exercise an influence. Internal disease must be present in order to enable impressions to exert their effects on the central nervous system.

Hay-fever belongs to this category of neuroses. It is a general observation that diseases, hampered by obscurity respecting their fundamental sources, always make rational therapeutics difficult; for this reason the physician is not infrequently called upon to make an uncertain diagnosis and employ a symptomatic therapy in order to satisfy the patient, and in so doing he himself unfortunately becomes satisfied and makes no further research. From the patient's point of view and demands, not a few symptoms of the disease require special attention, thus increasing the number of remedies for purposes of alleviation. A multiplicity of remedies will, however, become necessary, when we once fully understand the source of the disease and adapt our remedial measures accordingly and pay less attention to individual symptoms.

With reference to the so-called sensitive areas of the nose, acting as etiological factors of hay-fever, anatomically considered, they consist of a localized distribution of sensitive nervous filaments in certain parts of the nasal mucous membrane. Under local stimulation or irritation they are readily excited; they serve both physiological and pathological purposes and their degree of sensitiveness normally varies in different individuals. Physiologically they serve as safeguards to the upper air tract, but on the other hand, by oft-repeated and prolonged local irritation, the sensitiveness increases with a resulting hyperesthesia, which in turn becomes a pathological condition. Hyperesthesia of the nasal passages thus appearing is prone to lead to functional derangement of the sympathetic nervous system, and induce reflex symptoms and vasomotor disorders, such as coughing, sneezing, nasal fullness and discharges, tinnitis aurium, etc., etc. Though characterized by a neurotic physiognomy, it is nevertheless contended that the disease may be primarily organic, and that a pathological state of the antrum of Highmore, so far as my present observations and experiments extend, is the seat of the chief etiological lesion. Personal experiences demonstrate the theory in a practical way and set aside the illogical conclusion that the neurasthenia constitutes the malady. Errors are sometimes committed, by hastily formed conclusions with regard to the immediate cause of a sudden onset of the disease, as is instanced by the celebrated case of "rose-cold," or hyperesthetic rhinitis, which was presumably produced by the presence of an artificial rose, reported some years since, and which account is still fresh in the minds of many rhinologists. This singular circumstance will continue to be referred to whenever discussions arise with reference to the causation of hay-fever. Is it not possible that the artificial rose served only a coincident circumstance peculiar to the situation during the patient's visit? The history of the case is not sufficient to strengthen the argument in favor of "suggestion" as related to hay-fever, because a series of cases similarly affected would be required to give scientific value to the observation.

The will has a definite power over the operations of the body, both in health and disease, but psychic influence, however, must not be overestimated in its control over the physical organization. It no doubt serves a valuable purpose under extreme circumstances, as when faith in what is being done for the relief of suffering is exercised, because then an element of expectancy is introduced into the treatment, and the mind is thereby put at rest, and nutrition of the nervous system is reestablished and physical forces reassert themselves. This we see illustrated sometimes in physical ailments as well as in mental conditions of grief, fear, or undue anxiety. As applied to the induction of organic disease, psychic doctrines should not be too enthusiastically considered in these days of scientific medicine, as their supposed miraculous power in great measure is a relic of past ages. In the days when medical empiricism prevailed and the physician had no pathology and only a meager etiology to govern him in the selection of his remedies, there was some color of reason for such doctrines.

In the consideration of the alleged mental aspect of the disease the foregoing statements have been made, because hay-fever is not a disease of the mind; it is a disease under the domain of cause and effect, and in all probability, due to an organic lesion in which the antrum of Highmore is an important contributory factor.

Description of Cases.—As the limits of this paper will not permit a detailed account of each and every case under observation and treatment during the past three years, I will confine myself to descriptions of salient points developed in the experience in order to illustrate as specifically as possible the intimate connection between the antrum and hay-fever. In the period mentioned, there were under my observation ninety-one cases of hay-fever and rose-cold in varying degrees; two were treated in 1904, fifteen in 1905, and seventy-four in 1906, with uniformly good results. To justify myself against possible criticism, I said to each new patient, that while I firmly believed the treatment logical, yet the method was an experiment, and, apart from safety, no promises would be made as to the outcome. The results realized during the first two years were sufficiently satisfactory to encourage further inves-

tigations in a more extended manner, wherefore in the past year an especial effort on the part of some of my professional friends and myself was made to bring under observation as many instances of the disease as was expedient, whereby the gist of the theory could be verified.

Accessory Ostia and Typical Symptoms.—Mrs. B., aged thirty-three years, wife of a physician and mother of eight children, consulted me about eighteen months ago, with reference to hay-fever. She was of lithemic diathesis and suffered at times from intercostal and facial neuralgia. She contracted the disease in August, 1895, and has been a yearly sufferer since then with progressively greater severity; a dry, dusty day, a shopping tour, or smoke, sufficing to bring on an attack; the most troublesome symptoms being sneezing, hydrorrhea, pain in the nose, and asthma. At the height of the attack there were usually present excessive lacrymation, burning, and itching sensations of the eyes. Prior to her consultation with me, she had tried various remedies, such as Dunbar serum, adrenalin, cocaine, antilithemics, and many others; and besides these, intranasal surgery was employed for the reduction of hypertrophic and other irregularities of the nose, with the hope of overcoming the affection, all, however, without obtaining relief. Examination of the nose revealed an intensely red, swollen mucous membrane of both sides, which was very sensitive, as evidenced by violent reflex disturbances when the sound was used. The middle meatus on the left side around the orifice of the antrum was engorged and hypersensitive, whereas the right side in this respect was not involved in the same degree. After reducing the sensitive and swollen membrane by applications of cocain and adrenalin, thereby improving the local field of vision, I found by sounding that the opening of the antrum was supplementary and very large, and therefore concluded that this case came within the purview of the antral theory, and about the latter part of that season, treated her accordingly. After the first treatment, the eye, throat, chest, and severity of the nasal symptoms practically disappeared within twenty-four hours, and it is interesting to note that the patient's first night was passed comfortably, and upon a second application, within a very short time all the signs of the disease were dissipated. Prior to the treatment, she was unable to attend theaters, go shopping, or come in contact with hot winds or dust, or drive where exposed to weeds, without suffering discomfort or being compelled to remain in her room with closed doors and windows, and in order to test the theory, the patient attended the theaters, went shopping, and withstood the action of the elements and contamination of weeds, with the result that she slept well, felt no discomfort therefrom, and her asthma entirely left her. The malformed ostia favored instrumentation, as it was quite possible to introduce the cannula of the syringe or powder blower into the antrum. Applications of a warm solution of boric acid in the form of injections, removed from both sinuses an unusual amount of retained secretions, suggesting inflammation and hypersecretion. Mrs. B. continued well until housecleaning time arrived, when she was exposed to dust and odors from new grass-matting on the floors, an environment which in the past was always accompanied by an array of hay-fever symptoms regardless of the time of year, thus showing that some certain organ associated with the nasal air tract was implicated in the morbid process and formed the basis of disturbance on these occasions, owing to irritants acting from without. Between the season of 1905 and 1906, at the suggestion of her husband, a physician, Mrs. B. visited me at stated intervals for purposes of treatment to see whether the opinion that the maxillary sinuses were organically involved in the production of these symptoms, could be verified. The antra were regularly cleansed at intervals and afterwards medicated with an application of thymol iodide or a 25 per cent. solution of silver salt. Thereafter she frequently tested herself and found that she could expose herself to irritants, dust, and odors, with impunity. The past hay-fever season went by without much trouble, only one attack lasting about four days manifesting itself, and further treatment at this time being impossible owing to the delicate condition of the patient. She has since declared herself well and is perfectly able to go about and attend to her usual duties.

Asthma.—September, 1905, Mr. W., aged forty years, a furrier, constantly exposed to dust and odor peculiar to his occupation, was referred to me on account of asthma contracted two and one-half years previously, and which from its inception has increased in intensity both day and night. Upon careful examination, and beyond a periodic discharge from the nose, I was unable to find the presence of the usual lesions of the nose which would account for the paroxysms. There were no intranasal deformities or pressure contact and the only suggestion that the nose might have been responsible for the attacks was an intumescent thickening of the mucous membrane of the septum directly opposite the middle turbinate bodies, which fact was taken into consideration as a causative factor. I was of the opinion that the case was one of bronchial asthma, produced by the inhalation of fur dust, and with this view he was advised to keep away from his occupation, be exposed to the open air as much as possible, exercise judiciously, and take the medicine prescribed. Iodide of potassium alone, as well as in mixtures containing other antiasthmatic agents was faithfully tried without avail, and in fact almost the whole category of remedies recommended for the cure of asthma was resorted to in the course of time, with negative results. Concluding that constitutional treatment was a failure, the patient was given local treatment accompanied by intrabronchial injections of warm mentholated oil, and while this procedure yielded partial relief it did not cure him. The hypertrophied tissue on the septum opposite the middle turbinates was then cauterized, but without results, and as I was at this time directing my attention to the maxillary antra of patients afflicted with hay-fever, it occurred to me that perhaps his sinuses were affected by the entrance of dust or other infection arising from the character of his business and that similar treatment might dissipate the asthma. I treated him accordingly, and it was highly gratifying, and I found that the same substance came from the cavities as did from the hay-fever subjects, that is, a flaky-white or milk-curdle deposit. Upon receiving a visit from the man the following day he greeted me with, "You struck it this time; I had no asthma last night." At stated intervals he was treated six or eight times. At present writing the patient is free from asthma, and, after obtaining relief, he resumed his business and has been thus engaged ever since. I feel confident he will remain permanently free until such time, at least, as when the conditions of his environment may again disturb the sensitive nerve supply and mucous lining of the maxillary cavities.

Neurasthenia and Nervous Nasal Catarrh.—On June 18, 1906, Mrs. A., aged forty years, the mother of four children, came to me and stated that for a number of years she had been afflicted with the hysterical type of neurasthenia manifesting itself in various ways. After a long continued course of treatment by a gynecologist who entertained the opinion that the nervous symptoms were due to a diseased state of the pelvic organs, a nervous disturbance of the nose developed. Later on hyperesthesia of the skin of the right side of the face, extending down and over the shoulder and arm of the same side, appeared. The throat and tongue became involved, and she at first imagined that an apple seed had buried itself in the tissues of the right side of the throat and formed a focus of disturbance. The symptoms were accompanied by burning and itching of the mucous membrane, eyes, mouth, tongue, and throat, which still existed when she consulted me. There were present frontal and occipital headache, frequent paroxysms of sneezing, and excessive discharges of the nose, restless nights, and loss of appetite. Evidences of impaired nutrition and a feeling of melancholia which so often accompanies these conditions, existed in a marked degree. Coupling the signs of nervous nasal catarrh with these general nervous manifestations, it occurred to me that the chief causal factor of the complaint was of sinus origin. On examination of the nose, I found turbinal hypertrophy, hyperesthesia, and soggy appearance of the mucous membrane. The report of this case is not presented as one of genuine hay-fever. It is offered as an admirable illustration of a type of neurotic affections of the nose known as nervous coryza, characterized by a significant display of neurasthenic phenomena, strongly resembling the symptoms of hay-fever and coming from the same organic lesion located in the antrum of Highmore. Sounding the maxillary sinuses with a probe developed painful sensations in the middle meati. In fact, the whole interior of the passages of the nose was hyperesthetic and made the use of the instrument almost unbearable. In order to reduce the swollen mucous membrane and render instrumentation of the sinuses possible, adrenalin and cocaine were applied. The cavities were cleansed with a syringe and warm boric acid solution. From the left cavity came a fluid (four drachms in quantity) resembling buttermilk, while the right discharged a seromucous secretion. An interesting circumstance in connection with the case is that about nineteen years ago, Mrs. A. was struck on the right side of the nose and in consequence suffered total loss of the sense of smell as well as periodic attacks of intense facial neuralgia and pain in her upper teeth. Percussion over the cheek in the region of the antra elicited pain in the deeper structures. The patient was regularly treated for about two weeks and it is interesting to note that the sense of smell has returned in an exaggerated form; the nasal, head, and throat symptoms as well as the hyperesthesia of the skin, are dissipated and the improvement in every way is marked. She is now able to sleep all night; her appetite has returned; her mentality is changed, and the neurasthenic phases of the case have disappeared. No medicines except those used in the local treatment, were prescribed.

Test Case.—One man in particular, Mr. D., capitalist, consulted me seven days before the date of his periodic attacks of hay-fever, which always had been on August 7, to find out whether or not something could be done to prevent his having the disease. He informed me that he suffered severely for many years and that it rendered him perfectly miserable and melancholy for at least two months during each season. In fact, his mental condition was of such a character as to cause him to stay in the attic of his residence day and night in order to get away from fancied atmospheric influences of hay-fever. As he was urgently advised to see me by Mr. D., whose case is quoted at the beginning of this article, he came not wholly without confidence. Examination showed large accessory ostia on both sides and the maxillary sinuses catarrhally affected. The malplaced ostium and the readiness with which it could be entered, made me feel that the case was highly amenable to treatment and I so expressed myself to him. Treatment was begun on the same day of the examination and continued daily for some time thereafter for the reason that he looked upon it as a luxury. Results: The seventh day of August arrived, and no sign of hay-fever; the eighth, the ninth, and the tenth were likewise negative. About the eleventh, out of curiosity, he tested himself by making a tour of one hundred miles with an automobile through the country where all the elements peculiar to the exciting causes of the disease existed. The next day he reported his experience and aside from itching at the end of the nose, he made no complaint. Upon washing out the antra, however, I was amazed at the quantity of milk-curdle secretions that appeared in the catch basin. This evidenced valuable information with regard to the fact that the antra were undergoing an inflammatory disturbance and in a brief length of time would have ushered in an array of hay-fever symptoms through nerve irritation; insufflation of thymol iodide, however, arrested the process and no trouble came from the exposure. For a further test this same experiment was resorted to a number of times during the season, but nothing came from it to interrupt the comfort of the patient, except an occasional itching of the end of the nose.

Antral vs. Dunbar Treatment.—Mr. S., aged forty-five years, teacher, a victim of hay-fever for seven years; symptoms, sneezing, nasal discharges, coughing, and severe paroxysms of asthma. He first visited me August 10, 1905, at which time the Dunbar serum was prescribed in powder form and was continued until September 6, without effecting any benefit, and during this visit the antral method was recommended and applied, with the result that the asthma disappeared within the first twenty-four hours and after several subsequent treatments, and within a week he was able to follow his profession without any inconvenience and considered himself practically cured. At the beginning of the hay-fever season and about the first of August, 1906, while upon a business trip through Ohio, he was taken seriously ill with the disease, and, upon his arrival at his destination, he was again given the Dunbar serum treatment which was continued for about ten days and until his arrival in St. Paul, when he presented himself at my office. I found him suffering from his former usual symptoms, and asthma in particular. On request of the patient, I again applied the antral treatment, with the result that within one week he enjoyed perfect relief.

Large Supplementary Ostia, Deep Antral Cavities, and Decided Neurasthenia.—Dr. W., aged thirty-two years, neurotic temperament, good family history, came to me September last, complaining of neurasthenia, restless nights, stenosis of the nose,

paroxysms of sneezing, pain and congestion of the eyes, asthma, and profuse discharges from the anterior and posterior nares; these symptoms, without doubt, denoted an attack of hay-fever. Ten years before, he experienced his first attack, and suffered thereafter more or less severely. During this time surgical procedures brought about beneficial results, but as time elapsed their good effects gradually disappeared, as dampness, drafts, dust, overheated rooms, exposure of extremities while asleep, and decided weather changes always induced recurrence of the symptoms, regardless of the time of year; the symptoms intensifying themselves only during the hay-fever period, whereby the suffering was augmented. Four years ago the patient came to me afflicted with one of these violent seizures and I prescribed the usual palliative remedies then in vogue, but accomplished nothing beyond temporary relief. On seeing him the past season he was suffering unbearable tortures and the status of the case at this time was as is outlined above. He went East for the purpose of consulting with medical authorities regarding his case, and after being informed that his symptoms were largely imaginary, he returned to the West dissatisfied and discouraged with his Eastern experiences, and visited my office ostensibly for antral investigation and treatment. On examination I found the nasal passages unusually irritable and engorged, the mucous membrane being soggy and edematous. After intranasal sensitiveness and engorgement had been reduced by application of cocaine and adrenalin, it became possible to explore the location and character of the maxillary openings. They were found to be supplementary, very large and readily sounded, and occupied a position in the membraneous part of the nasoantral wall rather near the upper border of the inferior turbinated body. It was ascertained that both maxillary sinuses were of unusual size and had a capacity of six or eight drachms. The antrum on both sides was first washed out with a normal salt solution, and as the retained secretions proceeding from the cavity, mixed with the injected solution, appeared in the catch basin, they presented a reddish, muddy, and coffee-grounds aspect. Because of the unusual size of the antra, a certain percentage of the injected fluid was retained, which made it necessary to use the syringe in order to withdraw the remaining contents which resembled what was caught in the basin. This irrigating process was continued until the sinuses were thoroughly cleansed. Injections of a 25 per cent. solution of a silver salt were then made and the patient was requested to lie down and keep quiet for an interval of an hour so as to give the antiseptic a chance to remain in contact with the antral mucous membrane in order to accomplish its ulterior purpose. In this manner Dr. W. was treated for a period of a week at intervals of a day, each subsequent visitation evidencing improvement. Among the first symptoms to subside was the excessive nasopharyngeal discharge which always gave much annoyance and interrupted the comfort of the patient at night when in the recumbent position. Next to disappear was the asthma, and at the end of the week the symptoms were entirely absent and the patient considered himself cured. In order to prove the permanency of the results he afterwards took frequent drives in the country and exposed himself to the exciting causes of the malady without recurrence of any of the symptoms. Chiefly to be considered in this instance, in their bearing on the periodic nervous manifestations, are the various contributory external causes, the accessory openings and capaciousness of the maxillary sinuses, the high degree of antral inflammation, and the character of the hypersecretion of the cavities.

Preexisting Chronic Catarrhal Maxillary Sinusitis and Hyperesthetic Rhinitis.—On October 29, 1905, a man, aged forty-six, contractor, consulted me relative to excessive catarrhal discharges from the nose, persistent coughing and retching spells, regularly present in the mornings and usually after breakfast, dyspeptic symptoms with loss of appetite, and consequent decrease of body weight. This state of physical impairment existed for a number of years without apparent cessation. Twelve years prior he was attacked by vertiginous seizures, the dizziness lasting for long periods at a time. The vertigo was thought by his physician to have been of stomachic origin. On examination of the nose and postnasal cavities I found the former more or less occluded by turbinal hypertrophies and the latter occupied by disagreeable, tenacious secretions; a musty odor emanating from the air passages led me to believe that the so-called foul breath was due to the furred tongue and general gastric derangement. With the idea in mind that perhaps the obstructed nose had a great deal to do with the symptoms for which he chiefly sought relief, I reduced the intranasal hyperplasia, which made nasal respiration comfortable. The postnasal space was treated by local applications of iodine and nitrate of silver pigments, used interchangeably. This therapy in a manner afforded some benefit, but not enough to satisfy either myself or the patient. The morning retching continued and the offensive odor remained undiminished. During August last, after a long interval between visits, he again saw me with the statement that he had a severe "cold in the head," as was manifested by nasal stenosis, sneezing attacks, watery discharges from the nose, itching and burning sensations of the eyes and throat, and on inspection of the nose and taking into account the symptoms presenting, I diagnosed it a clear case of hay-fever. Inquiry developed that he had had similar attacks in previous years, but he supposed they were due to catching cold. At the time he came under my observation on this occasion, I was experimenting on the antrum of Highmore in other cases of hay-fever with regard to the relationship existing between the disease and the maxillary sinuses, ostensibly with the object in view to *prove* or *disprove* the correctness of the theory. The conclusion irresistibly impressed me that this case offered an excellent example for the purpose. Sounding the antral cavities demonstrated the practicability of entering them through the nasoantral opening with suitable instruments. It was discovered by the method employed that an opening or communication of the antrum in both nasal chambers was present in the middle meatus at a point posterior and inferior to the meatal termination of the hiatus semilunaris; these openings proved to be accessory ostia. This anatomical malformation both as to position and size of the opening, a condition frequently present in hay-fever subjects according to my investigations, gave rise to the suspicion that the maxillary sinuses were diseased and formed the basic lesion of the patient's trouble. Both cavities were washed out with a normal salt solution, the irrigation being continued until the return fluid as it appeared in the catch vessel was entirely clear and free from sediment or retained secretions. The discharge thus forced from the antra was not exactly characteristic of what is usually

noted in hay-fever conditions; it was offensive in odor and peculiarly muddy and granular in appearance, intermixed with mucoid material. A bacteriological examination of a specimen revealed a green bacillus, *B. pyocyaneus*. Six or seven consecutive treatments directed to both antra at intervals of twenty-four hours had the desired effect in curing the patient of his hay-fever. He grew fond of the treatments because of the good systemic effect produced, and after the hay-fever had disappeared, he wanted the treatment often and regularly. It was not long until he remarked that the coughing, vomiting, and retching had wholly disappeared as well as the postnasal discharges; his appetite and digestion at once improved, his weight increased, and the offensive odor was also brought under control and eradicated.

A point of particular interest so far as subjective signs are concerned in antral disturbances of this sort, is that those patients usually know when a storm is brewing in the antral cavities, as is recognized by a disagreeable, burning sensation in the region of the middle meatus of the nose and in the neighborhood of the ostium. The patient is always cognizant of what is going on at these periods and comes for a cleansing of the sinuses just as soon as the nasal sensations indicate the necessity, and one treatment usually suffices for a number of weeks. Catching cold or exposure to dust are the chief exciting causes in his case. The deductions are: First, that the opinion is substantiated that one or more of the associated sinuses of the nose when in a diseased catarrhal state, is as a rule one of the chief causes of so-called postnasal catarrh and its attending symptoms; second, that the history of the case furnishes a convincing argument in favor of the antral theory of hay-fever; and, third, that an abnormally large or an accessory maxillary ostium is a local anatomical predisposing factor in the etiology of catarrh and hypersecretion of the sinus.

General Remarks and Deductions.—The observation is borne out by this experience that in those cases in which unusually developed abnormal openings of the antra prevailed, the results of treatment were more prompt and satisfactory than in those where the abnormal dimensions of the communications were much less; the former favoring and facilitating instrumentation and the application of remedies, and the latter increasing the difficulties. The observance of this point offers a rational explanation on atomic grounds for therapeutic failures. Dissections have shown that the antrum of Highmore is a variable cavity as to its dimensions in different individuals, and also that an anomaly may sometimes exist, particularly as regards subdivision of the sinus into compartments by bony walls or partitions.

It was also observed that "rose-cold" or "hay-fever" of one or two seasons' existence in certain individuals, yielded on an average to treatment more readily than it did in those who had had the disease for many seasons or where it extended over a long period of time. It may be concluded from this that as yet the antral mucous membrane had not undergone permanent inflammatory degeneration or changes in those patients who thus were readily cured. If this observation can be further verified in the future, it certainly adds a valuable factor to prognosis.

Of the whole number of cases heretofore referred to, one was a total failure. Though treatment directed to the antrum was faithfully followed for a reasonable period, yet no impression could be made and the symptoms refused to yield. The ostia were abnormal in size and no difficulty encountered in the use of the probe or cannula, but whenever a fluid was injected or a powder blown into the antrum it was found to rebound instantly into the nasal passage. Experimenting in different ways with a view of forming some explanation for the presence of an impediment, it was finally thought that the sinus was anomalous, there evidently being present a number of cavernous compartments. In given cases, therefore, of catarrhal maxillary sinusitis or hay-fever in which local malformations obtain with regard to the location and size of the opening of the antrum, anomaly of the sinus must also be taken into account when dealing with a certain class where insurmountable barriers to treatment arise.

Also of this number three did not respond for lack of adequate treatment. Among the number there were twelve who were entirely relieved within a period of about two and one-half weeks and who had suffered in former years six to eight weeks each season, and the remainder were fully and completely relieved of the disease and its symptoms in a week or ten days, and, in exceptional instances, some in four days, treatment of the last two classes having been administered daily.

My observation has been that the reflex symptoms first to disappear were burning and other disturbances of the eyes, pruritus of the throat and ears, finally sneezing and discharges from the nose, and last *asthma* and cough.

That chronic catarrhal maxillary sinusitis is a morbid process productive of intranasal and postnasal catarrhal disturbances is not to be questioned, when it is understood that, by directing treatment to the antrum, many of these cases are relieved and get well. The history of the last case quoted in this paper is an illustration and corroborates the opinion, and, other instances coming under the same class can be referred to in detail as proving the fact.

For bacteriological investigations specimens of retained secretions were taken *directly* from the maxillary sinuses of a certain type of cases and it was found that the green bacillus, *B. pyocyaneus*, was present in 65 per cent. of the number. While this indicates nothing conclusive with regard to the rôle played by the pyocyaneus bacillus, yet it suggests further inquiry in this connection.

Will antral therapy prove productive of immunity? In a certain class perhaps immunity can be attained, provided a systematic therapy be applied to the antrum during the intervals between seasons; especially so in cases where degeneration of the mucosa is not advanced or intractable and where anatomical deviations are pronounced and advantageous with reference to the opening of the antrum.

Then again, in instances in which the antral cavity cannot be reached via a nasoantral communication, one would be justified in making an artificial opening with trocar and cannula into the sinus underneath the lower turbinated body for therapeutic purposes. Recently I adopted this method for the treatment of catarrhal maxillary sinusitis in three cases with excellent results following.

Considerable strength is added to the argument by results attained from treatment that in instances of asthma of antral origin, the irritation productive of the bronchial spasm, primarily takes place in the antrum. As has already been referred to in the description of the nervous circle involved in the creation of central nervous instability, reflex and

vasomotor disturbances of the upper air tract, the mucous lining of the maxillary sinus is abundantly supplied by sensitive nerve endings and secretory nervous fibers to render it possible for such a phenomenon to occur and give rise to the asthmatic storm destined to follow.

It is not intended that the above statement should convey the idea that all cases of bronchial asthma organically arise from the antrum, but the opinion is clinically demonstrated that not a few come from this source and that when all other means are exhausted as to cause and treatment the antrum of Highmore should always be interrogated before one's efforts should cease in ascertaining the foundation of the disorder. Within the past month only, and while this contribution was in course of preparation, a man whom I had previously seen in attacks of hay fever asthma, consulted me in reference to an obstinate and disabling attack of asthma from which he was then suffering. I found the nasoantral membranous wall of the left side of the nose badly disintegrated and for the greater part absent, thus forming an opening of unusual size communicating with the sinus. No difficulty was experienced in inserting into the cavity an instrument one-eighth of an inch in diameter. The sinus was washed out and the contents removed, followed by injections of a 25 per cent. solution of silver. Subsequent daily applications of a similar character were made and in a week's time he was well. The antiseptic had the happy effect of reducing the inflammation and checking hypersecretion of the sinus.

In instances in which hypertrophic or polypoid changes of the mucous membrane exist and induce stenosis or intranasal contact, the condition should be remedied as early as possible in order to modify or lessen irritation and vasomotor disturbance of the nasal mucosa, consequent to the action and effects of discharges proceeding from the antrum, due to inflammation and hypersecretion of the cavity.

The same rule applies to deformities of the septum narium. I frequently found that those cases in which intranasal pathological irregularities had previously been properly dealt with, the nasal and reflex symptoms of hay fever yielded more readily and permanently than otherwise to treatment directed exclusively to the antrum of Highmore. From the earliest days of rhinology to the present time the fact has been generally recognized that intranasal contact or obstruction is not infrequently productive of serious interference in some form or another with the function of respiration, and that surgical intervention alone was sufficient to alleviate the difficulty.

It stands to reason, therefore, that to enhance the efficacy of any line of treatment of the disease under consideration all important intranasal abnormalities should be removed.

In conclusion I beg to say that in the presentation of this report I do not wish to overestimate my observations or to appear too enthusiastic; I desire simply to state what my experience has been and to declare that, clinically, the antral theory of hay fever and its allied disorder, asthma, has a basis for existence and recognition.

Deformity in Pott's Disease.—Eikenbary says of this that: Cases seen before the stage of deformity should never be allowed to develop deformity. Deformities in the acute or subacute stage can be reduced one-half or entirely. Children under three years are best treated on the bent gas pipe frame; those over three years by a solid plaster-of-Paris jacket.—*Chicago Medical Recorder.*

A CLINICAL VIEW OF ULCER OF THE STOMACH.*

By FENTON B. TURCK, M.D.,

CHICAGO.

Out of all the tragedy in the life of the busy practitioner, there can hardly be drawn a more pathetic and discouraging picture than that of his relationship to the patient suffering from ulcer of the stomach. The uncertainty of diagnosis, the failure of all his plans for the alleviation of his patient's condition reflect in his countenance and conduct; that pinched, haggard face haunts his path of duty by day and dominates his dreams by night; the patient himself, alternately urgent for relief and overcome with despair, finally turns from the adviser and confidant of many years, seeking other counsel; while the sufferer's family, full of anxiety long sustained, demand help for the afflicted one, and alas! how often there has been no help.

But it seems to me the veil that has hitherto clouded this most distressing and perplexing malady is slowly but surely vanishing, and that at last we have a fair working basis upon which to build a solid and safe structure of etiology, diagnosis, and successful treatment. It is not my purpose in this brief address to survey the scientific field of gastric ulcer, but to bring, if I may, a message of light and hope from the laboratory, the microscope, and the clinic, to that pioneer in the realm of medicine—the man at the bedside.

Etiology.—For hundreds of years scientific men have busied themselves with the question why the stomach did not digest itself, even when in a physiological condition. Stahl, more than two hundred years ago, decided at the end of a long study of the subject, that the protection of all living bodies from self-destruction in the various life processes, was due to "the sensitive soul," and reasoned that "in any case the fermentation which takes place in the alimentary canal is not an ordinary fermentation, such as occurs in a merely compound, nonliving body, but a most special character is impressed on the change by the energy of the soul."

John Hunter, in a most learned dissertation on "The Digestion of the Stomach After Death," in 1772, expressed this same idea of the self-protection of all living bodies, but instead of "the sensitive soul," he called the medium the "vital power."

So we see that for centuries investigators have been diligently seeking, with the crude light their day afforded, an answer to the same question we are asking ourselves to-day, and the answer to which will be a clear light upon the etiology of gastrointestinal ulcer and a number of kindred diseases.

Dating from these investigators of old, two ideas seem to have had their birth, the one expressed by Stahl and Hunter, that ulcer was due to some general or constitutional condition, and the other that it was merely a local affair, to be treated locally. Virchow expressed this second view in his hypothesis that ulcer of the stomach was due to some local vascular obstruction or aneurysmal dilatation of vessels, and Cohnheim, Silberman and others followed in the footsteps of the great pathologist by attempting to cause gastric ulcer by such local disturbances as the injection of laked blood or some chemical, or by the infliction of some direct mechanical injury to the gastric mucous membrane. All these attempts were only negatively successful, how-

*Read at the annual meeting of the North Texas Medical Association, at Dallas, December 11, 1906.

ever, since in nearly all the cases such ulcers healed quite as promptly as would have similar injuries inflicted on any other part of the body.

In an earlier series of exhaustive experiments of my own, long ago reported as having negative results, I gave to dogs increasing doses of mustard oil, every two or three days, covering a period of from nine to fourteen months. At the end of nine months dog No. 1 died, and two months later dog No. 2 died, but there was no ulcer in the stomach or intestines of either. At the end of fourteen months dog No. 3 was chloroformed, but while there was dilatation of the stomach and chronic gastritis, no ulcer was found in either stomach or intestines.

I then made a series of experiments on the hypothesis that ulcer was due to systemic changes or constitutional conditions, and in this series I confined dogs and guinea pigs to exceedingly close quarters for periods running to nine months, giving them little air, no light, no exercise, but an abundance of food. All possible precautions were taken in these experiments, by a comprehensive system of sterilization, to prevent infection. I will not go into these experiments further than to say that in a few cases typical ulcer was formed, but in so small a number of instances that the results were reported as wholly negative, since I had not been able to direct the results and had achieved my purpose apparently by chance.

My last experiments, finally reported in a paper read before the International Medical Congress at Lisbon last spring, were likewise based upon the hypothesis that ulcer of the stomach and intestines was due to general and not alone to local conditions.

These experiments were begun with the common colon bacillus, because this is the organism found normally in large numbers in the intestines, and that which multiplies luxuriantly in catarrhal conditions of the stomach. Cultures of the bacilli were used, made up in bouillon of meat extractives, first by injection directly into the circulation, but later on they were fed to the animals with their ordinary meat diet. In some cases the meat extractives were increased until the total of the extractives fed amounted to twice the amount in the untreated meat they ate. The bacilli used for the cultures were taken from the feces of patients with ulcer of the stomach.

During the experiments observations were made of the blood changes, such as the agglutinating, hemolytic, and coagulating power, the bacteria in the blood and stomach, the systemic disturbances, the evidences of infection, and the symptoms of ulcer such as pain, hemorrhage, etc. The serum agglutinated colon bacilli in high dilution, the normal protective influences were reduced, the opsonic index was below the normal, the coagulating time of the blood was slower; but at no time were colon bacilli found in the blood, nor were the systemic disturbances great. I have covered the field of these experiments so fully in my former paper, which is reported in the proceedings of the International Congress, also in the *Journal of the American Medical Association* for June 7, 1906, that it will suffice here to say that every animal employed in the experiments developed a typical ulcer of the stomach, without round cell infiltration, and without the capacity to heal in the way of those ulcers formerly induced artificially by Cohnheim, Silberman, and their colaborers.

Not long since, in a paper read before the pathological section of the British Medical Association at the Toronto meeting, and published in the *British Medical Journal* for April 20, 1907, I followed another feature of these experiments, and showed that where the feeding of the bacilli was stopped before perforation or hemorrhage had occurred, and a month or six weeks were allowed to elapse during which the dogs were placed under treatment for ulcer, post-mortem examination revealed ulcers in various stages of healing, thus showing the direct relationship between the feeding and the formation of the ulcer, showing also that when the ulcer-producing conditions were removed at a sufficiently early stage of the disease, and the general conditions were improved, the ulcer healed. This point may be remarked as a lesson in prognosis as well as in treatment.

Diagnosis.—It is never easy, and often impossible, to detect the presence of a gastric or duodenal ulcer in the early stages, and even later on, when the disease has become typical in its manifestations, a clear differential diagnosis as against carcinoma in the early stages, gallstone diseases, gastric atony and displacement of one or all of the abdominal organs, often hinges upon so small a detail that it will baffle all but the keenest and most experienced observer. The acidity or otherwise of the stomach contents is by no means a safe guide, though hyperchlorhydria is a dominant characteristic; there may or may not occasionally be found a blood reaction in the feces, indicating some new break-down in the ulcer surface; usually there is pain, which in the later stages is focused upon some well-defined area, but this pain is by no means invariably present, nor when present is it always greatest after eating, though this is oftenest the case; this circumscribed pain is often associated with pain penetrating through to the back.

But these signs, or any of them, must be taken in conjunction with the patient's general condition; almost invariably sufferers from gastric or duodenal ulcer are of a low order of nutrition, and though sometimes fat and apparently well nourished, the experienced observer will detect the fact that this outward appearance is deceptive, and due largely to faulty metabolism. Sometimes there is puffiness over the epigastric region, "gases on the stomach," the patient will tell you, but this is not always the case, and while there is faulty digestion, and a retention of food beyond the physiological period, in many of the cases, this is not always so, and can only be regarded in conjunction with a vast number of other symptoms.

Indeed, it may sometimes happen that the physician is reduced to the humiliating necessity of carefully and laboriously excluding every other possible disease, before he can arrive at a satisfactory diagnosis of peptic ulcer. This question of the blood changes is highly significant in the diagnosis, especially the serum reaction. Its subnormal opsonic index to the intestinal flora, the lessened agglutinating power, the indications of undernutrition—all have a distinct bearing on the diagnosis of ulcer.

Prognosis.—Naturally it will be one of the first offices of the physician, immediately after he has concluded his examination of the patient, to inform him or his family of the chances of recovery. The literature on this point has not been reassuring; a close study of this literature, however, discloses the fact that nearly all the premises contemplate a diagnosis at a late stage, oftentimes after hemorrhage has occurred, or even after the ulcer has perforated into the peritoneal cavity or into some other part

of the intestinal tract. Of course the prognosis at this stage is grave and the mortality high. But as we come to understand better the distinctions of diagnosis at a far earlier period, learn more and more of the underlying factors concerned in the condition, we must of necessity achieve better results. I will not burden you with recitations of the experiences of special obserevrs in this field, and will only pause to assure you that the unfavorable outlook of even the most recent years is not a criterion of what we have a right to expect of the present, nor a fair comparison of what the near future holds for us in the way of a promise to these sufferers.

For my own part, when I have arrived at a safe position in the diagnosis of my case, at a stage before marked hemorrhage has occurred, and where the general conditions aside from the local manifestation have not reached a grave state of themselves, endangering the patient's life, independent of the ulcer, I am prone to draw upon the records of my more recent cases for a favorable promise. Especially is this true of younger persons who may naturally be expected to respond more readily to measures for the improvement of nutrition and metabolism—in which the splanchnic circulation can be quickened under some of the methods we shall have occasion to discuss in consideration of treatment.

And, too, I think that as we come to understand ulcer and its causes better, the range of non-operative treatment grows constantly broader, and hence the hazards of surgical interference have less frequently to be taken.

From the cases of the dogs in the last experiments, where the ulcer inducing diet of colon bacilli was stopped after certain periods of time, and treatment for ulcer was instituted, and where post mortem revealed ulcers in various stages of healing, much is to be learned of importance in the prognosis of the disease in the human family, especially from the standpoint of general systemic conditions.

One of the most important considerations in the prognosis of gastric or duodenal ulcer and one that is likely to bring us many grave misgivings is the tendency of the disease to merge into malignancy. Ulcer offers a most suitable nidus for the development of cancer. Whether there is even the remotest relationship between the two diseases, we do not yet know; but the fact of the one supervening upon the other appears the more evident in the light of recent observations of serum changes occurring in cancer showing the general character of the diseased condition, which permits its development on the site of such an injury as ulcer of the stomach. So that, in determining, even in our own minds, the results we are likely to achieve in any case, we must assume not only the facts of the disease as it exists at the time, but must take into consideration the general condition of the patient as pointing toward or away from a malignant sequel.

Treatment.—Assuming, now, that we have a clearly defined case of ulcer to deal with, what are the indications for treatment? Primarily, of course, if we are correct in our judgment that the lesion is a general and not a wholly local one, and that it is induced by alterations in the pabulum of the intestinal flora, thus lowering the resistance of a gastric or duodenal mucous membrane rendered peculiarly vulnerable by malnutrition, defective metabolism, visceral atony and a long train of predisposing elements, we must address our efforts toward the improvement of these constitutional conditions, and perhaps the steps of treatment may be divided into three, namely (1) proper nutrition for the whole body; (2) the reestablishment of functional activity or tone in the diseased organ, so that its power of resistance may be increased; (3) the employment of measures to inhibit the multiplication and change the character of the offending intestinal flora.

Nearly all these requirements point in the direction of a proper diet. It is good practice to relieve the patient's immediate pain and distress from the sense of bloating, especially after meals, that most of them suffer, by withholding all food until hunger becomes a pressing matter, then give those foods best calculated to furnish the greatest amount of nutrition compatible with the greatest amount of rest to the stomach, and these foods will be given at long intervals at first, say once a day, gradually increased to twice, and then oftener, as the stomach reassumes its normal functional activity. Foremost in the diet I employ is meat freed of its extractives by a process of maceration and boiling, in which the meat is allowed to stand for some hours in cold water, and is then boiled thoroughly. The extractives are now pressed out and discarded; the absence of the extractives of the meat deprives the harmful intestinal bacteria of the necessary media for development, and hence the toxins which they produce are reduced to a minimum; the maceration and boiling have also the effect of hydrolyzing connective tissue into gelatin, thus rendering it more easily digestible in its fine state, and there is less excitement to the production of hydrochloric acid in harmful amounts. Meat treated in this way passes out of the stomach before milk or any other food, thus obtaining the ideal condition of the greatest amount of rest to the stomach with the maximum amount of nutrition. Not only is this meat more easily digested and more completely assimilated, but in actual food value it contains 55 per cent. of proteid as against 20 per cent. in the ordinary meat that is scraped and fed partly cooked. Milk in various forms is employed as a most excellent liquid diet, whey, either alone or with the myosin of this meat product; also whole milk after it has been coagulated with rennett; milk administered in a fresh state is apt to clot in the stomach when acted upon by the gastric juice, and hence likely to act as an irritant. Koumyss may be employed in the same way. The lactic acid in milk fermentation seems to have a powerful inhibitory action on the intestinal bacteria, and at the same time it seems to be peculiarly free from the irritating effect on the mucous membrane such as we attribute to hydrochloric acid.

Mineral waters have a two-fold action in these cases; they are in a measure contraindicated because they excite the formation of hydrochloric acid, but oftentimes their utility more than compensates for this contraindication, because they serve to flush out the gastrointestinal tract, and thereby help to prevent the formation and absorption of toxins. The gases of carbonated waters are extremely useful in assisting gentle peristalsis and in helping to force the food out of the stomach and thus obtain rest for that organ. But the use of any water, whether mineral or otherwise, only serves to aggravate the atony of the stomach because of its dead weight under pressure, which has the effect of discouraging peristalsis.

Other foods than those outlined will occur to the practitioner that will furnish a large amount of nutrition at the least possible expense in the way of irritation, such as rice, cornstarch, fresh eggs, the more easily digested vegetables such as potatoes in

the form of puree, combined with meat prepared as suggested, the leguminous grains such as peas, beans, etc., but always with their hulls removed, to prevent irritation, and placed in the autoclave under steam pressure of one and one-half atmospheres. It is the purpose in all these foods to so prepare them that hydrolysis or partial predigestion is accomplished, again obtaining necessary rest for the stomach.

While the excitation of peristalsis is a prime consideration, to aid in the restoration of the tone of the gastrointestinal musculature the means employed to bring about this physiological activity must be carefully chosen, especially as applied to the site of the injury—that is, the stomach. We cannot know the depth of the ulcer or the extent of the destruction of the gastric wall, so the introduction of a tube must therefore be carefully undertaken, if at all, and instead of the rhythmic air pressure gymnastics that we would like to employ we must content ourselves with the more indirect administration of bicarbonate of soda in water, which, acted upon the hydrochloric acid of the stomach, sets free carbonic acid gas for purposes of mechanical but gentle distention when resident hydrochloric is absent, citric acid in the form of lemon juice may be added, which also adds to the palatability of the drink. We employ this distention because, as I have shown in other work, the only means we have of exciting contraction in the stomach muscle is stretching; it will respond to no other form of irritation. Similar excitation of gastrointestinal peristalsis in these cases of ulcer is more efficacious when applied through the colon, because irritation through the reservoir at either end of the alimentary canal has the effect of influencing action along the whole tract. To this end we employ alternate hot and cold water lavage of the colon, introducing a single or double tube as high as the sigmoid and injections either by reservoir or pump, small amounts of water, allowing each douche to flow away before another is used. The hot water is used at 50° C. (122° F.), and the cold at a little above the freezing point. Only small amounts of either are injected at a time. If desirable some antiseptic may be used toward the last of the douching, for its bactericidal effect on the intestinal flora. In consonance with this colonic lavage I am accustomed to stimulate rhythmic contraction and distention along the alimentary tract by the introduction of air passed through some disinfecting fluid, as high up as the transverse colon. This air pressure, sustained only momentarily and released, then repeated, speedily brings a responsive peristalsis higher up and the procedure is usually followed by an emptying of the whole lower intestine. This exercise is also of great utility in arousing the splanchnic circulation, thus clearing the whole area of a sluggish blood supply and increasing the metabolism of the injured organ.

The "rest cure" or confinement to bed is often helpful in these ulcer cases, and sometimes may be a necessity. The patient is ordered to bed; he may see friends, read light literature, and enjoy light conversation. He must not transact business or exert himself in any way, mentally or physically. This rest may be continued until all the most pressing symptoms of pain, anorexia, and flatulence are removed. The duration of this period of rest may extend from two weeks to six weeks, according to the condition.

A METHOD OF REDUCING OLD COLLES' FRACTURES: STIFFNESS FOLLOWING APPARENT CONTUSIONS OF THE ELBOW.

By CLARENCE A. McWILLIAMS, M.D.,

NEW YORK.

INSTRUCTOR ON SURGERY, COLUMBIA UNIVERSITY, ASSISTANT SURGEON TO THE PRESBYTERIAN HOSPITAL, SURGEON TO TRINITY HOSPITAL.

One occasionally meets a patient who complains of what is called a sprain of the wrist of some weeks' duration. Usually there is a history of a fall upon the hand three or four weeks prior to seeking advice. Often at that time no medical opinion has been sought, or, if so, many times the erroneous diagnosis of a simple sprain of the wrist is made. The swelling and disability of the wrist, not improving at the end of a month, cause the patient to seek expert advice. A tentative diagnosis of an old unreduced Colles' fracture is made and this is confirmed by an *x*-ray plate. Such a condition is shown in the accompanying illustration (Fig. 1) of one month's standing.

Fig. 1.—Old unreduced Colles' fracture showing the transverse fracture at A, with dislocation backward of the hand carrying carpus with it. Note styloid processes of radius and ulna on the same level.

The fracture is then left to heal consolidated and the question comes up at once whether anything can be done to improve the position of the fragments. Even with considerable deformity, in some cases the disability may be so slight as to indicate that good judgment would be shown in advising that nothing be done to improve the deformity, since in an attempt to correct this the disability might be increased. In other cases the disability and deformity are both marked, so that an attempt to overcome these by refracture is strongly to be advised, providing that this can be done without too great damage to surrounding structures. By using the hands alone it is almost impossible to produce a refracture in the same line as the old fracture, for it is difficult to obtain sufficient purchase with the hands alone on the small lower fragment to accomplish this. In this method the wrist structures are also severely strained, which is a great disad-

vantage. A procedure which has given me uniform satisfaction is the following. I do not claim any originality for it since I learned it from my chief, Dr. Ellsworth Eliot, Jr. My only reason for publishing it is that I have not seen it in print.

FIG. 2.—Method of refracturing an old Colles' fracture by means of a large monkey wrench.

The method is as follows: A large engineer's monkey wrench is procured and the blades are well padded. (Fig. 2.) The patient is anesthetized and the blades so placed on the wrist that they are entirely proximally situated to the fracture line, the edge of the dorsal blade resting against the posteriorly projecting upper edge of the lower fragment. The blades are then screwed together, so as to fairly tightly embrace the tissues. With the expenditure of very little force, a refracture through the old fracture line may readily be produced by twisting the wrench so as to flex the lower fragment on the upper. There is no strain whatsoever brought upon the structures of the wrist itself, which consequently remains uninjured. The damage to the tendons by the blades of the wrench is trifling and is soon recovered from. The after treatment is similar to that which obtains in cases of fresh Colles' fractures. Anterior and posterior wooden splints are used, which do not extend further than to the metacarpophalangeal joints, affording free play for the fingers. Three weeks is usually ample time to maintain immobilization in the splints. This method in almost all cases will do away with the necessity for any cutting operation.

Traumata to joints in general are most puzzling from a diagnostic standpoint, and in no joint is this more true than in the elbow, where the structures which make up the mechanism are so numerous and complicated. X-ray photographs are here invaluable and their systematic use even in slight injuries to the elbow is to be emphasized. By their employment I have lately explained a phenomenon which has several times before puzzled me. A typical case exhibiting this condition is as follows: A patient who has suffered a trauma to the elbow applies for treatment immediately after the injury. Careful palpation and even an *x*-ray photograph reveal no fracture of any of the bony structures in or about the joint. Treatment appropriate to a contusion or sprain is instituted. Then, to one's surprise and chagrin, about the third or fourth week after the accident, the elbow begins to show considerable restriction in the motions of flexion and extension. An *x*-ray photograph at this stage reveals a fragment of bone in the joint which did not appear in the previous picture taken immediately after the injury. The explanation of this seems clear that at the time of the accident a piece of the periosteum without any attached bone has been torn free from some of the bony structures of the joint. This periosteum does not appear distinctly in an *x*-ray picture. It, however, in the course of time proceeds to produce a fragment of new bone, which may lie between the bony articular structures, causing the gradually increasing restriction of motion. Usually by forced, persistent, passive motions, the new bony fragment may be crowded away from between the joint surfaces and good joint functions obtained. This would, however, be the final result only in cases where the patients were seen at a period of time after the injury before the new fragment was thoroughly ossified, while it was still malleable. In old standing cases it might be necessary to remove the fragment by open operation. The following picture shows an *x*-ray photograph of the elbow of a boy of ten who had fallen upon it a few hours before the picture was taken. There is no definite bony lesion to be made out distinctly. On looking at the plate (Fig. 3) carefully, one sees just below the external condyle at *A* a faint shadow which, in the light of the later picture, was probably a piece of periosteum torn off the condyle. This

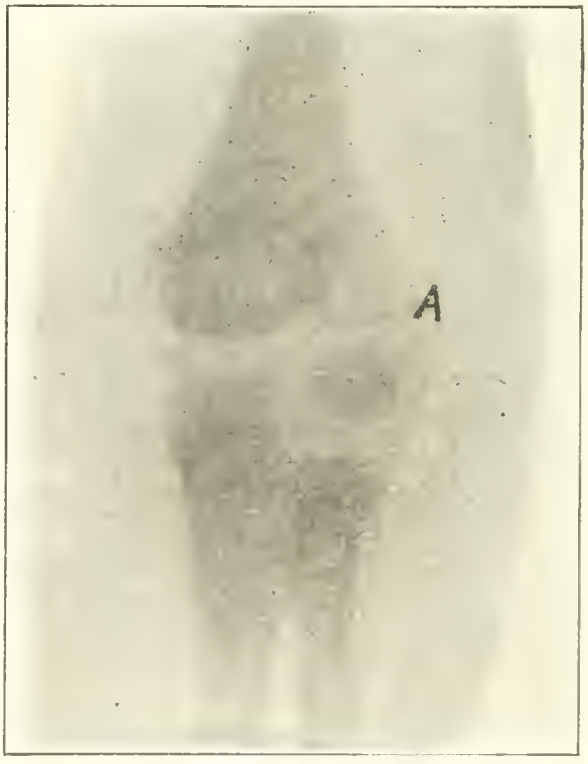

FIG. 3.

latter seemed normal, its outlines being perfectly regular and showing no defect. The boy was treated for a contusion of the elbow and did not return after a week's time.

Four weeks later the boy presented himself again, complaining of considerable restriction of flexion

and extension of the elbow. Fig. 4 represents what had occurred to cause the limitation of motions, namely, a proliferation of new bone beneath the ex-

Fig. 4

ternal condyle at *A*, due evidently to a piece of periosteum torn off at the time of the injury. Daily passive bending of the elbow soon restored almost normal mobility to the joint.

A STUDY OF BLOOD PRESSURE IN COMPRESSED AIR WORKERS.*

By HARLOW BROOKS, M.D.,

NEW YORK,

VISITING PHYSICIAN TO THE CITY HOSPITAL.

During the middle of the eighteenth century compressed air was very extensively employed, especially in Germany for the treatment of disease, and the literature of that day is replete with reports as to the wonderful results achieved by this method. The Germans employed compressed air in the treatment of practically every known disorder of the body and institutes or sanatoria devoted to this one method were scattered throughout the entire land. The idea was really first suggested by Henshaw, an Englishman, in 1664. A very considerable impetus to work both with artificially compressed and rarefied atmospheres was contributed by the Dutch school in the seventeenth century, but the therapeutic employment of compressed air had been largely discarded by the English and Dutch investigators before its rediscovery and widespread application in Germany. The result of all this work has been that compressed air is now but little employed as a remedial measure except in a few conditions in which it really appears to be an efficient agent.

Very little of value is found in the older writings concerning the actual effect of compressed air on the blood pressure, though it was assumed to act chiefly through its influence on the vascular functions. Most of the observations then recorded were based chiefly on guesses or on prejudiced clinical observation and not on accurate scientific determinations.

The importance of the study of compressed air to us to-day is mostly on account of its relationship to certain occupation diseases rather than as a remedial measure, for we have among us an already large and increasing class of workmen who live a considerable period of their working life in compressed air and the numerous recent experiments in aeronautics renders this also a possible future field for studies of the reaction of the human organism to marked and sudden variations in atmospheric pressure. The demands of modern engineering now so frequently require high air pressures that it becomes particularly necessary for us to record all observed data in regard to the effects of engineering pressures on the human organism.

Caisson disease is no longer misunderstood, at least by those physicians who are in frequent contact with cases of this complaint, for its cause and most efficient manner of prevention have been fully demonstrated, hence these observations are not directed with especial attention to this condition, but are an attempt to clear up certain points in regard to the behavior of the circulation under these abnormal but very necessary conditions. It is hoped that my results may be of some value in the selection or exclusion of candidates for work in compressed air and also that these experiments may throw a new and important, though largely negative side light on the ever interesting and pregnant question of the physiology of blood pressure and the manner in which it readjusts itself under rapidly variable external conditions. The matter is also of considerable general clinical interest since it applies very materially to the question of selection of the proper altitude for various classes of patients suffering from cardiovascular diseases. The recent communications of Zuntz and Loewe and of Müller and Caspari, ably summarized by Sewell of Denver, render all matters bearing on this subject of vital interest to every physician, and although the studies just cited are exclusively directed to blood pressure at high altitudes, they apply with almost equal force to conditions in which the pressure is augmented instead of decreased.

It has been currently believed, I feel warranted in stating, that the blood pressure is greatly increased under compressed air and most accounts describe the superficial vessels as compressed, contracted, and anemic with corresponding engorgement of the large trunks of the internal viscera. Most physicians in charge of the medical end of these engineering operations are of this opinion and most of the literature pertaining to the subject also leads to the same conclusions, in which I at first entirely coincided from my own personal experience and observation. Nevertheless it seemed to me worth while to make a systematic study of this question and the opportunity has been lately offered to me through the courtesy of Dr. McCort of the Belmont tunnel. With the assistance of Mr. Turnbull, his assistant, the following series of seventy-five cases has been compiled.

Of the seventy-five men on whom observations were made, all but two had been working in compressed air over one month and may therefore be considered as habituated compressed air workers. Forty-four had worked in compressed air less than one year, twenty-three over one year and less than

*Read at a meeting of the New York Academy of Medicine, April 16, 1907.

five, six over five and less than ten. Two men, both engineers, had worked almost continually with compressed air, one for twelve and one-half and the other for twenty-two years. No substantial difference in results was found in any of these various groups, hence it seems fair to assume that the statistics collected from the entire group is fairly characteristic for healthy men, for all these men had been subjected to physical examination and all were in the prime of working life, that is from twenty to forty-five years of age. Forty-three of them admitted using both tobacco and alcohol habitually, some of them to great excess, but without apparent effect on the point in question. Four used alcohol and four tobacco alone and the rest claimed freedom from both habits.

The instrument used for our determination was the familiar Janeway sphygmomanometer, the 13-cm. armlet being employed in every case. The pressure was taken from the right brachial artery with the armlet placed just above the bend of the elbow. Two consecutive estimations of the systolic pressure were made in each case and the results were averaged. The diastolic pressure was taken but once, and when it could not be satisfactorily obtained the case was thrown out of the series considered. The pressure in each instance was first taken just before entering the air, before which, at least theoretically, the subject is supposed to have been resting for not less than three hours. The determination in the compressed air chamber was taken after from one to two and one-half hours' work at a tube pressure which averaged about thirty-one pounds above atmospheric. The general lighting and hygienic conditions of the tunnel throughout were excellent and the physical work never excessive. The measurements taken after decompression were secured after the men had been returned to normal atmospheric pressure for from ten to fifteen minutes. Only one of the subjects was suffering from too rapid decompression, that is from caisson disease.

The average systolic pressure of the seventy-five men, taken before entrance to the air, was 116.19 mm. Hg. The average diastolic pressure taken at the same time was 91.08 mm. Hg. The average systolic pressure taken in the air was 128.88 mm. Hg. and the average diastolic pressure taken at this time was 87.68 mm. Hg. The average systolic pressure taken soon after decompression was 112.76 mm. Hg., and the average diastolic, 90.78 mm. Hg.

It then appears that the difference in systolic pressure of the resting man outside the compressed air and after an hour or more work in thirty-one pounds plus is but 12.69 mm. Hg., no more difference than would certainly be expected between a resting man and a man immediately after heavy exercise at ordinary atmospheric pressures. The difference in the diastolic pressure was but 3.4 mm. Hg., but in this case the diastolic pressure was decreased 3.4 mm. while the systolic pressure was raised 12.69 mm., so that the difference between systolic and diastolic pressure outside the air was 25.11 mm. while this same space under compression was 41.2 mm., again practically the same conditions found under ordinary atmospheric pressure after active exercise.

After decompression, which terminated a three-hour shift in the air, the difference between systolic and diastolic was 11.08 mm., or a loss in cardiac energy or vascular tone as compared with the resting condition of 13.13 mm. The difference between the diastolic after decompression as compared with that under the pressure showed the pressure under the air to be exactly 13.1 mm. lower.

The significance of these figures appears to me to be very simply and yet accurately expressed in the sentence that in so far as these experiments go, the changes in blood pressure after labor under a pressure of thirty-one pounds plus are practically the same as under usual atmospheric pressure and that about the relative space exists between systolic and diastolic in both conditions, again practically like those in the normal atmosphere.

It is entirely to be expected that after three hours' labor in the air the decompression systolic pressure should be decreased, but as only 3.43 mm. Hg. difference exists it is strongly confirmatory of the statement of the average workman that labor under the air is more easily accomplished than at ordinary pressures and this small loss is negative as regards the contention of Jaminet that excessive waste of the body energy takes place under these conditions, due, Jaminet asserted, to the too rapid oxidation of the tissues which he assumed, entirely on theoretical grounds, to take place. I must, however, admit that this slight fall may be otherwise explained according to the determinations of Zuntz who found a corresponding fall taking place in the rapid change to higher altitudes.

Several points bearing on the question of compressed air labor arise in connection with these determinations. One of the most important of these is the disproval of the theory that many of the deleterious effects on the circulatory apparatus of compressed air workers follows as a result of the high external pressure on the superficial vessels, Were this the case as asserted by many, notably by Smith and Bouchard, a marked rise in blood pressure must inevitably take place, due to peripheral compression, and on the contrary a lack of such rise indicates that the intracorporeal air or gaseous pressure is proportionately increased until finally balanced in compressed atmospheres, a fact which has also been abundantly proven by numerous experimental studies as well as indicated by the post-mortem findings in caisson disease, though still denied by some theoretical workers.

From these experiments and from other researches conducted on animals by myself I believe that very slight disturbance of the vascular distribution takes place under moderate decrease or increase of atmospheric pressure, when slowly accomplished, a point also corroborated by the conclusions of Zuntz who believes that variations in anterial and capillary capacity are altered more due to deficient or overly abundant oxygenation in rarified or compressed atmospheres. Brief observation of the respiratory activities in compressed air workers convinces me that this statement is thoroughly sound. If this fact is true we must completely reorient many of the ideas now commonly accepted which forbid patients afflicted with cardiovascular disease from living at high altitudes on the one hand, or at sea level on the other.

I hesitate somewhat in a further, but not unnatural deduction, and that is that moderate degrees of renal or circulatory disease should not necessarily exclude workers from labor under moderate compressed air pressure. I certainly think that this is indicated by these observations, and furthermore I know that this fact is well recognized by engineers and workmen, for a very large percentage of caisson workers are highly alcoholic and therefore nephritic, when you can get them to admit the

truth, which they will rarely do in this respect, since they fear disqualification.

The exhaustion expatiated on by some observers after labor in the caisson is negatived in so far as the circulatory functions are concerned, by the relatively slight loss in cardiac energy after return to normal pressures.

Finally, it appears demonstrated that the blood pressure is not abnormally raised under compressed air, and these few observations but confirm the now well established theory of gaseous liberation in the causation of caisson disease, and I hope put at rest forever the theory of vascular hypertension and unbalancement as etiological factors in the causation of this condition.

POPULAR EDUCATION IN MATTERS MEDICAL.

A PLEA FOR A MORE THOROUGH AND WIDESPREAD DIFFUSION OF KNOWLEDGE IN HYGIENE AND THE PREVENTION OF DISEASE.

By H. W. WRIGHT, M.D.,

ASTORIA, NEW YORK.

The present ignorance of the average citizen in regard to the care of his health and that of his children is a distressing sight to anyone who cares for the preventive side of medical work. We see the effects of such ignorance and carelessness in every community and among all classes of society. But it is especially among the poor that preventable misery is so widespread, from whom its results are so much further reaching than we realize.

It is not that the old-time superstitions regarding disease and in respect to remedies have any considerable influence to-day; but it is the indifference to the importance of simple cleanliness in the person, the food, and the home, the importance of normal, regular habits of living, of hydrotherapy and ventilation that is keeping up the foci of epidemics and the existence of all manner of digestive and respiratory disorders. I do not think it an exaggeration to say that a very large majority of our young people are growing up in total ignorance of and indifference to their own physiology and the simple rules of hygiene. When these marry they know even less about the care of their children. They may have "studied physiology" in the public schools, they may have even passed an examination in the subject, and so have been promoted to a grade where it is thought unnecessary to teach it; but the results of such study are not apparent, except that they are conspicuous by their absence. Consequently when these children become older they and theirs are an easy prey to the patent medicine or any other form of quackery, and charlatanism (including "Christian Science") that comes along.

Another disastrous result of such ignorance is the widespread perversion of the sexual functions and the spread of venereal diseases, with all their attendant miseries. The young are not taught at home regarding these matters because in many cases the parents don't know themselves, and in other cases because the subject is thought too "indecent" for consideration.

We see the results of this indifference to personal health more especially in large cities and crowded communities; among such the circumstances of life render people more susceptible. But I am willing to venture the belief that if popular education in hygiene were as thoroughly conducted as it ought and could be, the percentage of cases of all the infectious diseases, of chronic respiratory disorders, of chronic digestive disorders, and of venereal diseases would be reduced more than one-half in the next generation after such teaching had been so propagated. Such knowledge should be available by all, even the poorest. It is a mistake to expect dirt and disease to be inevitable and necessary accompaniments of poverty. They are rather accompaniments of ignorance, indifference, and loss of self-respect. Why are people's persons and homes dirty? Because they do not realize the necessity of keeping them clean. Why is their food badly cooked and unwisely chosen? Because they know no better. It isn't because it costs any more to do otherwise. Why are houses built in unsanitary places and badly ventilated, and poorly equipped with plumbing? It is in most instances because the builders do not *know* enough about the dangers of such conditions to *care*. Indifference goes with ignorance; as knowledge increases indifference diminishes. The same may be said of factories, unhealthy methods of manufacture, of child labor and long hours for women and children in unhealthy workshops. Most of the evils of these establishments are due to thoughtlessness, *i.e.* ignorance.

What then should the public be taught, and how should it be taught them? In the first place, they should be taught the physiology of digestion, respiration, and procreation, the nutritional values of various foods and how to prepare them, the science of ventilation, the danger of bad air and the safety of fresh air, in order to dispel the popular fear of the latter; the value of hydrotherapy; the physiology of infant life and nutrition; the sources of bacteria and how to prevent the introduction and spread of infectious diseases.

These, in a general way, are some of the subjects for popular education. How should these subjects be taught? The most available place for the instruction of the young is the school. Here there should be competent instructors and directors of physical culture and athletics who would also be teachers of physiology and hygiene, and preferably physicians. The present method of teaching physiology in the public and private schools is little short of an absurdity, so little time and care are given to it in proportion to its importance. Furthermore, such teaching is usually done by some one who needs the instruction quite as much as the pupils. In addition to the school instruction there should be public lectures and demonstrations for children and adults, with special courses for the latter in matters pertaining to procreation and the care of children. The public lecture on medical subjects of the present day is usually confined to a few vague remarks on the "Circulation of the Blood." A recent notable departure, however, should be greatly commended, namely the public stereopticon lectures on tuberculosis given by the New York City Health Board. The fact that these were received with indifference mixed with ridicule (according to the newspapers) is a strong argument in favor of their continuance and extension. The recent exhibits on the same subject are also steps in the right direction.

Another way of spreading such knowledge would be by more complete medical inspection in the homes of the poor and by the help of district nurses who, after such inspection by a physician, would be sent to correct unhealthy conditions of living by practical instruction and help. Literature upon these matters could be circulated freely in the form of a

monthly or weekly paper issued by the health board of the community.

In order to carry out such a system of popular education there would be necessary greater authority in the hands of the boards of health and education. Such authority could be obtained by proper legislation, just as the authority in matters of health has been acquired heretofore. Sickness is unquestionably an economic loss to everyone, directly and indirectly; and it is everyone's duty, from both a selfish and altruistic point of view, to do all that he can to prevent it.

INACCURACY OF DARE'S HEMOALKALINOMETER.

By FRANK P. VALE, M.D.,

WASHINGTON, D.C.

As some authorities had attempted to show a relation between the alkalinity of the blood and the activity of the organic exchanges between the blood and the tissues, I thought there might be alterations of the alkalinity of the blood of interest in shock and collapse. A little over two years ago, with the desire of following up this idea, I looked over the literature on the alkalinity of the blood, for the purpose of adopting the most satisfactory technique. In this way I became acquainted with the method of Dare (*Johns Hopkins Hospital Bulletin,* Vol. XIV., No. 148, 1903), and undertook its use with considerable enthusiasm on account of its ready applicability.

To compare the point of the disappearance of the oxyhemaglobin bands with the alkalinity as ascertained with litmus as an indicator, I was advised by my friend, Dr. E. R. Hodge, a practical chemist, to employ $\frac{N}{200}$ H_2So_4, instead of a like strength of tartaric acid. As a preliminary to a further use of the method, I examined forty patients suffering from various conditions, in many of which one might expect to find changes in the alkalinity of the blood, and obtained, in addition in each case, the hemaglobin percentage and number of red blood cells, so that the color index might enter into the data, as suggested by Dare.

The results were very constant; 1 c.c. of the sulphuric acid solution caused the disappearance of the absorption bands in three to five minutes; an additional 0.1 c.c. or 0.2 c. c. caused their disappearance in one-half minute. According to the instrument's scale, this meant an alkalinity of 133 mg. of NaOH per 100 g. of blood. Then I found with litmus as an indicator there was required but 0.4 c.c. to 0.6 c.c. to neutralize the same amount of blood—.018 g. With a standardized $\frac{N}{200}$ tartaric acid solution, prepared by Dr. Hodge, there was a still further discrepancy, as 4.5 c.c. was required to cause the disappearance of the absorption bands. (A tartaric acid solution, made according to Dare's formula, and *not standardized*, required 2.2 c.c.) A $\frac{N}{200}$ oxalic acid solution gave still a different result—3.9 c.c. A specimen of blood in which 1.1 c.c. of the sulphuric acid solution caused the immediate disappearance of the oxyhemaglobin absorption bands, 0.5 c.c. caused their disappearance by the end of twenty-four hours.

Dare found that 2 c.c. of $\frac{N}{200}$ tartaric acid solution was required to neutralize .015 g. of blood. (The pipette supplied with my instrument held .018 g.) Two cubic centimeters of any half centinormal acid solution is the equivalent of .0004 g. NaOH. To express the alkalinity of the blood in milligrams in terms of NaOH per 100 g. of blood the equation becomes: $\frac{1.0\%}{.015}$ multiplied by .0004, which is 2666. mg., and not 266. mg., as given by Dare.

As 2666. mg. of NaOH per 100 g. of blood is about four times as great as that given by any investigator, and as the alkalinity varied with the acid employed, I discontinued the use of the "hemoalkalinometer," concluding that others had found these inaccuracies, and that the method was being condemned by insufficient praise, for I noticed no further journal articles concerning it.

The method has, however, been noted in several text-books, some of them foreign, *e.g.* H. Labbé, Analyse Chemique du Sang. An authoritative monograph on Clinical Diagnosis just from the press (Chas. P. Emmerson, Johns Hopkins, 1906), describes the method as very ingenious and expresses the anticipation that some practical results may be obtained from its use.

I should not have related my experience, which was carried no further than a demonstration of the inaccuracy of the method to my own satisfaction, were it not for having read within a few days an article which appeared a year ago in the *Journal of Pathology and Bacteriology*, by Dr. Mercier Gamble (March, 1906), in which the above fallacies of the method are extensively set forth. I was led to this article by a recent review of hematological literature, in which Dr. Gamble's paper was referred to as questioning the reliability of the Dare method. The mildness of Dr. Gamble's phraseology, in criticism, might leave in the mind of the reader a hope for the Dare method, but any assimilation of the data there set forth would not, and it is the object of this memorandum to call attention to the latter.

THE USE OF PILOCARPINE FOR THE RELIEF OF PRURITUS, ESPECIALLY IN REGARD TO PRURITUS VULVÆ.

By JOHN J. REID, M.D.,

NEW YORK.

It does not seem to be be generaly recognized that pilocarpine has a specific effect in different forms of pruritus. My first knowledge of the value of pilocarpine in this way came from the late Dr. G. D. Holstern of Brooklyn. Dr. Holstern used it in pruritus coincident with jaundice and with happy effect. Since that time I have used it in pruritus vulvæ, pruritus associated with skin disease, and general pruritus without any assignable cause.

Pruritus seems to be a neurosis in some way allied to neuralgia, and has this in common with neuralgia that it is periodic and may occur without any immediate cause. In pruritus vulvæ I have found the same benefit from pilocarpine in cases occurring with and without diabetes. The ordinary dose is one-quarter grain to be given only when the itching manifests itself and is not to be repeated unless the itching returns. It is well to begin with one-eighth grain, inasmuch as some patients are very susceptible to the drug.

It may be of interest to note a case of pruritus occurring on a medical student at the time of his final examinations. Without the use of pilocarpine he would have found it impossible either to think or write. In this case 1-120 grain of atropine in conjunction with the pilocarpine prevented the sweating. In all of the cases referred to pilocarpine was given by the mouth.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 25, 1907.

THE RESPONSIBILITY OF THE COUNTRY PRACTITIONER FOR THE EXISTENCE OF TYPHOID FEVER.

THERE is nothing more definitely established in medicine than that typhoid fever is usually a country-bred disease and that its existence in cities whose water supply is drawn from running streams is due almost wholly to infection brought therein. We do not dispute the fact that the disease may be spread by the agency of flies, but this occurs chiefly or wholly in the country; nor that it is often acquired through eating of salads and raw fruits and vegetables, but these are brought from the country and the infection which they convey is of extra-urban origin. Certain of the lake cities which draw their water from the same place into which they empty their sewage may be examples of self-infection, but observation has shown that the water they drawn even from this source is not always polluted, and were the disease not continually reintroduced from without in the ice or in the raw food supplies it would soon die out. Dr. William G. Daggett of New Haven, Conn., stated this fact very forcibly in a paper presented to the Connecticut State Medical Society in May, 1904.

We have already commented upon this paper on two separate occasions (MEDICAL RECORD, September 3 and October 15, 1904), but it is a subject that will bear frequent repetition. Dr. Daggett's remedy for the evil was a system of control by a State sanitary police, the officers of which should inspect regularly and frequently privies and cesspools and also the wells and other sources of the water supply in rural districts. This would go far toward an abatement of the evil, but not far enough. Public officials could investigate the water supply in each community, but they could not supervise the management of each case of typhoid fever occurring therein. Such inquisitorial methods would become most unpopular and would arouse an antagonism which would surely defeat their ends. However ideally placed the well may be, its contamination or the contamination of some stream emptying into another from which a distant city may draw its water supply could not be prevented by official supervision.

The source of infection is the discharges, feces and urine, from one actually suffering or convalescent from typhoid fever, and the physician attending such a patient is the one to whom the community must look for protection. If every attendant upon a case of typhoid fever in the country were as insistent upon the disinfection of the discharges as upon the following out of his directions in regard to diet and medicine, the disease would be confined to the individual sufferer and there would be no possibility of its transmission to others in a city ten, twenty, or fifty miles away. We fear the practitioner in the country does not always appreciate the load of responsibility he carries for the health of his fellows in other communities. He is too often concerned with the individual case, and as long as this case is conducted to a successful issue he forgets the potentiality for evil it contains. If the discharges from every typhoid fever patient throughout the entire country were thoroughly disinfected before leaving the vessel in which they are received, the disease would soon be as rare as typhus, and thousands of lives would be saved.

RENAL DECAPSULATION FOR ECLAMPSIA.

THE severity which characterizes an eclamptic seizure has stimulated the introduction of certain procedures of a most radical nature. Thus Edebohls suggested and carried out decapsulation of the kidneys as a means of arresting the progress of this dreaded condition. Although a number of apparently successful cases have been reported, the method has by no means met with general approval and reports of its application by others are naturally of interest. De Bovis (*Semaine médicale*, No. 10, 1907) performed a renal decapsulation in a young woman who developed a severe eclampsia soon after delivery. None of the usual remedies seemed to have any effect and the patient grew rapidly worse. As a last resort, the capsule was removed from one kidney without any trouble, disclosing an extensive ecchymosis of the organ. The coma which had been present disappeared soon after the operation and the urinary secretion was at once increased. The patient recovered.

The number of cases in which this operation has been performed is not sufficient, however, to warrant the drawing of any definite conclusions regarding its value in eclampsia. Of five known cases, a fatal edema of the lungs was reported in one, and as the mortality of eclampsia has been stated to be about 20 per cent., the statistical evidence so far does not seem to warrant operation. As a matter of fact, however, it is usually only the severe cases in which uremia and anuria are prominent symptoms which are subjected to the operation in question. Another point to be borne in mind is that the kidney is not the only organ involved in eclampsia, so that it seems rather difficult to account otherwise for the improvement which has been noted in those instances where renal decapsulation has been carried out. Neither can the loss of blood be regarded as a possible factor, for it does not compare in extent with that which would be lost in an ordinary phlebotomy. It is quite evident that for the present the value of the operation referred to will remain *sub judice*, although future experiments and observations may contribute to its better understanding and appreciation.

THE SEVERE TYPES OF RUBELLA.

Rubella, or, as it is more commonly called, German measles, is usually regarded as a harmless disease which presents the characters of a mild febrile disturbance and requires but little treatment. Reports are to be noted here and there in the literature, however, which show that the disease, particularly in weak and emaciated children, may be accompanied by very severe complications dating from an involvement of the digestive or respiratory systems, among them being enterocolitis and bronchopneumonia. It has been claimed that these are cases of true measles rather than the so-called German variety, but this claim may with propriety be placed on the same plane, according to Cheinisse (*Semaine médicale*, No. 52, 1906), as the view that the disease in question is not a clinical entity but must be regarded as a mixed form of scarlet fever and measles. A typically severe case of rubella is reported by this writer as having occurred in a young woman of twenty-two years, who on the sixth day after the eruption was observed, developed a temperature of 105° F., became hoarse, and experienced difficulty in swallowing. The tonsils became greatly enlarged and the entire oral mucosa was markedly swollen. The tongue presented a thick coating which, in contrast to this phenomenon in scarlatina, was limited to the tip and the edges of the organ. There was also considerable general depression. With appropriate local and systemic treatment, the patient was well in a week, although she was considerably prostrated for some time afterwards.

Similar cases of secondary angina following rubella have also been described by a number of other writers and in one instance the appearance of an epidemic in a hospital was characterized by the development of bronchopneumonia, adenitis, meningitis, and otitis media in some of the patients. In this series of twenty-seven patients there were eight fatalities. It would seem from these adverse reports that we are not justified in regarding rubella as a disease without danger to those who may have contracted it.

The Etiology of Rachitis.

The theories relative to the nature and pathogeny of rachitis are very numerous, but it must be admitted that they appear to be either directly incorrect or at best far from satisfactory. A large proportion of the investigators who have interested themselves in this problem have taken as the basis of their views some error of nutrition. Some incriminate a too short period of nursing, others too protracted breast feeding, some seek the cause of the malady in some deficiency of the maternal milk, others in unsuitable artificial nourishment. Even the practice of pasteurizing or sterilizing the milk has been alleged as having an important bearing in the etiology of rachitis. Another suggestion in this regard is put forward by Esser (*Münchener medizinische Wochenschrift*, April 23, 1907) who considers that the anatomical changes in rachitis are the result of an increased formation of immature cartilage and osteoid tissue together with an abnormally increased absorption of the already formed bony structures. In order to explain this vice of development he endeavors to bring it into association with the function of the bone marrow, and points out that in rachitis there is always a hyperleucocytosis resembling in type that occurring in cases of long-continued overnutrition. As the result of the excessive stimulation of the bone marrow, growth is at first encouraged, but later the function is overtaxed and a perversion of development results. Esser supports his theory both by experimental evidence obtained by overfeeding animals and by clinical observations on a very large material. In every case of rachitis, he says, no matter whether the children were breast or bottle fed, and irrespective of any hereditary tendency, he found that there was a history of persistent overfeeding. While this theory will no doubt meet with opposition from many pediatric physicians it has at least the merit that it appears to render the therapeutic problem gratifyingly easy to solve.

The Rapid Demonstration of Tubercle Bacilli.

The method of securing certainty in suspected cases of tuberculosis by injecting some of the supposably infectious material into guinea pigs is satisfactory so far as reliability is concerned, but labors under the disadvantage of the length of time that must elapse before a definite result, particularly a negative one, can be obtained. In spite of this drawback the method at present, especially in view of the apparent complexity of the acid-fast group of bacilli, appears to be indispensable. This is particularly true in dealing with cases of genitourinary infection, in which the urinary sediment is so likely to contain confusing organisms that the guinea pig must nearly always be called upon to give the final decision. Bloch, working in Caspers' clinic, suggests (*Berliner klinische Wochenschrift*, April 29, 1907) a modification of the technique of the method by means of which it is possible to obtain a definite result in from nine to eleven days instead of from three to six weeks, as is ordinarily the case. It consists in encouraging the rapid proliferation of the injected tubercle bacilli by lowering the vitality of the tissues into which they are introduced. The centrifuged urine sediment is injected into the groin of the animal and the tissues of this part are rolled between the thumb and forefinger. On detecting the lymphatic glands as minute kernels they are crushed by strong pressure. If tubercle bacilli were present in the injected material the author states that they will multiply with unusual rapidity in these damaged tissues, and that they may be demonstrated in films or sections made at the expiration of the period mentioned. Smegma bacilli do not appear to be a source of error, and the method has given accurate results in the cases in which the author has tested it. If a more extended trial of the plan demonstrates its reliability it must be regarded as a valuable adjunct to our diagnostic procedures; but owing to obvious considerations a great many control observations will be required before it can be accepted among the trustworthy clinical methods.

Tuberculous Disease of the Bronchial Glands.

It occasionally happens that marked reactions to tuberculin injections manifest themselves in patients in whom no clinical evidences of tuberculosis are recognizable. In this class of cases, however, the subjective symptoms are usually well developed and are of such a character as to lead to suspicion

of the presence of true tuberculous disease. They consist mainly of pains in the back and chest, a dry cough, fatigue, and occasional night sweats. Neisser, who refers to this condition in the *Archiv für klinische Medizin*, Vol. 86, No. 3, states that, although we may be quite certain as to the presence of a tuberculous infection in the chest cavity, the question remains as to what particular organ is involved in the process. He believes that in such doubtful cases attention should be directed to the bronchial glands. If one of these has become painful in consequence of an inflammatory process evidence of the fact is obtainable in two ways. Indirectly it will give rise to tenderness in certain portions of the spinal area and directly the pain may be elicited by the pressure from a sound or bougie in the esophagus. Neisser found that in most instances in which the symptom complex noted was present he could elicit the sensation of pain in the region of the bronchial glands by an esophageal exploration in the manner referred to. The writer thinks that in these cases the symptoms are due to the development of a fresh tuberculous focus in one of the glands. Notwithstanding the many advances made in our knowledge of tuberculosis, there are many diagnostic points in the more obscure cases regarding which we need enlightenment, and consideration should be given to any procedure which will aid in clearing up this uncertainty.

The Action of Garlic in Tuberculosis.

The claim was made some years ago by Carazannis, an Italian investigator, that the ordinary garlic contained an ethereal oil which manifested a well-marked specific effect in tuberculous infection. The subject has again been made the subject of experiments in animals by Kathe (*Centralblatt für Kinderheilkunde*, 1907, No. 2), who administered a certain quantity of the juice to guinea-pigs daily. After three weeks the animals were twice subjected to an inhalation of dried and pulverized tuberculous sputum for a period of almost an hour. In both the control and previously treated guinea-pigs a tuberculous infection appeared, but strange to say in the latter group the mesenteric glands were not involved. Kathe explains this by assuming that the bacilli which were necessarily swallowed during the inhalations were destroyed by the oil of garlic in the intestinal tract, which acted as a local antiseptic, and whatever infection occurred took place through the medium of the respiratory passages. In another series the animals which had previously been treated with the garlic juice, received pure cultures of the tubercle bacilli subcutaneously. No inhibitive effect was apparently exhibited by the substance in these cases. The juice of the garlic, or rather its contained essential oil, therefore seems to manifest its antiseptic action only in the intestinal canal, and has no effect whatever on any tuberculous processes which may become localized in the lungs.

The Decomposition of Chloroform.

An ingenious device for automatically indicating decomposition occurring in chloroform intended for use as an anesthetic has been suggested by Breteau and Woog. It consists in making use of the indicator congo red for determining the development in the chloroform of even the minutest traces of hydrochloric acid. In order to do this conveniently a small disc of elder pith stained with a solution of congo red in absolute alcohol is placed in each bottle containing the chloroform. Normally the stained disc retains its color indefinitely, but if, as the result of the action of air, light, moisture, etc., decomposition begins, hydrochloric acid is set free and the indicator changes from red to blue. The chloroform then should be either discarded for internal use or be repurified. The *Lancet* states that it has tested this method and has found it extremely delicate.

Treatment of Inversion of the Uterus.

Among the interesting suggestions for the relief of this condition when it occurs after labor, is that made by Pinard, who advises the introduction of a rubber bag such as the de Ribe, in order to return the organ to its natural position. He has successfully employed this method in five instances. In the last, which occurred in a multipara with an easy forceps delivery, only a moderate amount of traction was made on the placenta, but the act resulted in a complete inversion of the uterus. The latter was readily reduced, and the patient suffered very little shock, but a few days later the organ again became inverted during an attempt to empty the bladder. Efforts at manual reduction then failed, and a de Ribe's bag was introduced and inflated with air. Its pressure caused no pain whatever, and within twenty-four hours the uterus returned to its normal position. Pinard in recommending the bag for this purpose states, however, that it should not be allowed to remain in place for more than eight hours.

News of the Week.

Medical Milk Commissions.—The Medical Milk Commissions in the United States will hold a conference at the St. Charles Hotel, Atlantic City, N. J., on Monday, June 3, 1907. There will be three sessions: 10 o'clock A.M., 3 o'clock P.M., and 8 o'clock P.M. The main objects of the conference are to determine the scope of the Medical Milk Commission, harmonize its working methods and requirements, and establish uniform standards for certified milk. Any member of a regularly organized Medical Milk Commission may be, by virtue of such membership, a member of the conference. The temporary chairman is Dr. Henry L. Coit, 277 Mt. Prospect avenue, Newark, N. J., and the temporary secretary is Dr. Otto P. Geier of 124 Garfield place, Cincinnati, Ohio.

The "Index Medicus."— The Carnegie Institute of Washington, which has been bearing most of the cost of publication of the present series of the *Index Medicus*, announces that as the journal has not met with the support from the profession that was hoped for, unless it appears that the *Index Medicus* is of greater service to the medical profession and can help to support itself to a greater extent than in the past, it may become advisable to discontinue its publication. The *Index Medicus* was established in 1879, under the editorship of Dr. John S. Billings and Dr. Robert Fletcher, and was discontinued in 1899. The present series began with the number for January, 1903. Each number of the *Index* presents the literature of the month named on its cover and is issued as early as possible in the succeeding month, time being allowed for the arrival of foreign journals. The present editors are Robert Fletcher, M.D., and Fielding H. Garrison, M.D. Communications relative to subscrip-

tions should be addressed: Carnegie Institution of Washington, Washington, D. C. Communications concerning the bibliography should be sent to: Editor of *Index Medicus,* Army Medical Museum, Washington, D. C. No numbers of the first series can be supplied. Copies of later volumes and numbers are available. The volume for 1905 contains 1,241 pages and the index to the volume 208 pages, the latter in double and triple columns.

Civil Service Examinations.—The State Civil Service Commission will hold an examination June 15, 1907, for Resident Physician, State Hospital for Crippled and Deformed Children, salary, $900 and maintenance. The last day for filing applications for this position is June 8. Full information and application forms may be obtained by addressing Mr. Charles S. Fowler, Chief Examiner of the Commission, at Albany.

American Surgeons Honored.—The Russian Surgical Society recently celebrated in St. Petersburg its twenty-fifth anniversary and elected as honorary members a number of foreign surgeons, among them being Professor Roentgen of Munich, Dr. William H. Watson of Utica, N. Y., and Dr. Nicholas Senn of Chicago, Ill.

Gifts to Mount Vernon (N. Y.) Hospital.—Mrs. James A. Bailey has contributed the sum of $10,000 to the maintenance fund of the Mount Vernon Hospital, and has announced her intention of donating a further sum of $100,000 for the erection and equipment of a new hospital building to be placed next to the present structure and called the Bailey Memorial Hospital. Mrs. Bailey has also promised to endow the new memorial hospital. By the will of the late Martin L. Sykes the Mount Vernon Hospital is to receive the sum of $5,000.

An Endeavor to Save the Lives of Christian Scientists.—A bill has been introduced into the legislature at Albany which amends the Penal Code by making it a felony for a person having in his charge, care, custody, or control a sick or disabled human being, to fail or omit to provide the sick person with the medical attendance of a competent licensed physician. If such person is unable to furnish a competent licensed physician he shall immediately notify the local board of health, and it shall be the duty of the board to furnish a physician with such medicines as may be prescribed.

Centenary of the College of Physicians and Surgeons.—The centennial celebration of the College of Physicians and Surgeons of this city is to be held in conjunction with the commencement exercises at Columbia University. On June 10 and 11 it has been planned to present to the visiting alumni an opportunity to see and inspect the modern methods of instruction and the present equipment of the College of Physicians and Surgeons. The laboratories and museums of physiology, anatomy, pathology, bacteriology, clinical pathology, and biological chemistry will be open for inspection, and the work in clinical branches at the Vanderbilt Clinic will be demonstrated. In addition there will be presented a number of clinical exercises in the several hospitals which will be conducted by the officers and professors in the school. On the evening of June 11 an alumni dinner will be held at Delmonico's, and on June 12 the commencement exercises will be held at the University and a general alumni luncheon will be given.

The Treatment of Pauper Cases.—At a recent meeting of the Champaign County (Ill.) Medical Society resolutions were adopted providing that in all cases operation fees and full fees for attendance should be charged for treating pauper patients on orders from supervisors.

Tonsillitis at Bryn Mawr.—Following a class celebration at which a loving cup was passed from mouth to mouth, twenty-eight students at Bryn Mawr College developed tonsillitis.

Plague in India.—The gravity of the plague situation in India is evident from a report stating that during the week ended April 13 there were 87,161 cases of plague and 75,472 deaths, an increase of 14,000 in the number of cases and 12,000 in the number of deaths from the previous week. During the six weeks ending May 11 the deaths reached a total of 451,892. From October, 1896, to December, 1906, the total deaths from the plague were 4,411,242, and during the first three months of the present year 495,000 deaths are known to have occurred. There has also been increased mortality from all other causes. The death rate for the whole of India has increased steadily for the last five years from 29 per 1,000 in 1901 to 36 in 1905.

Scurvy in Russia.—The report of the Medical Inspectors in the famine districts, made public on May 17, records the steady spread of scurvy in the famine provinces of Samara and Ufa and in the Turgai Steppes, Asiatic Russia. A large proportion of the patients are children. Since January 15, when scurvy first became menacing in Ufa Province, the cases officially registered have averaged 107 daily, but the average now is several times greater.

Opium Restrictions in China.—All the opium smoking dens in Foochow are reported to have been closed by the authorities, and it is declared that the Viceroy of Pe-chi-Li Province has ordered all the local magistrates to establish "anti-opium shops" for the reception of poor and needy opium smokers, who will be induced to live in these places free of charge with a view to curing themselves of the habit.

Cancroin Case Non-suited.—Prof. Adamkiewicz of the University of Cracow, who is the inventor of the so-called cancer cure, "cancroin," some time ago brought suit against a prominent chemical manufacturing firm, alleging breach of contract. Adamkiewicz had made a contract with the chemical firm providing that this should have the commercial rights to the remedy for a period of twenty-five years, and that in case of unjustified violation of the contract the offending party should pay a penalty of 250,000 marks. Adamkiewicz sued the firm for this sum, for after a short period it abandoned the manufacture and sale of the remedy. The testimony of the experts called was unfavorable to the remedy and the case was non-suited by the court.

Dr. C. W. Pilgrim has resigned as president of the New York State Lunacy Commission and has been reappointed to his old post as superintendent of the Hudson River State Hospital.

Defeat of Pasteurization.—The Aldermanic bill requiring the pasteurization of all milk sold in the city which fails to reach a determined standard of purity was defeated by a small majority on Tuesday of this week.

American Laryngological, Rhinological, and Otological Society.—The thirteenth annual meeting of this organization will be held in this city on May 30, 31, and June 1, 1907, at the Academy of Medicine. The president is Dr. Wendell C. Phillips

of this city, and the secretary Dr. Thos. J. Harris of this city.

International Laryngo-Rhinological Congress.—It has been decided by those in charge of this congress, which is to be held in Vienna April 21 to 25, 1908, to include an exhibition of instruments, apparatus, books, etc., relating to laryngology and allied branches, and all those interested are invited to take part in this undertaking. All communications, accompanied by an exact description of the objects to be exhibited, are to be addressed not later than December 31, 1907, to the Secretary of the Congress, Professor Dr. Michael Grossmann, Wien, IX., Garnisongasse 10, in order that they may be correctly catalogued. Exhibits should be sent not later than February 15, 1908, to Herrn Ober-Ingenieur Jaroschka, Inspektor des k. k. Universitätsgebäudes in Wien, with whom they will be deposited. All objects will be insured against theft, fire, and damage. The import and export of exhibits has been declared as duty-free by the authorities. Exhibitors are requested to apply to the secretary for all information in connection with the exhibition.

Utah State Medical Association.—At its annual meeting held in Salt Lake City on May 8 this organization elected officers as follows for the coming year: *President*, Dr. H. D. Niles of Salt Lake; *Vice-Presidents*, Dr. C. G. Plummer of Salt Lake, Dr. E. H. Smith of Ogden, and Dr. H. A. Adamson of Richmond; *Secretary*, Dr. W. S. Ellerbeck of Salt Lake; *Treasurer*, Dr. J. H. Harrison.

Nebraska State Medical Association.—Officers were elected as follows at the annual meeting of this association held in Omaha on May 9: *President*, Dr. H. Gifford; *Vice-Presidents*, Dr. M. L. Shaw and Dr. Inez E. Philbrick; *Secretary and Treasurer*, Dr. H. W. Orr.

Bristol South (Mass.) District Medical Society.—At the annual meeting of this society, held in New Bedford, officers as follows were elected: *President*, Dr. Garry Hough; *Vice-President*, Dr. W. T. Learnard of Fall River; *Secretary and Treasurer*, Dr. A. J. Abbe of Fall River.

Middlesex East (Mass.) District Medical Society.—Officers as follows were elected at the meeting of this organization held at Stoneham May 9: *President*, Dr. C. W. Harlow of Melrose; *Vice-President*, Dr. F. E. Park of Stoneham; *Secretary*, Dr. H. A. Cole of Winchester; *Treasurer*, Dr. Chas. Dutton of Wakefield.

Hampshire Country (Mass.) Medical Society.—At the meeting of this association held in Northampton on May 10 officers as follows were elected: *President*, Dr. J. G. Hayes of Williamsburg; *Vice-president*, Dr. G. B. Thayer; *Secretary*, Dr. A. G. Minshall; *Treasurer*, Dr. H. A. Hoadley.

The Mississippi Antituberculosis League.—At its session held in Meridian on May 10 officers for the ensuing year were elected as follows: *President*, Dr. R. W. Shipp of Gulfport; *Secretary*, Dr. R. F. Hall of Clinton; *Treasurer*, Dr. D. P. Price of Boonville. The next meeting will be held at Gulfport on the second Wednesday in January.

National Association of U. S. Pension Examining Surgeons.—At the sixth annual meeting of this organization held in Washington on May 8 officers were elected as follows: *President*, Dr. G. Lane Teneyhill of Baltimore; *Vice-Presidents*, Dr. Porter Farley of Rochester, N. Y.; Dr. J. W. Houston of Lancaster, Pa.; Dr. D. S. B. Armsburg of Chicago, Ill., and Dr. M. P. Creel of Center City, Kan.; *Secretary*, Dr. P. Y. Eisenberg of Norristown, Pa.; *Treasurer*, Dr. Chas. H. Glidden of Little Falls, N. Y.

Texas State Medical Association.—Officers were elected as follows at the meeting of this society held at Mineral Wells on May 9: *President*, Dr. C. E. Cantrell, Greenville; *Vice-Presidents*, Dr. H. S. Barnes, Tulia; Dr. D. S. Weir, Beaumont, and Dr. A. B. Small, Waxahachie; *Treasurer*, Dr. C. A. Smith, Texarkana; *Secretary* for three years, Dr. I. C. Chase, Fort Worth.

Kansas State Medical Society.—The election of officers for this society held at the annual meeting in Kansas City on May 11 resulted as follows: *President*, Dr. J. E. Sawtell, Kansas City; *Vice-Presidents*, Dr. T. Kirkpatrick, Garnett; Dr. M. E. Jarrett, Fort Scott, and Dr. G. M. Gray, Kansas City; *Secretary*, Dr. C. S. Huffman, Columbus; *Treasurer*, Dr. L. H. Munn, Topeka.

American Laryngological Association.—Officers for the ensuing year were elected as follows by this organization at its closing session in Washington on May 9: *President*, Dr. H. S. Birkett, Montreal; *Vice-Presidents*, Dr. J. Payson Clark, Boston, and Dr. J. E. Rodes, Chicago; *Secretary and Treasurer*, Dr. James E. Newcomb, New York; *Librarian*, Dr. J. H. Bryan, Washington.

Iowa State Homeopathic Medical Association.—This association at its meeting held in Iowa City on May 9 elected officers as follows: *President*, Dr. T. F. H. Sprong of Sioux City; *Vice-Presidents*, Dr. Genevieve Tucker of Davenport, and Dr. R. W. Homan of Webster City; *Secretary*, Dr. Gardiner A. Huntoon of Des Moines; *Treasurer*, Dr. M. A. Royal of Des Moines.

The Late Dr. Solly.—At a meeting of the Board of Directors of the National Association for the Study and Prevention of Tuberculosis, held in Washington May 7, 1907, the following resolutions on the death of Dr. S. E. Solly, a former member of the board, were unanimously adopted: *Whereas*, The Directors of the National Association for the Study and Prevention of Tuberculosis have learned with sincere sorrow of the death of their colleague, Dr. S. E. Solly of Colorado Springs, and *Whereas*, by his great medical ability and no less by his unusual personal charm he had both endeared himself to them and proven a wise counsellor in their deliberations, therefore be it *Resolved*: That in his death they have lost a member whose place cannot easily be filled; one whose distinguished professional attainments did honor to this body to which he belonged and whose remarkable gifts of heart equally with those of mind made him ever welcome in their midst; and be it further *Resolved*: That the secretary be directed to send a copy of these resolutions and assurances of our deep sympathy to this bereaved family; that a copy be spread on our minutes, and that they be published in *Colorado Medicine*, the official organ of the Colorado State Medical Society, in the *Journal of the American Medical Association*, in the MEDICAL RECORD, and in the *Journal of Outdoor Life*, the official organ of the National Association for the Study and Prevention of Tuberculosis.

Obituary Notes.—Dr. ISAAC M. RIDGE of Kansas City died on May 7 at the age of eighty-one years. Dr. Ridge was born in Adair County, Ky., and in 1834 was brought by his family to Lafayette County, Mo. Fourteen years later, after receiving his degree from Transylvania University, Lexing-

ton, Ky., he began the practice of medicine in Kansas City. He had retired from active work many years ago.

Dr. Albert H. Humes of Boston died suddenly at his home in Woburn on May 8 at the age of fifty-two years. He was born in Douglas and was a graduate of the New York College of Physicians and Surgeons. He had practised in Boston about twenty years.

Dr. Charles Williams Ottley of Atlanta, Ga., died in Baltimore on May 9 at the age of thirty-six years. Dr. Ottley was a graduate of Princeton and Johns Hopkins University. For four years he had been a medical missionary to Turkey.

Dr. Noyes N. Learnard of Charlestown, Mass., died on May 11 at the age of eighty-two years. He was a native of Vermont and had practised in the south end for many years.

Dr. John G. Broadnax of Greensboro, N. C., died suddenly of heart disease on May 9 at the age of seventy-five years. He had served as Confederate army surgeon through the Civil War and was one of the oldest practising physicians in that part of the country.

Dr. John M. Harlow of Woburn, Mass., died on May 13 at the age of eighty-seven years. He was born in Whitehall, N. Y., and was graduated from the Jefferson Medical School in Philadelphia in 1844. After practising for fifteen years in Cavendish, Vt., he went to Minnesota for his health and some years later settled in Woburn. He had held numerous public positions, both in the municipal and the State governments, and was a trustee of the Massachusetts State General Hospital.

Dr. Charles A. Foster, physician to the New York State Hospital for the Insane on Ward's Island, died suddenly on May 19 at the age of fifty-eight years. He had formerly been a resident of Saugerties, N. Y.

Dr. Eugene Wiley died at Philadelphia on May 17 at the age of sixty-two years. He was graduated from Jefferson Medical College in the class of 1860.

Dr. David H. Goodwillie of Yonkers, N. Y., died on May 17 at the age of seventy-four years. He was a native of Barnet, Vt., and received his medical education at the college of medicine of the University of Vermont and in Edinburgh, Scotland. He had practised for many years in this city as a laryngologist and was a member of numerous medical organizations. He retired from active work about six years ago and went to Yonkers to live.

Dr. Charles Neill of Toronto died suddenly on board a railroad train near Chicago on May 15 while on his way to Texas for his health.

Dr. J. A. Cummings of Omaha, Neb., died of pneumonia on May 12 at the age of thirty-five years.

Dr. Shuler Craft of Denver, Col., died of pneumonia on May 12. Dr. Craft was born in Fort Wayne, Ind., in 1878 and was graduated in medicine from the University of Denver two years ago.

Dr. John C. Sturgis of Seattle, Wash., died after a brief illness on May 6. He was born at Charleston, Ind., in 1858 and received his medical degree from the University of Michigan. After practising for a time in Indiana he went to Seattle in 1889.

Dr. James E. Casey of Mohawk, N. Y., died on May 19 at an advanced age. He was graduated from the Albany Medical College in 1855, and had practised in Herkimer county for over fifty years.

Correspondence.

DR. KNOPF MISQUOTED.

To the Editor of the Medical Record:

Sir:—I take this method of trying to correct the outrageously false impression given by many of the newspapers of the country of the statement of Dr. Knopf before the Clinical and Climatological Section of the National Association for the Study and Prevention of Tuberculosis, at its recent meeting in Washington. I was present as chairman of the section when Dr. Knopf made his remarks. He was within a few steps of where I sat, and I was paying close attention to his remarks. I understood him, and all others with whom I have spoken on the matter since the meeting understood him, to state plainly the need of using morphine to relieve painful symptoms in the last stage of the disease. Any physician who heard the remarks must have known that the morphine was used not for shortening life, but solely for making it easier, and every physician also knows that life is generally prolonged by that sort of treatment. As I have expressed myself before this regarding the shortening of lives of seriously sick people, I need hardly say that had Dr. Knopf advocated anything like the administration of large or dangerous doses of morphine I would have vigorously protested. I hope that physicians who are asked about the matter will contradict the newspaper statements and seize the opportunity of explaining the real object of the treatment.

George Dock, M.D.

Ann Arbor, Mich., May 17, 1907.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BENINDEN SANATORIUM—BILL TO PREVENT PRACTICE BY COMPANIES—SURGICAL AFFECTIONS IN THE RIGHT ILIAC REGION—LOCAL ANESTHESIA FOR OPERATIONS FOR GOITER—ADDISON'S DISEASE—DEATHS UNDER ANESTHETICS IN RELATION TO LYMPHATISM—DEATH OF MARKHAM SKERRITT.

London, May 3, 1907.

The Princess Christian of Schleswig-Holstein opened the first part of the new self-supporting sanatorium for working class persons suffering from tuberculosis. I have previously given you particulars of this movement. Nineteen beds are already occupied, and when completed the institution will have 200. Sir Clifton Robinson, one of the vice-presidents, said he would like to see a supplementary organization, by means of which those who had been brought into the country and cured would be enabled to settle for good on the land, instead of returning to the dense centers of overcrowded towns. There would then be the best chance of their cures being permanent.

The bill to prevent the evasion of the medical acts by companies engaging in practice has passed the second reading in the House of Lords with the blessing of the Government, who, Lord Crewe said, are of opinion that it meets something which nearly approaches a public scandal. A doctor should be personally responsible, and not able to shelter himself behind a company. A doctor who allowed himself to be employed by a company would be a derelict of the profession, and it was better not to encourage this sort of practice by companies. The bill, and the parallel bill respecting dental companies, having passed this stage, some are hoping that both may become law. But note the reasoning of the Government spokesman. He had no notion of protecting the profession, or even the public. It was just as well not to encourage companies, but he had not the courage to declare such companies swindlers or impostors. Free trade must deal gently even with such combinations—much as the public may suffer.

At the Medical Society of London, Mr. Waring read a paper on certain iliac affections which simulate more or less closely appendicitis. He restricted his remarks to cases of acute or subacute attacks of pain beginning mostly in the umbilical or epigastric regions, sudden in onset, and localized later in the right iliac fossa, with nausea or vomiting, and muscular rigidity of the lower part of the wall of the abdomen on the right side. He related two cases of acute infective osteomyelitis of the ileum, where it forms the deep boundary of the fossa. So tuberculous, deep glands in the fossa might last some time without decisive symptoms. Glands which became the seat of secondary infection might also imitate appendicitis; so might abscess secondary to a septic state of the right broad ligament or Fallopian tube. In one instance adenopapilloma of the mucous membrane of the cecum around the opening of the appendix set up the symptoms. Hematoma of the right ovary at an early stage, a displaced right ovary, injury to

the region, breaking down of a malignant growth, rupture of a blood-vessel, and other affections, had given rise to difficulties. In all cases it was necessary to ascertain, if possible, the precise mode of onset and the chronological sequence of the symptoms, as well as to consider carefully all the facts available in connection with the previous history, to make a complete clinical examination of the abdomen and pelvis, and, if still in doubt, to examine the blood.

Mr. Lynn Thomas described a mode of producing local anesthesia he had found effectual for removing goiters. He draws his scalpel along the line of Kocher's collar incision so lightly as to cause a thin red line, under which he injects one to two drams of 1 per cent. cocaine solution, thus forming a subcutaneous ridge from end to end. The collar incision is then made and the operation completed with very little loss of blood, every exposed vessel being clamped by two Kocher's forceps and divided between them, as it appears.

At the Medico-Chirurgical the paper was on Addison's disease, by Dr. Grunbaum, and chiefly as to early diagnosis. He said the two chief symptoms, asthenia and pigmentation, might both or either be present in other diseases. He found that oral administration of suprarenal extract did not raise the blood pressure of healthy persons, but that a rise followed this medication when there was renal inadequacy. In doubtful cases three-grain doses *ter die* for three days could be utilized, and if there was a distinct rise it was very suggestive of Addison's disease in the absence of valvular heart disease. The opsonic index after inoculation with tuberculin often pointed to a tuberculous condition of the adrenals.

Dr. Rolleston agreed as to the effect of the extract given by the mouth on the blood pressure, and said that a condition of inadequacy existed short of Addison's disease, and might perhaps be thus indicated. He attached little importance to pigmentation of the mouth, which might be induced by bad teeth. Dr. F. P. Weber said prolonged asthenia after infection suggested Addison's disease, and told of such a case, when months after influenza pigmentation took place and death occurred in a syncopal attack, both suprarenals being found at the postmortem caseous and matted across the aorta. Dr. Tooth remarked that bromide occasionally caused pigmentation. Dr. Ewart referred to the variation in the symptoms of Addison's disease. In one case asthenia was most prominent, in another pigmentation, the latter being less severe than the former. He related one case in which pigmentation was present for many years.

In his reply, Dr. Grünbaum said he had not met with a case of pigmentation produced by bromide. If the suprarenals were removed in animals pigmentation did not follow, but if they were damaged or infected it did. In rapid destruction of them, as by cancer, there was no pigmentation. The more rapid the disease the less pigmentation occurred. In a case in which only the solar plexus was involved there was pigmentation on the trunk more than on the limbs.

The death of a young baronet under an anesthetic (chloroform and ether combined) was the subject of an inquest last Friday, when a verdict of death by misadventure was returned. The evidence showed that Sir H. L. Huntington was twenty-one years of age, 6 feet 3½ inches in height, and was thought to have outgrown his strength, but was in good health. Dr. Frankish said that two years ago he had a mild attack of diphtheria, but made a good recovery. He prepared him for the operation and called in Dr. Hilliard to give the anesthetic. On the first incision the patient stopped breathing and changed color; he recovered at once, and the operation was resumed, but before it was completed the pulse stopped, the breathing became shallow, and artificial respiration was resorted to without effect. Dr. Spilsby, pathologist of St. Mary's Hospital, made the post mortem and found fatty degeneration of the walls of the heart with a little dilatation, a very unusual thing in a young man. He added that "he also found the status lymphaticus, a condition that only recently engaged the attention of pathologists in this country, and not recognizable during life, although its subjects seemed specially liable to sudden death from trivial causes." In this case death was due to syncope. In reply to a question, he said the condition named represented a new danger in anesthesia. Dr. Hilliard, asked if he had seen such a death, said he had never seen a death under anesthesia, although he had dealt with 12,000 cases.

Another inquest was held on Saturday which may be compared with the above. It was on a boy of nine, who died at Guy's Hospital under ethyl chloride. The Coroner, Dr. Waldo, said he knew of twenty-two fatalities, and had held four inquests following deaths from this anesthetic. The clinical assistant said three cubic centimeters were given. Deaths under ethyl chloride were one in 3,000. There were less under ether or chloroform. It was given in this case, as the operation was a short one—appendicitis. The house physician said 3 c.c. was a careful dose. He had made a post mortem and found fatty degeneration of the heart. The direct cause of death was the anesthetic, but the poor condition of the child had a bad effect. Verdict, misadventure and no blame to anyone.

In connection with the foregoing cases I am reminded of some remarks made last month at the Dublin Academy, when Dr. Peacocke related a case of cerebrospinal meningitis in a child of five, the subject of lymphatism. The attack was fatal in eleven hours. At the post mortem Dr. Peacocke found very large thymus, enlarged mesenteric glands, hypertrophied Peyer's patches, and solitary follicles, and on section of the spleen prominence of the malpighian corpuscles. The idea of lymphatism did not occur during life, for there were no symptoms, and the only sign likely to be detected was such dullness as the large thymus might cause. Dr. Kirkpatrick said the condition of lymphatism had been found in a number of cases in which sudden death had occurred during the administration of anesthetics, so that its recognition if possible would be of practical importance. Professor White thought lymphatism had much to do with infection. Most fatal cases of cerebrospinal meningitis had had trouble with adenoids, and it was possible they were infected through the lymphoid tissue at the back of the nose, where there were a number of diplococci in some healthy persons. It was difficult to distinguish some of these organisms from that of cerebrospinal fever. In the only case he had examined post mortem in the present epidemic lymphatism existed.

Bristol is mourning the loss of the senior physician to her General Hospital, Dr. Markham Skerritt, who died on Monday and was buried yesterday amid signs of the city's regret for one who had served her long and faithfully. Dr. Skerritt was a man of great attainments. He took the B.A. of London University in 1868, proceeding to M.B. and B.S. with honors in 1873, and M.D. the next year. In his college course he took numerous prizes and the chief scholarship. At the University he was gold medalist in medicine and obstetrics at both the M.B. and M.D. examinations. In 1875 he was elected physician to the Bristol Hospital, and continued to serve it for the rest of his life. He became one of the most distinguished consultants in the west of England. A member of the London College of Physicians in 1876, he was elected a Fellow in 1885, Bradshaw Lecturer in 1897, and Councillor in 1904. He served the chief offices in various medical and scientific societies, and contributed valuable communications to them, as well as to the journals. He was Examiner in Medicine for the R. A. M. C. For more than a quarter of a century he was Professor of Medicine and Dean of the Medical Faculty in the University College of Bristol. He resigned these and some other appointments in 1905, having some time previously lost his daughter and only child, and his wife having begun to lose her sight. He was an active man, and used to hunt until his bereavement. Modest and rather reserved, he was destitute of push, and attained his great position by merit and the good will and affection of his patients and his fellow citizens by his kindliness and consideration for all. He was in his usual health until Sunday week, when he felt indisposed, on the Wednesday he took to his bed, and was found to be suffering from pneumonia of a severe type, which terminated fatally on Monday, in his fifty-eighth year. The city and the profession join in deep sympathy with his widow.

THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Special Correspondent.)

MANILA, P. I., March 1, 1907.

THE fourth annual meeting of the Philippine Islands Medical Association was opened most auspiciously on the afternoon of February 27. Delegates from China, Japan, and Hongkong were in attendance, and the meeting promised to be one of the most successful that had yet been held. The great interest manifested, not only by medical men, but by the laity, and the governments in nearby countries, was a great inspiration to the medical men of the Philippine Islands who are engaged in combating the diseases that prevail here, and who are making a study of the many problems connected with tropical medicine.

The first session was a general one, and not devoted to strictly scientific purposes. The Governor-General of the Philippine Islands made the opening address, and stated, in substance, that it gave him great pleasure to meet the men who are engaged in organized efforts to combat disease in the tropics. He said he felt that he expressed the feeling of the community when he stated that everyone is deeply appreciative of the fact that many of the medical men here were sacrificing their time, and in some cases even their lives, in the interests of their fellow men. He said that

it was with particular pleasure he noted that scientific men who were born and reared in the Orient, and thoroughly conversant with the best means of combating the diseases which have heretofore made severe inroads into Oriental life, had come here to take part in this meeting of the Association. He invited particular attention to the fact that up to twenty-five years ago the medical man was not an important political factor in the community, because he devoted himself so exclusively to the interests of his patients that he did not seem to find time to form medical associations which would make his influence felt, but by the general organization of the medical profession throughout the civilized world the influence of the medical man was now felt in almost all legislative bodies, and that many measures which had found their way into the statute books during this period had done much to improve public health and lessen diseases, and was ample testimony of the value of medical organization. It was by such unions that the great opposition which was often encountered in enforcing sanitary regulations was successfully met, and that furthermore it gave him great pleasure to state that his experience with medical men, which had been a large one, had shown conclusively that even though the faithful discharge of public duties often led to much unpleasantness, yet he had never found that the medical man shirked this responsibility.

The next feature on the program was an address by Dr. Paul C. Freer, the President of the Association, entitled: "A Consideration of Some of the Modern Theories on Immunity" Dr. Freer took the ground that the indications now are that the future progress in immunity must be rather through chemistry than through biology. He stated that after having given this subject most careful study during the past few years, and by observation of natural and acquired immunities under various environments, he felt convinced that in the future the preservation of public health must be looked for more through vaccines and serums than through hygiene. His address was a very able one and will be published in full in the Philippine *Journal of Science*.

In the evening, at 8:30, Colonel John Van R. Hoff, Assistant Surgeon General of the United States Army, gave a picture talk on "Russian Sanitary Ways and Means in Manchuria, 1905." The data, statistics, and other evidence which he presented came as a matter of surprise to many of the audience, because it seems to have become the generally accepted view that the Russians did very little in a sanitary way. The evidence presented by Colonel Hoff showed conclusively that practically as favorable results were obtained by the Russian medical officer as by the Japanese medical officer. The proportion of disability and deaths due to disease, which has heretofore obtained in previous wars, was reversed in the case of the Russians just as in that of their opponents; three men dying on the field of battle as against one from disease.

The next on the program was a paper entitled "Mosquitos in the Philippines, Their Breeding and Habits, with Methods for Their Suppression," by Charles S. Banks, Entomologist, Biological Laboratory, Bureau of Science. His exhibition of the various forms of mosquitos was most excellent. The specimens showed great care in their preparation. His talk was also profusely illustrated, showing the places in which mosquitos breed. He stated that the two mosquitos that caused the greatest discomfort to the residents of the Philippines were the stegomyia in the daytime and the *Culex fatigans* at night. In Manila practically no anopheles are encountered.

On the evening of February 28 Dr. R. P. Strong gave a dinner in honor of the foreign guests, and to the members of the society. Among the foreign guests present were Dr. J. M. Atkinson, the Honorable Principal City Medical Officer at Hongkong; Dr. Kannosuke Miyajima, Delegate from His Imperial Japanese Majesty's Government; Dr. Sia Tien Pao, Delegate from His Imperial Chinese Majesty's Government; General Wood, and the chief medical officers of the Army, Navy, and Public Health and Marine Hospital Service were among those present. The dinner was most successful and will probably be very productive in cementing those friendships and unions which are so necessary and helpful to a better understanding among medical men.

At the third session, held on February 28, the first paper read was entitled "The Prevalence of Hydrophobia in the Philippine Islands," by Dr. F. W. Dudley, St. Paul's Hospital. The writer stated that the object of his paper was to show the prevalence of hydrophobia in the Philippine Islands, and the necessity for making available, modern prophylactic treatment for the purpose of combating it. He posted notices in practically every pueblo in the Philippine Islands and corresponded with all medical men from whom he could expect to obtain some data, and in this way he was able to collect, during the period from March 1, 1902, to February 28, 1907, 36 cases in human beings, 225 cases in dogs, 1 in a cat, 1 in a carabao, 2 in horses, 10 in pigs, 3 in rats, and 1 in a monkey. In his opinion, the incubation period in the Philippine Islands was rather long. One authentic case was reported within ten days, but there were also three authentic cases with incubation periods of eight, nine and ten months respectively. During the month of February a dog bit a child in the city of Manila. The dog was immediately killed and taken to the Bureau of Science for investigation but no Negri bodies were found nor have any symptoms appeared in the rabbits which were inoculated from material taken from the dog. He had nothing particularly new to offer in the way of treatment. He recommended that the Pasteur method should be employed, and stated that the same is not available in the Philippine Islands. In conclusion, he urged that the Government make available immediately a modern prophylactic treatment for this disease.

The next paper was entitled "Clinical Observations on Uncinariasis," by Dr. Edwin C. Shattuck, Attending Physician, Bilibid Prison. He stated that during the past few months 849 inmates, taken in the regular order in which they were admitted to the prison, were examined. Of these, 243 were found to have uncinaria, or about 24 per cent. They occurred in prisoners who were received from practically all the different provinces in the islands, which shows that the distribution of the disease must be widespread. He reported that at first thymol was used in the treatment, but later the treatment by eucalyptus oil, as recommended by Phillips in the London *Lancet*, February 3, 1906, was adopted, which consists of 2.5 c.c. of eucalyptus oil, 3.5 grams of chloroform, and 40 c.c. of castor oil. This is divided into two doses, given on an empty stomach, at intervals of one-half hour. He increased the dosage to 30 c.c. with excellent results. The use of the oil is preceded by a dose of magnesium sulphate, and two hours after the last dose of oil another dose of magnesium sulphate is administered. After this has acted, light diet is permitted. Of the 345 cases treated with eucalyptus oil, 270 only required one treatment, 58 two and 16 three, and in one case four treatments were necessary before the stools were negative.

The next paper, "*Vectator americanus* in Natives of the Philippine Islands," was read by Lieut. Clarence L. Cole, Assistant Surgeon, U. S. Army. His experience was practically that of other observers in this field.

Then followed an address entitled "Methods of Combating Plague in Hongkong," by Dr. J. M. Atkinson, the Honorable Principal Civil Medical Officer of Hongkong. He stated that the methods of combating plague in Hongkong were now practically the same as those employed in most civilized states where this scourge exists. He brought out one new point, however, that is, that in a house where plague has been encountered guinea pigs are now set free, with the idea of having any fleas that may be about the premises collect upon the guinea pigs and capturing them by this method. Otherwise the usual disinfection of premises, with the obliteration of the rat-runs and general cleanliness, were carried out, the cases themselves being isolated at the plague hospital.

The next paper, entitled "The Physiologically Active Constituents of Some Philippine Medicinal Plants, Arrow Poisons, and Fish Poisons," by Dr. Raymond F. Bacon of the Chemical Laboratory of the Bureau of Science, was most instructive and by far the most exhaustive treatise that has appeared upon the medicinal plants since American occupation. The paper will be published in full in the *Phillippine Journal of Science*.

The last paper of the Third Meeting, entitled, "Native Medicinal Plants," was read by Elmer D. Merrill, Botanist, Bureau of Science. He stated that Philippine systematic botany has been in a chaotic state since the publication of Blanco's "Flora de Filipinas," and that in 1837, due to the fact that Blanco and some of his successors, notably Lanyos, Fernandez-Villar, and Naves, had no conception of the geographical distribution of species, and credited to the Philippines plants that did not grow in the archipelago, and accordingly, referred to extra-Philippine species a great number of local plants which were really very distinct from those which are described by various authors for the Asian continent and Malaya Subsequent workers, however, Vidal among them, did much to clear up this confusion, but after his death, in 1869, very little work in Philippine flora was done up to the advent of the Americans, who resumed the work in 1902. He stated that the two essentials for a thorough revision of the Philippine botany were a complete herbarium and a representative botanical library, and both of these were supplied by the Bureau of Science. He stated that sufficient material and data was already on hand to warrant the commencement in the near future of a publication on the flora of the Philippines that will be fairly complete and accurate, but

that such a work must treat of from eight to ten thousand different species of plants, and it would of necessity be greatly delayed in its compilation. He stated that many official and officinal plants were found in the Philippines either wild or cultivated, and that some of these were of especial interest, the principal ones being castor oil, strychnos ignati, otherwise known as St. Ignatius bean, and that the latter contains a larger proportion of strychnine than the strychnos nux vomica, from which it is usually obtained, and also that this is only found in the Philippines. He laid special stress upon the fact that most pharmacopœias erroneously referred to it as Chinese. Among others, he mentioned papaya, pomegranate, and the tamarind. He also stated that many of the plants would no doubt be commercially profitable if pains were taken to exploit this feature of the work.

Progress of Medical Science.

New York Medical Journal, May 11, 1907.

Unrecognized Diphtheria in Children.—I. Friesner calls attention to the fact that nasal diphtheria in children is very often overlooked. The patient does not seem very sick, has but a slight rise in temperature, not much change in pulse or respiration and may eat well. Often these children are credited with only a cold in the head. Occasionally the nasal discharge is confined to one side and the nasal vestibule on that side, together with the lip, is red and slightly swollen. The cervical glands are not always enlarged. There is as a rule a discharge of yellow, glairy mucus, which may later become greenish. Sneezing may occur, but it is not as common as in coryza. In fact, the discharge and lip discomfort are the symptoms principally complained of. In the early stages examination of the nares shows only an acutely inflamed mucosa. Later, as the disease develops, a more or less typical membrane develops. The grave danger of such cases both to the patient and those about him render careful bacteriological examination necessary so that if the disease proves diphtheritic the proper precautions may be taken. Two illustrative cases are detailed. The author thinks that careful examination of the nose in sick children is just as important as the examination of the throat, which is now so regularly done.

Danger of Fire in Formaldehyde Disinfection.—C. H. LaWall calls attention to the dangers attending the modern method of disinfection by the formalin-permanganate plan, stating that on several occasions the mixture has been known to take fire spontaneously. In the formalin-permanganate method it has been customary to use two parts of formalin to one part of permanganate, adding the latter to the former and quickly leaving the room before the violent evolution of gas which shortly takes place has time to affect the operator. Working with quantities in some cases as high as one pound of permanganate, the amount of heat developed must be very great, and if there are any uncertain factors present, such as organic matter in the container which has been imperfectly cleaned, the danger of possible ignition is that much greater. The flame which has appeared on these occasions of combustion has been of a pale blue appearance, reaching several feet in the air from the container. The gas may be ignited from a 40 per cent. solution of formaldehyde by simply heating it and applying a match to the surface after ebullition has begun, and when the formalin-permanganate disinfection proportions are used in as small a quantity as one ounce of formalin and one-half ounce of permanganate, using a beaker for a generator, the flame of the ignited gas has been observed to have a length of more than one foot. In view, therefore, of the uncertainty regarding the cause of the ignition of the vapor in these observed cases and in recognition of the hitherto overlooked fact that formaldehyde vapor is very inflammable, it would be well to practise this method of disinfection with the precautionary measures of using small quantities of the ingredients (not over one-quarter or one-half pound of permanganate to a charge) in several containers, surrounding these containers with larger ones containing water, being careful to extinguish all gas jets, pilot lights, fire, and other possible causes of ignition, and keep the generators away from the sides of the room where a flame might be communicated to inflammable material. It is not believed by the writer that this method of disinfection need necessarily be abandoned, but it is essential that its limitations and dangers be not overlooked in its future use.

Appendicitis in Pregnancy.—H. N. Vineberg calls attention to this subject and gives some interesting statistics. He refers to the figures taken from the Mt. Sinai Hospital records covering a period of eight years. During this time there were 2,003 cases of appendicitis, 731 occurring in females. The association of pregnancy occurred in only nine cases. Two of these were not operated on and the diagnosis was based on clinical manifestations alone. The author therefore concludes that pregnancy does not predispose to the development of acute appendicitis. Differential diagnosis compels the consideration of the following possible conditions: Pain in the right side of the abdomen, which is not uncommon in pregnant women, rupture of an ectopic gestation sac at an early date, pyelitis of pregnancy, disease of the right adnexa, and typhoid fever. As regards treatment, the author declares that simply because pregnancy is present in an undoubted appendix inflammation one should not become panicky and consider that an immediate operation is always necessary. If the attack be a mild one, the patient can safely be treated palliatively, and one may wait for further developments. Should another attack occur within a short time and exhibit symptoms of greater severity, then, it seems to him, one should not defer surgical intervention, in the hope that further attacks will probably not recur. In an attack manifesting very acute symptoms one should act just in the same way as if pregnancy were not present. It is well to administer opiates freely during the first seven or eight days after the operation, so as to avert premature termination of pregnancy. If abortion or premature delivery becomes inevitable, one should follow the recognized method of treatment, of emptying the uterus completely. In the presence of a large appendicular or postcecal abscess, one should not attempt to do more than make an incision and employ drainage, disturbing the relation of the abscess cavity as little as possible. The absurd procedure advocated by some to empty the uterus by forcible intervention immediately after operation met with the fate it deserved, being universally condemned. With ordinary precaution the uterus, even in the abscess cases, will not expel its contents until after the lapse of several days, when the local conditions will be such that no danger will ensue from the altered relations of the abscess cavity that such an event will bring about.

Chronic Muscular Diseases of the Heart and Their Treatment.—T. Schott states that whatever may be the etiology of this class of maladies, in special processes of change in the substance of the muscle of the heart, and the collateral symptoms, one fact is common to all, the final incapacity of the heart to perform its work, which is commonly defined as "muscular insufficiency." This latter condition generally follows chronic myocarditis, be it with or without symptoms of angina pectoris, whether consequent to fatty changes of the heart, with or without valvular lesions, or whether it follow overexertion or the changes due to chronic poisoning through such substances as alcohol or nicotine. The author then goes on to describe the plans of treatment which are generally known as the Nauheim treatment, placing his reliance on weak and always carefully controlled thermal saline baths, containing carbonic acid. For a lower percentage of such patients the strongest form of the so-called effervescent flowing baths is very beneficial. On many occasions we have demonstrated this method of treatment and the marked success which attends it; and we have given proof that the effect of the baths is very similar to that of gymnastics, indeed, almost identical. The difference is merely that what the baths do by means of the sensory nerves the therapeutical exercises do through the motor nerves. The mechanical treatment presents itself under three different forms: Climbing exercises according to the teaching of Oertel; the Zander treatment by machinery; and the treatment by exercises with resistance and self-resistance as taught by his brother August Schott and himself. It is certain that, although the chief impulse toward this line of treatment was due to the labors of Oertel, the *Terrainkur* which he advocated is only fit for a limited number of patients suffering from heart disease. It is most effective in the case of fatty heart in a young patient with normal muscular strength and quality of blood. In such cases it has been used with the best results. In the fatty heart of later life, however, or in connection with other complaints, cardiac or others, the greatest caution should be observed. Climbing exercise has in such cases often proved to be a most dangerous remedy, and especially in complicated forms of chronic muscular disease of the heart, whether associated or not with valvular trouble. The author gives an interesting series of pulse tracings before exercise and after various forms of exercise, and details the clinical histories of five personal cases. He says that, according to his experience, we have a reliable criterion as to the advisability of the treatment in the following effects. After a mild brine bath (1 to 1 1-2 per cent.) of 93° to 95° F., five to eight minutes' duration, or after gymnastic exercises with slight resistance, the heart, even if there is a passing ac-

celeration, will beat more quietly and with stronger impulse, hence the pulse must be of a fuller volume and the breathing easier. If we obtain these results from the baths or the exercises and continue this treatment slowly and prudently, we can look for success even in long standing cases of muscular diseases of the heart.

Journal of the American Medical Association, May 18, 1907.

Adrenalin in Unilateral Renal Hematuria.—H. H. Young reports a case of unilateral renal hematuria, of supposed traumatic origin, of sixteen months' duration, and without evidence of nephritis, cured by adrenalin. Pain was constant on the right side, the side of the injury, but the hemorrhage was from the left kidney. The adrenalin was injected through the urethral catheter; only one injection of 6 c.c. of a 2 c.c. adrenalin in 8 c.c. of sterile water was given. Some pain was caused at first, but soon disappeared and the urine cleared up entirely in about ten days, and there was a general improvement in the patient's condition. Three months after the treatment the man was in almost perfect health, having only occasional slight pains in the back and headaches much less severe than those formerly troubling him. Young reviews the recent literature of unilateral hematuria without nephritis, which he thinks shows the great importance of study of these cases, and the need of due efforts to determine their etiology. Bilateral catheterization should always be performed. The case reported, he thinks, demonstrates the importance of attempting to stop the hemorrhage by the injection of adrenalin through the ureteral catheter, and the excellent result in this case proves conclusively its therapeutic value in certain cases. Even with definite lesions present it would appear not to be contraindicated, and it may be of great diagnostic value. The weakening effect of the hematuria would be abolished and a more careful study of the urine facilitated. If in this way we can effect a cure, as in the case reported, the patient would be saved the ordeal of a cutting operation. In case of an ulceration of a tumor into the urinary passages, the use of adrenalin would not necessarily delay an exploratory operation if indicated. Young is convinced that the intraureteral injection of adrenalin is practically free from danger.

Vascular Lesions Following Laparotomy.—W. A. N. Dorland calls attention to the vascular lesions—hemorrhage, thrombosis, and embolism—as after-complications of laparotomy. The case of hemorrhage he reports was not due to slipping of the ligature, but to rupture of a distended broad ligament vein, an accident which he considers rare, though Byron Robinson speaks of it as frequent, but easily explained by the thinness of the vascular walls caused by the development of the tumor and the increased vascular pressure from its removal, the ligation of the arteries, etc., in the operation. The change from the Trendelenburg posture after the operation also favors the occurrence of bleeding from an obscure open vessel or torn adhesions, as Buckmaster has shown; hence the abdomen should not be closed until after thorough ocular inspection in the normal position. Primary postoperative hemorrhage may be intraperitoneal, due to (1) slipping or loosening of the ligature; (2) oozing from large raw surfaces; (3) spontaneous rupture of pelvic veins; (4) subperitoneal hemorrhage from imperfect ligation of the peritoneum or connective tissue over and in front of the open mouth of a retracted vessel. In any case, the danger is from the lowering of tension from loss of fluid rather than from diminution in number of red corpuscles; hence the value of physiological salt solution injection to restore the tension. The second case Dorland reports was one of typical, light, right-sided phlegmasia alba dolens occurring on the eleventh day after a simple salpingo-oophorectomy without complications. There had been no excessive handling, no evidence of sepsis, the operation had not been prolonged or severe or hemorrhagic, and the patient was not unusually anemic or run down in health. There had been, however, some excess of traction on the left broad ligament to bring the diseased part in view. He remarks on the comparative infrequency of postoperative thrombosis and the scantiness of its literature, and quotes Dearborn's suggestion that probably some of the cases are overlooked, and that it is possible that some of the pulmonary complications of surgical operations may be due to this cause. He says that, except in the comparatively small percentage of cases resulting from sepsis, hemorrhage, and severity of operation, we do not yet know the true etiology of this curious and frequently fatal condition. There is here a field for interesting original research. The most important fact in the symptomatology is the persistent frequency of the pulse, out of proportion to the rise of temperature, and this occurring during convalescence from an operation should always suggest, as Dearborn says, the possibility of a thrombosis. The main point in treatment is absolute rest. Immobility of the affected limb, external warmth, emollient and antiphlogistic applications along the course of the thrombosed vein, and thorough asepsis of the primary wound, comprise about all that can be done to relieve the patient.

The Tuberculin Test.—C. P. Ambler maintains that the use of tuberculin with proper precautions is the most efficient remedy we have in the fight against tuberculosis, and that is a most valuable early diagnostic test. A tuberculin test will frequently clear up the diagnosis where without it the condition would have remained obscure until the disease had become more advanced, and valuable time had been lost. Experience shows that the more recent case will give a better reaction and to a smaller dose than will one more advanced. All other available means, however, should be first exhausted; not because the test is dangerous or aggravates the disease, but because the depression, fever, etc., of the reaction are not desirable if they can be avoided, and this is especially true in tuberculosis. It is particularly useful, he says, in joint troubles, bone disease, persistent wasting without pulmonary symptoms, chronic pleurisy, bladder trouble, and especially in adenitis. Ambler thinks that the slowly increasing method of using the test is faulty, as sometimes producing a tolerance that interferes with the reaction, and himself gives in the average adult case 2 mg. at the first injection, preferably late in the evening, and continuing the temperature record begun several days before at three- or four-hour intervals for two days more. If no reaction has then occurred, 5 mg. is given on the third day. The tuberculin is diluted with an 0.5 per cent. solution of carbolic acid and filtered sterilized water; the local discomfort is slight. The general and local reactions are described, the symptoms are sometimes severe, but may be very slight. The most characteristic sign is the change in temperature. The reaction, as has been said, is less positive in the more advanced than in the recent cases, a certain degree of tolerance or partial immunity having been gained. In conclusion, Ambler reiterates his belief in the efficacy, safety, and positive diagnostic value of a properly conducted tuberculin test, and says that, while a failure to react is not proof positive that the disease does not exist, a clearly defined action must be accepted as diagnostic proof of the existence of tuberculosis.

The Metric System.—The advantages of the metric system over the present measurements used in medical prescribing are pointed out by W. A. Jolley, who also gives details of methods to convert the measures now in use to the metric measurements. The convenience of the system is shown by a number of practical examples. He also gives a table by which the tablet triturates in common use can be prescribed according to the metric nomenclature, and shows how to use this system in prescribing ointments and liquids. One advantage of the system is the facility with which it can be adapted to the dosage required for children. Consider as 20 the age of an adult, and use that age as the denominator and the child's age as the numerator. Let the dosage for an adult be the total required in a mixture containing 100 c.c., then allowing 5 c.c. for a teaspoonful, this will be the dose for a child 1 year old. For a child 2 years old twice as much, and so on up to the adult. Actual practical work with the adaptation of the common measures to the metric equivalents will soon produce familiarity with prescribing by this method.

The Lancet, May 4, 1907.

Animal Blood-Serum in Surgery.—Some preliminary notes are offered by W. Stuart-Low on this subject. He has had some recent and satisfactory experiences with the healing of wounds under an oiled-silk dressing, a revival of a practise which was given up long ago. In thinking over the matter, he came to the conclusion that the good results were due to the blood serum or lymph and the assistance given to the surface circulation. Dry dressing in contact with a healing part absorbs the normally exuding serum and becomes adherent to the growing tissues, and thus blocks the exudation and therefore the surface circulation and dries the granulations. The oiled silk does not, but allows a constant exudation of serum from the surface vessels, and being itself nonabsorbent keeps the wound always bathed in serum. Such a surface serous bath prevents sepsis and aids superficial circulation in the healing region. In the one case the growing tissues are continuously having the blood serum sucked from their surface, whereas in the other case this is not so, there being always a layer, even though sometimes only a thin one, of blood serum maintained upon the healing area. Low simply washes the protective in sterile water or boric solution before applying it to the wound. In order to have a supply of serum on hand, he procures supplies of fresh beef blood, which he allows to clot, and siphons off the clear

supernatant serum at the top of a tall cylindrical vessel. The blood supply from the butcher's is renewed every three days, and on alternate days the serum is drawn off and placed in smaller receptacles. This serum is used to wash and dress wounds. It is alkaline in reaction, and from albuminous matters held in solution has a slight viscosity that gives it to a considerable degree air-excluding, and to a lesser degree adhesive, covering, and protective properties which are all conducive to healing. It is now admitted by all pathologists, too, that normal blood serum possesses restraining influences on bacterial growth because of the antibodies it contains, and Sir A. E. Wright's researches have proved that blood serum also contains those substances which have the marvelous power of preparing microorganisms for ingestion by the white blood corpuscles—viz., opsonins.

Primary Sarcoma of the Liver in a Child Aged Four and a Half Months.—The case is reported by E. W. Carmichael and H. Wade. The growth was of the round-celled variety. The abdomen enlarged rapidly, an increase of four and one-half centimeters taking place in the circumferential measurement at the level of the umbilicus in three days. There was no associated emaciation, no vomiting, no diarrhea. There was a marked degree of infiltration of the whole organ by the neoplasm, the few liver cells which remained being in a state of extreme degeneration. Only two cases have been recorded in younger patients. The patient was admitted to hospital on account of swelling of the abdomen—nothing more. This, as stated, increased so rapidly that a laparotomy was done, under the idea that some inflammatory process was present. The liver was found to be of a mottled purple color, soft and elastic in consistency. A trochar and cannula were inserted deeply into the substance of the organ, but the enlargement was found uniform throughout. The child died in twelve hours. The investigation of this case would seem to show that from the clinical standpoint primary sarcoma of the liver in children, although of rare occurrence, presents definite characteristics, which, although simulating an acute infective condition of that organ, are sufficiently distinctive to warrant a diagnosis of a malignant condition being made.

The Opsonic Power of the Serum with Reference to the Meningococcus of Cerebrospinal Fever Occurring in the Belfast Epidemic.—A series of sixty-three determinations of the opsonic power of the serum in cases of cerebrospinal fever occurring in the recent Belfast epidemic is tabulated by T. Houston and J. C. Rankin. The deductions which the authors seem inclined to draw from their tabulated results are as follows: (1) From the sixth day onwards all the cases examined (with one exception on the seventh day) showed an opsonic index of over 4; several of the cases from the second day onwards also gave an opsonic index of much above 4. (2) The opsonic index seems to be a more delicate test of infection than an agglutinative experiment (dilution 1 in 3, incubator temperature, limit 15 minutes); the agglutinative effect was never noticed until the index reached five times the normal, while after that, with one exception, it was always well marked. (3) The combination of this agglutinative effect and the opsonic determination will furnish in this disease a specific test of great value in diagnosis. The low opsonic power always found in normal or non-infected sera, so that even when moderately thick emulsions are used two or three cocci were the maximum found in any leucocyte, and the uniform absence of all agglutinative effect in all preparations containing normal serum forms a striking contrast with the very high opsonic effect found in preparations containing the serum from all cases of the disease on or after the sixth day and in several cases before this date, such preparations always showing leucocytes packed with cocci and also dense clumps of cocci not yet ingested. In fact, the picture is so characteristic that a diagnosis could in the majority of cases be made by simply mixing some washed corpuscles, serum from the patient, and meningococci, and incubating the mixture for a short time without the use of any control. Usually opsonic determinations for purposes of diagnosis require most careful and accurate counts, while in the case of this disease a glance at the preparation is usually sufficient. (4) From the very definite nature of the results obtained it would seem likely that this method will prove of value: (a) in diagnosing sporadic cases of the disease; (b) in settling the etiology of posterior basic meningitis in infants, and (c) in determining the nature of a doubtful coccus. In the presence of an epidemic it will always be possible by this method to decide whether or not a coccus isolated from a case is the true meningococcus. Several pathologists are of opinion that some strains of the meningococci may be Gram-positive. This test would, the author believes, definitely settle the nature of such a coccus. In this epidemic two Gram-positive cocci isolated from the blood and one from the cerebrospinal fluid proved not to be meningococci when tested by this method, although at first sight they closely resembled it. (5) Two of the main elements on which the process of immunity in this disease depends are the opsonic and agglutinative powers of the serum. A therapeutic serum therefore having no opsonic or agglutinative power on the meningococcus could not be expected to have much value as a remedial agent in this disease. Several samples of serum on the market were tested by the author and found to have neither opsonic nor agglutinative power.

Berliner klinische Wochenschrift, April 29, 1907.

Exophthalmic Goiter and Pseudoleukemia.—Caro suggests that possibly exophthalmic goiter and pseudoleukemia may have something in common and offers the opinion that the pseudoleukemic stage may be the result of the general condition of intoxication that we term Basedow's disease. He relates the history of a case in point in which death took place under evidences of hyperthyroidism after a partial strumectomy. An evidence of the severity of the autointoxication is the fact that the patient's urine taken before the operation and injected into a guinea pig produced no symptoms, but the same quantity taken during the period of hyperthyroidism and injected into another guinea pig produced death in a comparatively short time. Another noteworthy feature of the case was the high percentage of iodine present in the thyroid gland.

Münchener medizinische Wochenschrift, April 23, 1907.

The Röntgen Ray Treatment of Exophthalmic Goiter.—Freund prefers the medical treatment of this condition to surgical procedures and states that he believes the *x*-ray treatment to be the most satisfactory of all. He describes five cases of his own in which either great improvement or an apparent cure was effected by this means. In three of the cases no other remedial measures were employed, so that the complete relief of the symptoms that resulted must either be attributed to the action of the rays or it must be taken for granted that the condition had undergone spontaneous retrogression, the latter being an assumption which the author does not believe is justifiable. In another case the symptoms disappeared only after the radiotherapy had been begun, and in the fifth case, although great improvement in the subjective conditions had been effected, the ultimate result is not yet certain. The author believes that the Röntgen rays fulfill the causative indications in exophthalmic goiter, since they cause the abnormally active thyroid gland to diminish in size. They always exert a beneficial influence on the body weight and on the nervous manifestations, while the other symptoms, such as heart murmurs and exophthalmos, may also be caused to disappear. The prognosis is best in dealing with soft vascular goiters, which may completely subside under the treatment, while in the cases with hard nodular growths this is less likely to occur. The effects are more satisfactory the shorter the duration of the case has been.

A Case of Drug Eruption with Unusual General Manifestations.—Gregor, in speaking of drug eruptions, reports a case that is unusual on account of the severity of the general symptoms that accompanied it. The patient was a woman forty-two years of age, suffering from paranoia, accompanied with marked motor excitability, in order to control which various sedatives and hypnotics were administered. In consequence of the administration of two doses, given twenty-four hours apart, of 2 g. each of chloral hydrate, an eruption appeared, covering most of the body and consisting of dark red maculopapular lesions, which in some spots were hemorrhagic. About the face large bullæ filled with serous fluid developed, and it was something over two weeks before the symptoms had entirely subsided. The appearance of the rash was accompanied by a rise in temperature, which on the eighth day reached 39.8° C., and other manifestations were hemorrhagic bronchitis, conjunctivitis, and marked somnolence.

Deutsche medizinische Wochenschrift, April 25, 1907.

The Staining of the Spirochæta Pallida.—Giemsa contributes a very detailed disquisition on the theoretical and practical considerations involved in staining microorganisms and discusses particularly the demonstration of the *Spirochæta pallida*. He says that of the many methods that have been devised for this purpose the most satisfactory for routine clinical use is the modification of the Giemsa stain, suggested by Preiss. Giemsa, however, presents a further improvement of this method, which he considers superior and by means of which he says it is possible to secure satisfactory preparations in about three minutes. The tissue juice obtained under proper precautions is smeared on a slide and is fixed by passing three times through a flame. The slide is held in a clean forceps and

the freshly prepared staining fluid, consisting of 10 drops of the stock Giemsa solution in 10 c.c. of distilled acid-free water, is poured on it. The slide is held about 5 cm. above the flame until steam begins to rise, and is set aside for fifteen seconds. The stain is poured off and the film is immediately flooded again; the warming is repeated, the slide is set aside for fifteen seconds, and the procedure is carried out four times in all, except that the last time the stain is allowed to act for a minute. The preparation is quickly washed off in running water and is then ready for examination. It is of the greatest importance that all the glass ware and also the forceps used be scrupulously clean and the presence of even the minutest traces of acid must be avoided.

The Treatment of Ischemic Muscular Contractures.—Kleinschmidt says that Volkmann's original teaching in regard to the paralyses with contractures following the application of tight bandages to the extremities was that the muscular lesion was the result of deficient oxygenation. The paralysis was a direct consequence of injury to the muscle itself and a primary affection of the nerves was to be excluded from the etiology of the condition. Kleinschmidt believes that this view must at least be modified owing to animal experimentation that has been carried out by several authors, and considers that it is no longer possible to maintain that affections of the nerves play no part in the development of the condition. In addition to the restricted supply of arterial blood the stasis in the veins is an important factor, and in some instances the condition may be caused in severe injuries, such as fractures, without any compressing bandage having been applied. Particularly in fractures about the lower end of the humerus should careful investigation be made in order to determine whether the large vessels have been injured or are compressed. The treatment of contractures of this sort may be carried out according to two methods: One of these consists in resecting portions of the long bone or bones involved in order to shorten the distance to be covered by the muscle or its tendons, and the other consists in lengthening the tendons by a plastic operation on each one. The author prefers the former method, as the latter especially in injuries of the forearm is likely to require operation on a large number of tendons. He describes one case in which resection of the radius and ulna for this condition was performed with very good ultimate functional result, although the patient's recovery was delayed through the non-union of one of the resected bones. To correct this condition at a secondary operation a portion of periosteum was taken from the patient's own tibia and wrapped like a cuff about the two juxtaposed fragments, union promptly following this procedure.

French and Italian Journals.

Study of Four Cases of Hereditary Syphilis in the Fetus.—C. Fouquet has studied the pathological findings in four fetuses that died of hereditary syphilis at birth. The author gives us his conclusions. The more we search for the *Spirocheta pallida* in the tissues the more are we convinced that it is the pathogenic agent in syphilis. All the organs may contain the organism in cases of hereditary syphilis, even when macroscopically they appear healthy. The abundance of the parasites in a viscus bears a relation to the extent and gravity of the lesion in that viscus. In three cases in which there was an infection a short time before pregnancy, parasites were very abundant. When syphilis in the parents was of long standing the lesions were less marked and the parasites fewer. In many cases the parasites are so abundant that the product of conception succumbs before birth to a true syphilitic septicemia. Not all of the parasites die, and it is allowable to ask what becomes of them. In all probability their number and virulence grows less under the influence of antisyphilitic treatment. Some become dormant either as spirilla or in some unknown form and are capable at any time of taking on new activity. When the organisms reach the ductus coledochus they set up a true edematous inflammation of the bile ducts, which may be the cause of icterus in the newborn. In the kidneys, especially in the glomeruli and uriniferous tubules, they may be present in the urine. When in abundance in the spleen they explain the destruction of the red corpuscles, and the anemic and pseudoleukemic forms of syphilis. In the testicle they explain the infection of the spermatoid. A practical conclusion is that every child of syphilitic parents should be treated, whether they show any evidence of syphilis or not, since the parasites may be dormant.—*Bulletin de la Société d'Obstetrique de Paris*, January 17, 1907.

Curves of Weight and Temperature in Gastrointestinal Diseases of Infants.—Lucien Rivet has made a study of the curves of temperature and weight in infants afflicted with gastrointestinal affections as they were seen in the Children's Hospital. He gives us the conclusions derived from his studies and the use of different methods of feeding. The water diet is the best method of combating these diseases, and at the end of twenty-four to forty-eight hours the substitution of cereal gruels. Vegetable soups retard the appearance of emaciation, but do not prevent it, and may cause retention of chlorides and anasarca. The emaciation may last a long time after the disease is cured and may progress to a cachectic condition. Secondary infections must always be taken into account since they may produce true septicemia or gland suppurations. Flesh may be gained under any diet, but the best is breast milk. In other cases raw meat or cereals are useful. In debilitated subjects with an hereditary taint it is difficult to cure the lesions under any diet, but they go on to cachexia and emaciation.—*Revue Mensuelle des Maladies de l'Enfance*, February, 1907.

Meningo-Cerebellar Syndrome in Tertian Malaria.—Ficucci records a case in which a child of fifteen years of age, with alcoholic heredity, subject to epilepsy, was attacked by symptoms of general weakness, rigidity, and pain in the cervical region of the column. König's sign, anisocoria, staggering walk with a tendency to fall backward and to the left, intense headache, and vomiting. He had quotidian fever, which fell after ten hours with sweating. All the symptoms mentioned were worse during the fever, remitting between the attacks. The blood examination showed tertian parasites. After two weeks' treatment with quinine the symptoms disappeared. Lumbar puncture and the ophthalmoscope gave no grounds for a diagnosis of meningitis. The intimate connection of the symptoms with the fever, absence of paralysis, clearness of the mind, excellent effects of the quinine, and quick recovery of the patient supported the diagnosis of malarial infection, and excluded tubercle and meningitis of the cerebellum.—*La Riforma Medica*, March 2, 1907.

The Employment of Antidiphtheritic Serum in the Diphtheria of Birds.—Battier reports an epidemic of diphtheria which attacked birds housed in his aviary. Three of the birds had already succumbed to the disease when it occurred to the writer to try the effect of antidiphtheritic serum on the remaining birds. The result of the injections of 1 c.c. of this serum were excellent. Besides this treatment the throats were cleansed with antiseptic lotions. This treatment put an end to the epidemic and the birds recovered. The incident is interesting from several points of view. From the standpoint of comparative pathology one may ask if human diphtheria is not a modified form of the diphtheria of birds, the human antidiphtheritic serum having an effect on the latter. From the viewpoint of general pathology the observation shows the tonic effect of the antidiphtheritic serum. Finally by this treatment these epidemics which are so common and of such importance to the bird fancier can be quelled.—*Le Bulletin Médical*, December 29, 1906.

Latent Appendicular Alterations in Cases Cured Medically—P. Fiori describes cases of appendicitis that were supposed to have been cured by medical means in which there were continuous symptoms that indicated that the cure was only apparent. In three of the patients the symptoms were slight, while in the fourth they were of severe nature. In the slight cases the symptoms lasted but a few days, while in the severe one treatment extended over a month or more. In the slight cases the recurrence occurred in two or three months after the first attack, and the author calls our attention to the dangers of operation in the interval and the inadvisability of allowing the patient to believe himself entirely cured when the cure is only apparent and operation may be needed at any moment. Late observations demonstrate the accord between the clinical symptoms and pathological findings and the advantages to be derived from examination of the blood.—*La Riforma Medica*, December 22, 1906.

Poisoning by CO and CO_2 and Pneumonic Infections.—Cesare Biondi and Francesco Leoncini, having observed two cases of accidental poisoning by CO and CO_2 in which a pneumonic infection was precipitated by the poisoning, have experimented on dogs to ascertain whether there were evidences that the asphyxia produced by gas poisoning continued for some hours would so reduce the resistance of the tissues as to render them peculiarly susceptible to the action of the pneumococcus. The animals were subjected to inhalations of CO and CO_2, and afterwards injections were made into the trachea of a moderately virulent culture of the bacillus of Fraenkel. The conclusions at which the authors arrived were that both of these gases so reduce the resisting power of the lung tissues as to make the animal an easy prey to the infection. Animals treated by the same injections without gas poisoning did not take pneumonia.—*Rivista Critica di Clinica Medica*, December 8 and 17, 1906.

Hysterical Tachypnea with Organic Respiratory Affection.—Mercurio Candela says that in hysterical cases the severe symptoms frequently appear to be due to organic causes. This is especially so with respiratory symptoms. Hemoptysis, dyspnea, and tachypnea may occur. Hysterical dyspnea is due to four causes—spasm of the glottis, paralysis, or contracture of the diaphragm, spasmodic condition of the bronchi, and thoracic hyperesthesia, or gastric disturbances. These symptoms supervene in debilitated persons. Glottic spasm is not rare, and is so severe in some cases as to necessitate tracheotomy. The attack comes on suddenly, with frequent, shallow respiration, and incomplete movements of the abdomen. The patient cannot speak or swallow, but is conscious. The pulse becomes quick and the extremities covered with cold sweat. In paralysis of the diaphragm there is retraction of the epigastrium and hypochondrium and absence of abdominal movements. Spasm and contracture of the diaphragm is rarer. It may be clonic, or in the form of hiccough, and vomiting may occur. Tachypnea should not be confounded with dyspnea, as the first may occur without the second being present. The patient breathes very rapidly without any difficulty of respiration, and while lying quite calm and comfortable. Respirations may be as fast as 180 to the minute, and attacks may appear several times a day and last for some hours. Temperature and pulse will show no variation. Suggestion or distraction of the patient's mind will stop the attack, and it disappears in sleep. The author describes a case of this kind in which the hysterical symptoms had continued for some time in a man, when an organic disease of the pleura supervened which caused his death.—*Giornale Internazionale delle Scienze Mediche*, January 31, 1907.

Experimental Chronic Tuberculosis in the Rabbit.—Askanazy has recently performed some interesting experiments on animals in relation to the production of chronic tuberculosis. Since the discovery of Koch, innumerable inoculations have been made in rabbits and guinea pigs in order to produce experimental tuberculosis. Askanazy in his experiments has especially insisted upon one condition as being necessary for the attainment of success. In order to provoke processes closely resembling the affection in man, he considers it important to inoculate very few bacilli and to seek to produce pulmonary phthisis without appreciably affecting any other organs. Askanazy has injected extremely small quantities of the bacilli of the bovine type in the vein of the ear of a rabbit. The animal seemed in good condition for several months, but finally it began to lose flesh. At the end of eight months it died. Autopsy revealed the existence of a chronic tuberculosis of the lungs without tuberculous focus in any other organ, save a few miliary tubercles in the hypertrophied right kidney. The left kidney had been previously extirpated.—*La Presse Médicale*, January 2, 1907.

The Galvanic Current of High Intensity in Trigeminal Neuralgia.—Francesco Blasi, after having tried the continuous current of ordinary intensity in trigeminal neuralgia, and found it successful in obtaining a cure only in the slighter cases, began the use of a current of high intensity, used with great care to prevent any shock due to interruption of the current. He obtained the best of results in the exceedingly severe cases that are not relieved by any other form of treatment and that render the life of the patient unbearable. The apparatus in use must be capable of giving a current of very high intensity, but of the greatest smoothness. The ordinary machines are useless for this form of treatment. The current must be increased very smoothly and gradually and reduced in the same way. The positive pole is placed over the painful point or over the entire surface supplied by the trigeminus, and should be a large flat plaque. Several thicknesses of gauze must be placed over the skin so as to prevent electrolytic effects on the skin. The sittings should be from twenty to thirty minutes long when the current is very intense, or of one hour if of less intensity. It has a calming, paralyzing action on the nerves. In the neighborhood of the electrode there develop by secondary action acids which act on the ultimate ramifications of the sensitive nerves, diminishing irritability.—*Annali di Elettricita Medicale Terapia Fisci*, December, 1906.

Prophylaxis of Syphilis.—G. Petges considers prophylactic measures against syphilis in the light of recent discoveries and experimental researches. As to the excision of the chancre, it may lessen the amount of the secondary phenomena, and thus by preventing the patient from taking a thorough mercurial treatment early in the disease, may precipitate late manifestation of great severity. For these reasons it is not to be advised. Previous application of mercurials, that is, before a dangerous contact, has been shown to be of use in experimental cases. Friction with an ointment of calomel, thirty-three parts to one hundred parts of lanolin, an hour before inoculation has prevented infection. This may be of use to physicians, nurses, and laboratory workers who must handle dangerous material, but as to the general public taking any practical advantage of such prophylaxis there is very small prospect. A false security would be worse than doing nothing. The only true prophylaxis, then, must be by abstention from dangerous contact.—*Gazette Hebdomadaire des Sciences Médicales*, February 3, 1907.

Uterine Fibroma Complicated with Grave Anemia.—Paul Petit tells us that when a patient is near the menopause and is suffering from fibroma uteri, if there are no signs of acute malignant degeneration, and no marked symptoms of compression, it is wise to abstain from operation, even if there is a severe anemia. Expectant treatment by rest, medication, and electrolysis to restrain hemorrhage are the best measures to use. If, on the contrary, the patient is in active genital activity and there are serious symptoms, it is best to operate. If she is anemic and there is degeneration of the internal organs, as a result of frequent and severe hemorrhage, it is necessary to temporize and to use supportive treatment until the patient is in a sufficiently good general condition to bear the strain and shock of operation. Hydrochlorate of hydrastine is the best hemostatic, used by hypodermic injection. Locally tampons of a solution of chloride of zinc, fifty per cent., are an efficient hemostatic, cause no pain, and are exceedingly well borne. When the patient is prepared for operation, if the tumor is hard, benign, hemorrhage is only menorrhagic, and development abdominal, a double castration will produce rapid atrophy. If the serious conditions mentioned are present a hysterectomy should be done.—*Gazette des Hôpitaux*, February, 1907.

Chloroanemia of Infants.—Méry says that there are certain cases of anemia which arise without any appreciable cause, or which seem to arise from digestive troubles, and yet are not cured by changes in foods, that are much better affected by medication containing iron. The best form to administer is the protoxalate of iron. The symptoms are pallor of skin and mucous membranes, apathy and intellectual slowness, and weakness, but without emaciation. There is no enlargement of the glands or spleen. There may be a slight elevation of temperature and insomnia. There is a marked decrease of the hemoglobin, while the number of blood corpuscles is not much changed. In the infant, soon after birth, the amount of iron that is stored up in the tissues is much greater than in the adult. There is little iron in milk, and this stored-up iron is used in place of that which would be furnished by the food. This iron is probably contained in the hemoglobin to a great extent, while some of it is in the oxydases, or blood ferments, and here it exercises a very complicated function.—*Journal de Médecine et de Chirurgie Pratique*, February 10, 1907.

Spontaneous Cure of Tænia Nana.—Scipione Riva-Rocci states that tænia is less common in infants and children in Italy than in other countries. Concetti found but thirteen cases among 40,000 children observed during six years. This small proportion is not so remarkable as it seems when we remember that it is the custom to treat these cases at home without the aid of a physician. Tænia is the rarest of all tapeworms according to the published literature. But the author found that in many cases the parasite became unrecognizable a few hours after the passage of the stools, all that was left being shreds that appeared very much like the ordinary shreds of mucus that are observed in gastrointestinal diseases or that may be mistaken for oxyuris. The parasite becomes rapidly decomposed, and even microscopic examination of stools will not reveal the true nature of the threads. Preservation of the feces by solutions of formalin were not successful in preserving the parasite intact. The author describes a case that came to him in a healthy child that had manifestations of an acute gastrointestinal catarrh, and it was the microscopic examination of the stools that showed the presence of tænia nana. In some of the stools examined it was found that the parasites were so changed that they were unrecognizable. This was the case in stools passed after the second day of the disease, although no anthelmintic had been given. There were absolutely no symptoms that could be referred to the presence of the worms and no symptoms of a chronic gastrointestinal trouble. The disease was recovered from without treatment, and observation extending over four years has not shown any return of the worms. The author refers the cure of the disease to the production by the acute catarrh of the intestine of some substance that was poisonous to the parasite.—*Rivista di Clinica Pediatrica*, January, 1907.

Book Reviews.

DICTIONNAIRE DE MÉDECINE ET DE THÉRAPEUTIQUE MÉDICALE ET CHIRURGICALE, Comprenant le Résumé de Toute la Médecine et de Toute la Chirurgie. Par les Docteurs E. BOUCHUT, Médecin de l'Hôpital des Enfants Malades, Professeur agrégé a la Faculté de Médecine de Paris, et ARMAND DESPRÉS, Chirurgien de l'Hôpital de la Charité; Professeur agrégé à la Faculté de Médecine de Paris. Septième Édition, Revue et Mise au Courant de la Science, par les Drs. G. MARION, Professeur agrégé a la Faculté de Medicine de Paris, Chirurgien des Hôpitaux, et F. BOUCHUT. Paris: Felix Alcan, 1907.

IN the seventh edition of this encyclopedia of medical science, the revisers have brought the subject matter thoroughly up to date, the revision being most carefully done in the articles relating to bacteriology, opotherapy, orrhotherapy, hygiene, and electrotherapy. In the surgical articles the newest operative measures have been fully described, and many new instruments and prosthetic appliances have been pictured. The therapeutic indications for each disease are given with great care, and other subjects fully treated are those included under the heads of obstetrics, ophthalmology, dentistry, materia medica, and mineral waters. To the reader of French the book will prove very useful as a work of ready reference, and as a dictionary to define various French terms occasionally employed in English medical literature.

L'ÂME ET LE SYSTÈME NERVEUX. Hygiène et Pathologie. Par AUGUSTE FOREL, Ancien Professeur de Psychiatrie a l'Université de Zurich. Paris: G. Steinheil, 1906.

THIS is a semipopular treatise on the mind and nervous system, with special reference to the prophylaxis of psychical disorders. Professor Forel's writings on this theme have already had a wide circle of readers. His recent book, particularly "La Question Sexuelle, Exposée aux Adultes Cultivés," has attracted wide attention, and is one of the best examples of semipopular medical writing "for intelligent adults." Beginning with a sketch of the elements of psychology, the general anatomical facts pertaining to the brain, the cord and the nerves, Forel leads the reader by very easy gradations into the mysteries of mental pathology. He dwells upon the causes of nervous and mental disease, and thus brings the reader to the rules for their prevention. Here he speaks of every phase of life, of school life, family life, etc., and preaches the doctrine of moderation in living, in work, and in pleasure, as a mode of preventing insanity and nervous affections. He closes with a chapter on the sociological or public aspect of the hygiene of the nervous system.

The book should be translated into English. It would make most interesting reading for our cultured patients, and also would bring its useful teachings more generally before the American medical profession.

THIS LABYRINTHINE LIFE. A Tale of the Arizona Desert. By GEORGE ALEXANDER FISCHER, Author of Beethoven: a character study. New York: B. W. Dodge & Co., 1907.

THIS volume describes camp life in the desert. It is not only the tuberculous, but also the overworked and those on the verge of nervous prostration, who might benefit much by a sojourn in the open air of the desert. But the conditions must be favorable, and many hesitate to avail themselves of this method of treatment through ignorance of the conditions involved; and some who do undertake it make a failure of it for the same reason. What these conditions are will be found fully discussed in this tale of the Arizona desert. Physicians will be benefited by reading the volume, and many families will welcome the information so entertainingly provided therein.

A TEXT-BOOK OF OPHTHALMIC OPERATIONS. By HAROLD GRIMSDALE, M.B., F.R.C.S., Ophthalmic Surgeon and Lecturer on Ophthalmic Surgery to St. George's Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital; and ELMORE BREWERTON, F.R.C.S., Ophthalmic Surgeon to the Metropolitan Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital. Chicago: W. T. Keener & Co., 1907.

THE volume is one of 340 pages, is well printed and quite fully illustrated by simple, rather crude, original, and very effective drawings. Only two or three of the illustrations are borrowed from other works. The authors have entered upon their task without indulging in the time-honored custom of writing a preface, and have omitted appendices. The subject is treated in a masterful, terse, direct manner. The work is not exhaustive, the operations on the eye and its adnexa that are of greatest value only being described. A short bibliography is found at the end of each chapter. Fifty-one pages are devoted to a description of the anatomy of the extrinsic ocular muscles, physiology, and the operations on these muscles. Then follow chapters on operations for ptosis, operations on the lids, enucleation and its substitutes, operations on the lacrymal apparatus, bones of the orbit, cataract, after cataract, for glaucoma, operations on the cornea, sclerotic, and iris. The value of each procedure, according to the opinion of the writers, is given. Much consideration is given to the more modern methods. The book is evidently written by men of experience, and its teachings can be relied upon. It will find its widest usefulness as a ready reference work for the busy ophthalmic surgeon.

EXPLORATION DE L'APPAREIL URINAIRE. Par le Dr. GEORGES LUYS, Ancien Assistant du Service des Voies Urinaires à l'Hôpital Laribosiere; Lauréat de la Faculté de Médecine de Paris. Paris: Masson et Cie, 1907.

THE diagnosis of affections of the urinary apparatus is becoming more and more nearly an exact science, thanks to the new methods of precision which are now used in the exploration of the urinary passages. Among those who have done the most to further this branch of diagnostic science—Nitze, Leiter, Albarran, Kelly, Valentine, and others—the author of the work before us holds an enviable place, his modification of the urethroscope having done much to popularize the use of this valuable instrument in France, and his ingenious method of separation of the urine having greatly facilitated the diagnosis of renal lesions. In this book Dr. Luys treats in turn of all the methods employed in the examination of the urinary tract, describing in detail the various instruments and procedures and illustrating them with numerous figures in the text and five excellent colored plates of the urethroscopic and cystoscopic images. The book is divided into four parts: Exploration of the urethra, exploration of the bladder, exploration of the ureter and renal pelvis, and exploration of the kidney itself. The work treats not only of instrumental examination, but of every method—chemical, manual, clinical, and instrumental—which may aid the surgeon in his investigation of the urinary organs. It is, indeed, a complete treatise on the diagnosis of diseases of the urinary tract, valuable alike to the specialist and to the general practitioner. It is the most complete, as it is the most recent, work of the kind published in any language and is one which no genitourinary surgeon and no diagnostician can well dispense with.

AIDS TO MEDICAL DIAGNOSIS. By ARTHUR WHITING, M.D., M.R.C.P., Physician to the Tottenham Hospital and Assistant Physician to the Mount Vernon Hospital for Consumption and Diseases of the Chest; Lecturer in, and Dean of, the North-East London Post Graduate College. New York: William Wood & Co., 1907.

THIS little volume is written from the clinical, rather than from the pathological, standpoint; and appeals to the reasoning powers, instead of taxing the memory with a multitude of diagnostic minutiæ. The book is not intended for beginners, but for those who already have some knowledge of systematic medicine. To such it will prove useful in affording a help in the differentiation of diseases presenting somewhat similar symptoms.

AIDS TO DENTAL SURGERY. By ARTHUR S. UNDERWOOD, M.R.C.S., L.D.S. Eng., and DOUGLAS GABEL, M.R.C.S., L.R.C.P. Lond., L.D.S. Eng. Second Edition. New York: William Wood & Co., 1907.

THIS compend covers the subject of general dental surgery, omitting all purely manipulative procedures. While obviously intended for dental students, the book contains material that may be of interest to the physician.

AIDS TO THE DIAGNOSIS AND TREATMENT OF DISEASES OF CHILDREN. By JOHN MCCAW, M.D., R.U.I., L.R.C.P. Edin., Physician to the Belfast Hospital for Sick Children. Third Edition. New York: William Wood & Co., 1907.

THIS is a very complete epitome of the Diseases of Children. In addition to the chapters on the diseases of the various organs and systems of the body, there are important introductory sections dealing with the anatomy and physiology of infancy and childhood, and with the hygiene and diet of infants and children. The volume contains more information than is generally found in compends; important facts are duly emphasized, and there are several tables containing much matter in a small space. In this new edition will be found articles on Friedreich's ataxia, thrombosis of the cerebral sinuses, influenza, congenital hypertrophic stenosis of the pylorus, food fever, Still's disease, rheumatoid arthritis, acute pyelitis, and a chapter on the diseases incidental to birth. The writer has carefully gleaned from the best current literature on pediatrics, and has produced a book which will be of real service to students and practitioners.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Nineteenth Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the MEDICAL RECORD.)

PRESIDENT B. K. RACHFORD, M.D., OF CINCINNATI.

Tuesday, May 7—First Day.

The Use in Practice of the Theoretical Resources Provided by Percentage Feeding.—Dr. CHARLES HUNTER DUNN, Boston, said the chief step in advance had been the chemical recognition of the component elements of milk and the attempts to imitate nature as exactly as possible; the second great step was the recognition of the individual idiosyncrasies of each baby. The fact remained, however, that the subject of percentage feeding still presented difficulties to the general profession. The failure of modified milk feeding must be due either to limitations in the value of the resources or their improper application, and the writer suggested that it was due to the latter, and presented a plea for more careful use of the methods already in our possession. He thought the difficulties due to two factors: the inherent unsuitability of cow's milk to the digestion of the infant, and the variability of the digestive powers of different infants. Too much stress had been laid upon the first and too little upon the second; we were too apt to attribute the chief rôle to the unsuitability of cow's milk. He referred particularly to the use of the so-called split proteid feeding, and thought that by using whey a very close conformity to human milk could be had. The cereal diluents, he said, contained starch, which was not indicated by nature as desirable for the infant, and in practice the giving of these diluents was often protested against by nature, although, of course, in many the starch would be digested. When the starch digestive function had been developed of course they could be used. The same arguments as those against the indiscriminate use of cereal diluents were applicable to the widely advocated use of the alkalies, lime water, sodium bicarbonate, etc. Any of these artificial methods might have a place in certain individual cases, but must be due to the individual idiosyncrasies of digestion.

Some Conclusions from our Knowledge of the Proteids of Milk.—Dr. THOMAS S. SOUTHWORTH, New York, spoke of the early misconceptions concerning the proteids of milk and the gradual steps of enlightenment which began only with chemical analysis. The endeavor was made to imitate breast milk closely by the so-called modified milk, but it was soon found that many infants were not able to digest the modified milk except when modified to each individual case. There were many difficulties in the way of knowing the composition of breast milk, and therefore of comparing it with cow's milk, and our chief knowledge of cow's milk was derived from commercial, not medical, investigation. The writer referred to the close analogy between cheese-making and human digestion of milk; the important compounds formed with casein by ferments, alkalies, and acids, and the necessity for the recognition of these compounds, both as chemical entities, and of the part they play in facilitating the digestion of cow's milk. The real difficulty in infant feeding was not with the digestion of casein but of paracasein. Lactate of casein was readily digestible, as shown by the use of buttermilk, which had had less vogue in this country than abroad. Decalcified casein was easier of digestion, and sodium citrate made milk more digestible by decalcifying it. The writer thought a new departure was necessary if students were to learn to feed intelligently and be enabled to overcome the difficulties they met with in practice. An understanding was necessary of the physiological and the pathological digestion of the elements of cow's milk if empiricism was to give way to intelligent scientific methods in infant feeding.

Cane Sugar Feeding in Its Relation to Some of the Disorders of Childhood.—Dr. CHARLES G. KERLEY of New York read this paper. The study was undertaken as the result of an impression the writer had received by the observation of many children that cane sugar was not without harm to many. There was a class of cases defined as sugar susceptibles, usually children of rheumatic or gouty ancestry, with one characteristic peculiar to all, a tendency to recurrence and to chronicity. He included those who had recurrent persistent colds, asthma, urticaria, eczema, rheumatism, and recurrent vomiting. Seventy-eight cases comprised the series, fifteen from his own patients whom he had cared for from infancy. Recurrent vomiting in 8; eczema, 7; asthma, 4; frequent colds, 17; chorea, 11; rheumatism, 4; rheumatism and endocarditis, 6; urticaria, 2; recurrent bronchitis, 6. More sugar was taken than was for the best interest of the individual cases because of the craving of child life for sweets, and because the sugar-eating habit is so easily acquired. In the majority there was sugar incapacity. When a child was presented for treatment cane sugar was excluded from the diet and a small quantity of saccharine substituted. They very soon adapted themselves to the deprivation of sugar from cereals, and it did not appear to influence their well being or growth. In those suffering from rheumatism, recurrent vomiting, eczema, and asthma, there was also interrupted medication. The most satisfactory results were obtained in the affections of the upper respiratory tract. Abstinence from free sugar in the diet broke up the tendency to recurrent colds in children in whom the removal of the tonsils and adenoids had been without benefit. The writer concluded that free sugar was sufficiently toxic in certain individual infants to produce perversion of function, and in some to allow bacterial invasion, as in acute articular rheumatism and endocarditis.

Dr. THOMAS MORGAN ROTCH, Boston, thought these investigations of Dr. Southworth of great importance as tending to put the subject of percentage feeding on a proper basis.

Dr. FREEMAN, Boston, considered the use of whey fluid one of the most valuable aids in difficult cases, and thought it should be ordered from the laboratories where that was possible. It was important that it had been shown that these recurrent colds in children might be due to indigestion and not to exposure.

Dr. L. EMMETT HOLT, New York, had been following out Dr. Dunn's suggestions with reference to the routine use of whey mixtures for very young infants, and had been surprised to see how it relieved chronic constipation. The proteids could be raised gradually, the fats being kept low, with relief of indigestion and avoidance of troublesome symptoms. He agreed with Dr. Freeman that the mixtures should be ordered from the laboratories. He agreed with Dr. Kerley as to the ill effects of free sugar in the diet of many infants.

Dr. CHARLES G. KERLEY had used the whey mixture extensively for two years, and felt that while it was a very useful measure, applicable in a considerable number of cases, it was by no means a solution of the infant feeding problem, its chief fault being that children did not gain on it. He thought it could not always be relied upon.

Dr. J. P. CROZER GRIFFITH called attention to the recent studies upon the difficulty of digesting foreign albumins, and said the albumins of the cow were necessarily not the same, and not so digestible as those of the mother; there were certain principles in the mother's milk necessary to the digestion of many children, and they could not get along without it.

Dr. F. S. CHURCHILL, Chicago, did not see how anyone who had used the split proteids or whey mixtures could help being enthusiastic believers, because the majority of babies so fed invariably did well. Whey mixture was such a simple food that few babies could fail to digest it.

Dr. Walter Lester Carr, New York, said Dr. Kerley's statement was borne out by his own experience, that whey had a decided place in the feeding of premature infants and congenitally weak children, but that after using it for a time it seemed impossible to get a gain of weight. In eliminating the sugar it must be borne in mind that faulty oxidation might be one of the features.

Dr. Eaton deprecated the habit prevalent in some parts of the country of feeding babies according to a set of tables, without regard to the individual idiosyncrasies. He had used the whey mixtures with great satisfaction.

Dr. Saunders had used the whey mixture for many years with great satisfaction. One of the mixtures with which he had had most rapid gain was that of whey and condensed milk.

Dr. Crandall's experience bore out what Dr. Kerley had said as to the use of the whey mixture.

Dr. Dunn, in closing, called attention to the fact that some of the patients that seemed to do well on condensed milk had done even better when fed on a laboratory prescription of the same composition.

Dr. Southworth added his testimony to the value of the split proteid feeding; he had had excellent results with it.

A Case of Hemothorax; Aspiration, Recovery.—Dr. W. P. Northrup of New York reported this case, the patient having been seen three times by a well-known member of the society, who pronounced it bronchitis. He saw the case after the child had been ill two months. A poorly developed child of five months, pale, respirations 80 a minute; left chest flat; heart displaced to the right; no fever. Taking the infant on a pillow on its back, nothing happened as long as it lay quiet, but when turned toward the right the child had an attack suggesting the cessation of all vital functions. *X*-ray showed the chest filled with an opaque fluid. Two ounces of a black fluid was aspirated, when the pulse improved and the heart returned to its normal position. The fluid was blood, which coogulated quickly in the bottle. A year after the aspiration the patient is doing well, the only cause for anxiety being rapid respiration.

Anorexia Nervosa in Children.—Dr. F. Forchheimer of Cincinnati presented this paper, which referred to the several previously reported cases under somewhat different names, the condition having been usually looked upon as one of the manifestations of hysteria. According to the present state of our knowledge, we were justified in calling it a neurosis. As a rule, the children who have the disease have grown up without discipline, being allowed to choose their own diet. Female, 7 years; mother and father both neurotic; child always had its own way; at the age of 6 made up her mind that she would not eat but certain articles, practically nothing but cheese; none of the stigmata of hysteria were present; she was intelligent and consistent in her responses. Under proper treatment she soon recovered. Female, aged 12; mother and father neurotic; child brought up on artificial food; would only eat pickles and olives; if they tried to get her to eat anything else she vomited. Was very much run down, irritable and cross, backward in studies, cried easily, and slept badly. Under proper treatment she gained fifteen pounds in a few weeks. Male infant, one year of age; mother and father neurotic; father had had syphilis; child had never been ill in any way; breast-fed. From the ninth month attempts made to feed artificially. The child would not take any food. Was taken to the hospital and for four days nothing given by the mouth; then feeding began, but in vain; child would take water, but nothing else. Gavage used for two weeks, when the child recovered. Boy three years old, only child of parents married late in life. Neither of the parents believed in disciplining the child. For some time the boy had been cutting off articles of diet until he would touch nothing for several days, except a piece of fried bacon or a piece of banana. Had a degree of emaciation that the writer had rarely seen surpassed; three weeks later the child died from starvation. The writer believed all these cases could be cured by proper treatment and discipline, especial stress being laid upon discipline. Gavage should be held out as a last resource.

Dr. Charles G. Kerley, New York, had had a case of a four-year-old girl, who always vomited food, even at the table, but who when allowed to eat in the kitchen never had these attacks. The child was finally cured by removal to the house of her aunt and association with other children.

Dr. Putnam, Boston, had often succeeded in the milder forms of this disease by having the parents desist from saying anything about food or trying to force the child to eat.

Dr. J. P. Crozer Griffith referred to a case, the child of a physician, some months over a year of age, who could not be weaned, and in which gavage had to be used, and now at the age of four they still had difficulty in getting the child to take food.

(a) Three Cases Illustrating Typhoid Fever in the First Year of Life. (b) A Case of Articular Rheumatism in an Infant. (c) A Case of Congenital Biliary Cirrhosis.—Dr. J. P. Crozer Griffith, Philadelphia, presented these cases, three cases of typhoid fever, one of five months and the other two of nine months. In the first case there was an excellent opportunity of studying the beginning of the temperature record, and death occurred from intestinal hemorrhage. There was absence of the step-like rise characteristic of the adult's chart. There was positive Widal, rose spots, and enlarged spleen. In the second case, nine months, there was nothing unusual except the instance of relapse, with the opportunity of studying the temperature from the beginning to the end of the relapse. It had been the custom of the mother when putting the baby in the tub to cleanse the mouth with the spigot water. Typical spots and enlarged spleen. Third case, nine months; ordinary course; rose spots and enlarged spleen; the history suggested the possibility of persistent house infection. The child was fed partly by breast and partly by unboiled cow's milk; the bottles had been boiled, but the nipples kept in unboiled cold water. The case of articular rheumatism was a baby five months old, with rheumatism of hands and ankles. Treated with orange juice to exclude scurvy, without effect; under the use of salicylates it gradually recovered. The case of biliary cirrhosis, five months old, jaundice said to have been present from birth; child lost weight steadily. After being brought to the hospital there was intense jaundice; liver much enlarged; everything possible done to make it gain in weight, but in vain. Black material passed from the bowel, which appeared to be decomposed blood. Child became steadily worse and died: autopsy showed typical cirrhotic liver with the duct of the gall-bladder entirely obliterated.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held April 16, 1907.

Dr. Warren Coleman in the Chair.

A Case of Larva Migrans.—Dr. N. E. Brill reported this case. The patient was seen on October 25, 1906, when he entered the hospital because of advanced emphysema and endocarditis. On the dorsum of his hands was noticed an eruption, and, when questioned regarding it, it was found that two and a half years before he had been working in the fields in Florida. One noon he felt an itching sensation on the ankles of both feet, along the inner aspect of the malleoli, and, looking at his ankles, he found an elevated pimple about one-eighth of an inch in diameter and of the same height. The next day the pimple had progressed forwards and upwards for about two inches. The progress of the eruption was steadily onwards and up-

wards until the eruption showed a long line running from the ankle to the knee. It then continued on both legs upward until it reached the groin. It stopped there on the right side. On the left side, however, it went up over the left side of the abdomen, over the thorax and across to the right side, then down the right side of the trunk, down the abdominal region to the axilla, then under the axilla to the back, and then across the back to the left shoulder, down the left shoulder to the arm, then the forearm, and finally to the hand. The eruption appeared to be of parasitic nature. In looking up the literature on the subject Dr. Brill found that the case reported was exactly similar to one reported by Lustgarten under the title of "Creeping Eruption of Lee."

The history of this disorder dated back to 1874, when Dr. R. J. Lee made a communication to the Clinical Society of London with the title of "A Case of Creeping Eruption," the nature of which he could not determine and about which he could get no information. Three dermatologists were appointed, W. Howship Dickinson, Tilbury Fox, and Dyce Duckworth, who were to make further investigations regarding it, especially on the microscopical findings, but their results were negative. In 1884 Lee again presented to the Clinical Society of London a second case appearing in an adult, and he thought that the linear eruption might be due to an "active parasite or animalcule," as he called it. After that no mention was made of this disease until 1890 when Crocker reported a case similar to Lee's. In 1895 Neumann of Vienna showed a wax model representing "a new skin affection," and in the discussion Peterson referred to a communication which showed that Samson had reported "a case of creeping eruption" and had asked in an open letter whether anybody in Russia had seen such a case. He had seen such a case in Southern Russia. These observations were contained in *Vratch,* dating from 1895. In answer to his letter several communications were received, and in one it was stated that in 1888 Sokolow had seen these cases and had isolated from them a parasite which he said was a worm which resembled the larva of a fly. This parasite from Sokolow's patient was submitted to Prof. Cholodkowsky and an entomologist and it was proven to be the larva of the bot fly. In 1898 Kaposi reported a case in Austria and he called it "hyponomoderma," a "skin passage," or tunnel. In 1893 Crocker gave it the name of "larva migrans." In 1902 a doctor in Philadelphia reporting three cases, called the disease "creeping disease of Lee." In 1903 Stelwagon reported another case. In 1904 Hamburger of the Johns Hopkins Medical School reported an additional case occurring in a boy of four years, and recognized it as the creeping eruption of Lee. In 1905 another case was reported from Russia and was called the "linear creeping epidermatitis." The case reported by Dr. Brill he claimed to be the only one reported in the literature of New York.

The eruption was elevated and measured about 2x2 millimeters. It always extended in a linear way, and never spread laterally and preserved the same diameter throughout. It sometimes progressed seven inches in twenty-four hours; at other times it might go no measurable distance. In the case Dr. Brill reported it extended 2.5 c.m. The patient was in the hospital four weeks; when he left the eruption had advanced from the thenar eminence to the back of the first phalanx. Most of these cases appeared in children and usually upon the exposed parts, such as the ankles, buttocks, and hands. In children the bare buttocks on damp ground favored its development. In Dr. Brill's case the man wore low shoes and worked in the field. Only sixteen cases had so far been reported in the literature since 1874.

Dr. Harlow Brooks said that three years ago he reported a case which he believed to be due to the direct infection from the bot fly. The man gave a history of having worked in Panama where the bot fly was frequently encountered. When he entered the hospital there were two raised circular lesions which looked like boils, and from the top of them the head of the larva was recognized; when these were dug out the lesions healed.

Dr. Alexander Lambert said he had seen a case which had extended from the clavicle to the elbow, over the humerus, and upper part of the body. There was a black oozing. When the "worm" was cut out it looked like a chestnut worm and very fat. In this worm were two black "stickers" and, when the worm was stirred up, the man would squirm. On the isthmus it was called "castanea del monte."

Dr. Brill said that only in the Russian cases had the larva been extracted.

A Study of Blood Pressure in Compressed Air Workers.—Dr. Harlow Brooks read this paper. (See page 855.)

Dr. Alexander Lambert said that his experience was confined more to the higher air than to compressed air. But when the bridge was in course of construction across the Harlem river a friend of his was in charge and he complained that the veins of his legs were markedly varicosed. So in order to learn the conditions he went for the first time into compressed air. The air was compressed about twelve or fifteen pounds above the pressure of the atmosphere. He stayed down only a short time, and came out slowly, and he learned that the veins were but little affected. Then with the same pressure they were let out as fast as they could be gotten out and the only effect noted was a sudden distention of the internal saphenous vein. It made a tremendous difference. Yet no trouble was encountered when they came out slowly. Dr. Lambert said that these men were very careless about it. The application of an elastic bandage soon relieved him of his complaint. His other experience was with two or three patients who came to him with attacks of angina pectoris and asked if it would be safe for them to go to Colorado Springs, which was situated 6,200 feet above the sea level. At first he said they should not go, believing that it was wrong that they should go and that their condition would be aggravated. One man listened to what Dr. Lambert said and then went and spent the summer there. He felt so much better and improved so that Dr. Lambert said his eyes were opened when he saw the patient in the fall. Two doctors, friends of his, in Colorado Springs were interested in this patient and made studies of the blood pressure on Pike's Peak, which had an altitude of 14,000 feet. The blood pressure was much lower on the peak than in Colorado Springs. As one increased the altitude there was a decrease in the blood pressure. So long as one did not overexert and was ordinarily careful as regards exercise, he would be fairly comfortable. Dr. Lambert said that it was a question of oxygen, and that it should be remembered how quickly the red cells increased in high altitudes within one month. From observations made in South America it was noted that the red cells increased up to six or seven millions. This was apparently a physiological endeavor to gain more oxygen to the tissues. At 9,000 or 10,000 feet altitudes even animals suffer from quick exertion or exercise. Dr. Lambert said he had seen a black deer quickly aroused when he approached near; the deer stood with legs thrown forward, with tongue out, and unable to move, although he was seen. When the animal got its breath it ran away. The animal was simply gasping for breath on account of the high altitude.

On Some Therapeutic Applications of Adrenalin.—Dr. George B. Wallace read this paper. He said that, with the exception of the local action of adrenalin, its hemostatic action, knowledge of the therapeutic effects was in an unsatisfactory state, and marked differences of opinion existed concerning the benefits, or lack of bene-

fits, following its use. The purpose of his paper was to attempt to define some clinical applications of adrenalin in the light of experimental facts. He briefly recalled some of the main facts brought out by animal experimentation, the most striking of which was on the circulation. When a fraction of a milligram of adrenalin was placed directly in the blood stream there occurred a remarkable rise in the blood pressure of not over ten minutes' duration, due chiefly to the intense vascular constriction by a stimulation of the sympathetic, vasoconstrictor nerve endings. It was the splanchnic vessels which reacted most strongly and a fact of importance was that the pulmonary vessels did not share in this constriction, a fact which was taken as proof of the non-existence of vasomotor nerves in these vessels. These effects were seen when adrenalin was placed directly in the veins, but it was generally agreed upon by pharmacologists that they were entirely absent when it was given by the mouth or by subcutaneous injection. Another fact established was that adrenalin had no dilating effect upon the bronchioles. The effects on the central nervous system were not very striking. As in the case with all new drugs of any promise, adrenalin had been given a very extensive and indiscriminate trial clinically. He then considered a few of the diseases in which it had been used. In general there seemed to be no specific vascular abnormality in which adrenalin was especially employed, other than the indefinite one of circulatory weakness. The reports of its beneficial effects in circulatory collapse from a sudden injury and in cardiac dilatation from a long continued cardiac disease, and in pulmonary edema, were not by any means entirely satisfactory. The majority of the attacks of asthma were immediately checked by subcutaneous injections of adrenalin. An understanding of the therapeutic application of adrenalin could best be obtained by definite knowledge of the range of action of adrenalin when given by subcutaneous or intramuscular injections. With this in view a number of experiments had been performed on animals by Dr. Diamond and himself, in which they confined themselves especially to the effects on the circulation of subcutaneous or intramuscular injections. An appreciable rise of blood pressure in these animals, especially in the case of a dog, from a subcutaneous injection of adrenalin might be considered an exception and not the rule. With intramuscular injections quite a different effect was seen. In the rabbit intramuscular injections acted practically like intravenous injections, the rise coming on quickly, being marked and persistent only for a few minutes. They were of the opinion that the injection was in truth an intravenous one, that the manipulation resulted in the tearing of a small vein, and that some of the adrenalin thus gained entrance directly into a vein. This was in harmony with the fact that the rise was by no means constantly obtained, and further explained its short duration. They had endeavored to control their results by injections into man; and in considering the results obtained, one was tempted to conclude that subcutaneous injections of adrenalin caused a rise in blood pressure in man. In one case, one of myocarditis, an injection of 1 c.c. of water caused the pressure to rise from 92 to 108 mm. Adrenalin injected in the same amount raised the pressure from 92 to 110. Plainly in this case there was no difference discernible between water and adrenalin. On the whole, there seemed little reason for explaining them as due to the absorption and subsequent action of the adrenalin injected. As a matter of fact, the more negative animal experiments were much more satisfactory and convincing. The animal was unconscious from the anesthetic, and the effects of suggestion, mental activity, and reflex stimulation were largely eliminated. They had given adrenalin subcutaneously in a few cases of pulmonary edema, from pneumonia and cardiac failure, and in no instance was any improvement noticed. Concerning the clinical bearing of these and other experiments, one conclusion would be that in circulatory or cardiac disorders requiring a stimulant treatment, but little dependence could be placed on adrenalin given by subcutaneous injection, and it would be more desirable to use instead some drugs of proven value. In cases of pulmonary edema, its general use would seem of no benefit. Finally in cases of acute asthma there seemed to be no question that adrenalin might relieve the attack. It should always be borne in mind in using adrenalin for any period of time that there was a possibility of inducing not only local necrosis, but permanent pathological conditions in the liver and arterial walls as well.

Dr. Egbert Le Fevre said that he would take some exceptions to Dr. Wallace's findings from a clinical standpoint. First in relation to the circulatory system. Since its introduction, in spite of its uncertainty of action, it had been extensively used in the hospital. He agreed that in cases of myocardial disease, or primary valvular lesions with consequent myocardial degeneration, with failure of the circulation on account of muscular weakness, adrenalin failed to improve, and generally produced unfavorable results. On the other hand, in those cases where there were disturbances of the circulation not dependent upon cardiac power, but dependent upon loss of control over the circulation, it had stood him in good stead better than any other drug. In acute diseases of toxic type, as in collapse during the second, third, or fourth week of typhoid fever, where without previous diseases there were evidences of degeneration in the heart itself, the patient going into collapse, with marked cyanosis, in those cases where they usually depended upon camphor dissolved in oil, the use of adrenalin had saved many lives. In the past two years he had been unfortunate enough to see four cases of that condition where, under ordinary circumstances, imperfect results would have followed the use of such cardiac stimulation as from hot plates, etc., marvelous results followed the use of adrenalin. Dr. Wallace had stated that no good effects followed the use of adrenalin in the pulmonary edema of pneumonia. Dr. Le Fevre said that pulmonary edema should be divided into two classes. First, where late in the disease there was a gradual but progressive failure of the heart, and with that some failure in the vascular control, in these cases better results were obtained from such agents as camphor, caffein, or digitalis than from adrenalin. But, on the other hand, in those cases where, early in the disease, without evidence of cardiac failure, they had sudden attacks of edema, adrenalin was better than other drugs. During the past three months Dr. Le Fevre had at Bellevue Hospital five cases in which he was able to show the immediate effects of adrenalin in this type of edema. In vascular collapse, not cardiac *per se*, adrenalin was indicated. With regard to asthma he agreed that in the spasmodic types of breathing that occurred in acute cardiac and renal disease, and in other forms of toxemia which also occurred in asthma, which once were called spasmodic asthma, adrenalin acted but little. But in the cardiac and renal diseases with intercurrent attacks, that were nearly like true asthma, there was some effect to be had from adrenalin, but not the marked effect one would get in true asthmatic conditions. He said he had seen a number of cases of asthma where the use of adrenalin was attended by unusual symptoms, especially the early blanching, and here a question arose as to the cause of the blanching. Just how adrenalin acted was still a mystery. In asthma, with spasm of the bronchioles, no effects resulted from the administration of adrenalin. But in cases of angioneurotic edema, with the peculiar condition of the nose, the sneezing, and profuse discharge, etc., the giving of adrenalin would be accompanied by a blanching of the mucous membrane and much relief given. The question, and an important one, arose

as to the danger of producing changes in the blood-vessels of chronic asthmatics by the use of adrenalin, given in amounts necessary to give relief. The case in which he had used it longest extended over four and a half years, and nothing of a permanent nature could be detected. Another case had used it three and a half years. There was no doubt that adrenalin was preferable to morphine for use in these asthmatics.

Dr. W. Sohier Bryant said he had been using the suprarenal gland for ten years, and very extensively in nasal work, and the variability of its effects was something none seemed to understand about. He was fond of using it for diagnostic purposes to determine the nature of the cause of asthma. If there was a local cause the adrenalin controlled it immediately. In those cases the asthma was a reflex disturbance caused by some pressure upon or in the nose.

Dr. George B. Wallace said that no doubt there were some types of asthma in which adrenalin had no effect whatever. The question that most interested him was how this agent produced its effect. As a whole the effect upon the circulation was bad. The clinical cases in which adrenalin was expected to do good were rare; in ten cases there might be one case which showed improvement, while the others would not.

The Comparative Actions of Isopral and Chloral.—Dr. R. A. Hatcher presented this paper. He said that a student of materia medica could not fail to observe that many substances came into notice, rose to popularity, and sunk back into obscurity, only to give place to others which followed the same course. This observation should tend to make all conservative. While they were tardily coming to appreciate the indecency of permitting themselves to be made the dupes and unpaid agents of the makers of worthless compounds which were forced upon their notice in high sounding, but often meaningless, phrases, they should be more guarded in accepting too optimistically the statements of those who had an interest in making reports upon compounds sold at fancy prices; they should remember that the enthusiast and the investigator who sold the report were prone to accept insufficient evidence as the basis for highly colored reports, if, indeed, their reports were not pure fabrications. Isopral was being extensively advertised as a safe hypnotic of the chloral group, and as acting more efficiently than chloral in one-half the dose, and without effect on the heart and nervous system. The use of isopral by clinicians was apparently based upon the pharmacological investigations of Impens, who gave figures purporting to show that isopral was much safer than chloral hydrate. It did not seem to Dr. Hatcher that his conclusions were in any way justified, and the table taken from Impens' article was shown for comparison with results obtained by him in experiments upon a number of animals, including 13 dogs, 10 rabbits, 8 cats, and 2 guinea pigs. His conclusions were that he believed that his experiments on rabbits and cats and Impens' experiments on rabbits showed that there was no essential difference between the action of isopral and hydrated chloral in effective doses on the respiratory centers, while his experiments on dogs showed that isopral was more than twice as active in depressing the vasomotor and respiratory centers and the heart. Dr. Hatcher's figures for the relative toxicity were almost precisely the same as those given by Impens for the relative efficiency of the two drugs for the dog.

Dr. A. N. Richards discussed the paper.

Dr. Hatcher closed the discussion.

Chloride of Ethyl in Neuralgias.—The local application of chloride of ethyl spray has sometimes not only relieved, but also cured some forms of neuralgia. Hemicrania, lumbago, and supraorbital neuralgia have all been cured in this way.—*The Hospital.*

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held April 15, 1907.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Report of the Committee on the Death of Dr. George B. Fowler.—Dr. Egbert H. Grandin, Chairman. (Read by the Secretary. See page 906.)

Symposium on Milk.—The President, Dr. Satterthwaite, said that a word or two of introduction seemed necessary, especially in view of the fact that he had recently received a letter asking if the object of the meeting was to advocate the municipal pasteurization of milk. His reply was that this Milk Symposium was planned months ago, when public attention was first called to the city milk question. There was not, and never had been any intention or desire on the part of the Association to advocate pasteurization, inspection, modification, certification, or in fact anything new, but it was intended and hoped that through the cooperation of the best experts obtainable, the milk question would enter on a new phase, rising above the level of personal, political, or local considerations. He felt that the whole subject would be reviewed from a common sense standpoint, and that some light would be thrown, directly or indirectly, on such features as bovine tuberculosis and infant mortality; the inspection of dairy farms and their products; pasteurization, its benefits or disadvantages, and its applicability; the adulteration of milk; the proper bacterial standard for milk; the certification of milk; raw milk and bottle-fed babies, and so on. The milk question presented a number of difficult problems that could not be entirely solved in a day or a year, so that it was too much to expect immediate harmony in conflicting views. More facts were needed for the complete solution of the question. There was no doubt, however, from the published accounts, that much of the city milk was impure, and also that the mortality among bottle-fed infants was too high, and that our best efforts should be directed toward checking it.

On the Bacteriology of Milk.—Professor H. W. Conn of Middletown, Conn., Director of the Bacteriological Laboratory of the Connecticut State Board of Health, discussed this phase of the subject. He stated that there was entirely too much misapprehension concerning the relation of bacteria to health. While some bacteria were harmful, others were perfectly harmless, while still others were distinctly useful, and among the latter were those of the lactic acid variety, which developed in milk, and might prevent the growth of other and harmful organisms. To the manufacturer of cheese and butter they were indispensable. While there were those who would advocate the destruction of all bacteria in milk, on the same principle as that advanced by the man who would kill all birds because a hawk occasionally kills chickens, yet as a matter of fact, from the standpoint of the bacteriologist, there were only certain bacteria in milk that were to be feared. These were, first, the tubercle bacilli; second, the typhoid fever bacilli; third, the diphtheria bacilli, and, fourth, the germs of scarlet fever, which were thus far unrecognized. Of these four, only the first was positively known to come from the cow; the other three were from some form of human contamination. In addition to these four, the speaker said, there was a type of diseases which was characterized by intestinal disturbances, such as were commonly known as summer complaint, cholera infantum, etc., and though they were distinctly traceable to the use of milk in many instances, their causation was as yet unknown. While they were probably due to toxic products contained in the milk, we had no certain knowledge on that subject, but we did know that lactic acid bacteria were not responsible for this type of troubles. Professor Conn said that three chief methods of milk purifica-

tion had been advocated and were more or less in use. Each of these had its advantages, and each possessed certain weaknesses. The first was that of proper dairy inspection. This was fairly new, although it was first suggested about fifteen years ago, and first adopted by milk supply companies in Berlin and London. While dairy inspection was of extreme value, it did not furnish a guarantee that the milk was free from the germs of tuberculosis, typhoid fever, diphtheria, or scarlet fever. While it might accomplish much, it could not cover the whole question.

The second method was a bacteriological standard. The bacterial standards of milk adopted by different cities varied widely. One city, for example, placed its bacterial standard at 500,000 per c.c.; another city at 100,000, and another for special purposes at 30,000. The speaker said that in his own city of Middletown, Conn., it would be a very easy matter to obtain milk with a bacterial standard as low as 10,000, while in New York City it was doubtful whether a standard of 1,000,000 per c.c. could be satisfactorily maintained. That did not imply, however, that the milk in Middletown, Conn., was one hundred times better than that in New York; on the contrary, it was probably not one iota better. Buttermilk had a bacterial content of two, three, and even five hundred millions to the c.c., and still there were many physicians who did not hesitate to recommend it as a wholesome article of food. As a matter of fact, these countless numbers of bacteria in buttermilk and sour milk were practically all of the harmless and even useful lactic acid type, and thus sour milk usually represented a pure culture of lactic acid bacteria. It was not the number of bacteria upon which the healthfulness of the milk depended, but the kind. The wholesomeness of the milk depended upon whether its bacteria belonged to the harmful or harmless types, and it was a difficult, or even an impossible matter for any bacteriologist to distinguish between the different kinds; while it could be done, the methods were too slow and unreliable to be of practical application. Hence too much reliance should not be placed upon bacterial milk standards. Moreover, they did not always work fairly. They were often unjust to the milk producer, and we in the cities were too prone to lose sight of the other end of the milk route. No milk standard could guarantee that a certain sample of milk was entirely satisfactory. Its bacterial content might fall below 500,000 per c.c. or any other standard, and yet it might be filled with typhoid or tubercle bacilli. It might, on the other hand, contain twenty or thirty millions of bacteria to the c.c. and be perfectly harmless. Under existing conditions a bacteriological standard placed the emphasis on the wrong spot. We should emphasize the type of bacteria and not their number. Some day, perhaps, that could be done; up to the present time it had not been done, simply because it was impracticable to do it. Coming to the third method of guarding the milk pasteurization, Professor Conn said that much could be said for and against it. In the first place, the fact should be borne in mind that pasteurization was the only method within our reach at the present time by which we could *guarantee* that any sample of milk was free from the danger of the germs of specific diseases, such as typhoid fever, tuberculosis, etc. But, in order to accomplish that, the milk must be properly pasteurized. Pasteurization which simply raised the milk for a moment to a moderate degree of heat accomplished little in the way of destroying the resisting pathogenic bacteria. It must be done thoroughly, and in the proper way if the milk was to be guaranteed as free from the tubercle bacillus. Another fact to be borne in mind was that pasteurization destroyed the lactic acid bacteria and left others alive, which afterwards developed rapidly, being unhindered by the lactic acid bacteria. Therefore, after pasteurization, the milk must be utilized without much delay. Again, it had been said that pasteurization placed a premium on carelessness in the dairy, because, if the milk was to be thus treated, the farmer naturally might think it would make no special difference whether he was cleanly or not. While this objection might have some weight, it might be overcome by proper dairy inspection. Some believed that pasteurization decreased the digestibility of milk, but this, he said, depended on the temperature to which the milk had been subjected. Prof. Conn stated that he had reason to believe that in the near future there might be placed upon the market a type of milk known as concentrated milk, which had about four-fifths of its watery content removed by exposing it to a temperature of not more than 140 degrees for a period sufficiently long to destroy all the pathogenic germs. By this method of treatment, the bacterial content of the milk was reduced from any number of millions to a few thousands, and the milk itself brought into a condition in which bacteria would scarcely thrive. Prof. Conn said he had been experimenting with this concentrated milk for several months, and he could state positively that when kept at a temperature of 50 degrees or below it would remain unchanged for five or six days without any appreciable increase in the number of bacteria, and that when subsequently mixed with three times its bulk of water it could not by any ordinary means be distinguished from fresh milk.

Clean Milk.—Dr. Mary E. Pennington of the Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C., said that because of the great difference in the production of milk in various parts of the country, and the time and conditions intervening between drawing it from the cow and its delivery to the consumer, a bacterial standard was exceedingly difficult to fix. If such was maintained, it must be regarded in the light of an indication as to what was going on at the dairy quite as much as an index of the condition of the milk itself. Clean milk was that from healthy cattle, wholesomely fed, kept in clean, light, airy surroundings, and drawn by clean milkers. It should be collected in covered buckets, and then, as quickly as possible, be cooled and bottled on the farm away from the disease-bearing dust of the city. Being of all foods the one most subject to deterioration, every effort should be made for its rapid transportation to the consumer, and for the continued maintenance of a temperature below 55° F. during this interval. Milk so produced and cared for did not contain polluting organisms from the barn, which were generally those of cow manure, nor from dirty hands, nor from foul air and water. If kept cold, the bacteria would scarcely increase at all during the first twenty-four hours, by which time, even in the large cities, it should reach the consumer. If dirt entered, neither art, science nor patented machinery could remove such dirt, and leave intact the original properties of the milk. Any process having that end in view was objectionable, because it placed a premium on dirty, diseased milk, which was always more easily obtained than the clean variety, and hence could be sold at a greater profit by the dealer. Pasteurization, as practised commercially, could not be guaranteed to kill off pathogenic organisms, such as tubercle bacilli, typhoid bacilli, streptococci, etc. It did kill the lactic acid formers normally found in milk, because they were more easily destroyed by heat, but, on the other hand, it left the heat-resisting spore formers and other organisms which commonly caused profound chemical changes in the milk without first curdling it, and therefore without any indication to the housewife that the milk was not fit for food. It did not protect the milk from reinfection by dirty air, employees, and containers. Furthermore, milk was often heated two or three times before it was fed to the baby, by which time it contained not only the life products of millions of organisms which might be toxic, but also their dead bodies and excreta. The speaker emphasized the importance of bending all energies toward the education of the people, including the dealers, to know, demand, and pay for clean, good milk.

Some Points on the Chemistry of Milk.—By Professor L. L. Van Slyke of Geneva, N. Y., of the Department of Chemistry, N. Y. State Agricultural Experiment Sta-

tion. The chief purpose of this paper was to point out some of the common and widespread misconceptions regarding the chemistry of cows' milk, and add a few words regarding some of the dairy problems that had been investigated, and some of the unsolved problems that might be of interest to physicians. After discussing normal milk and its composition, the speaker said that this varied widely, but naturally less in milk derived from herds of cows than in that taken from individual cows. Milk, as it often came into a city market, varied in composition much less than milk from individuals or from single herds. When, therefore, we spoke of the composition of normal milk, without any qualifying statement, we were dealing with quantitative relations that might be about as definite and fixed as the quotations of the stock-market. The average of about 5,500 American analyses of milk, mostly made at the State Agricultural Experiment Stations and under known conditions of production, gave approximately the following figures: Water, 87.10; solids, 12.90; fat, 3.90; casein, 2.50; albumin, etc., 0.70; sugar, 5.10; ash, 0.70. After referring to the relation of casein to albumin in cows' milk, and the action of acids and rennet on casein, Professor Van Slyke said that the following were some of the problems that had been under investigation: (1) Different breeds of cows and the composition of milk; (2) a study of the relation of milk to the manufacture of cheddar cheese; (3) the ripening of cheddar cheese; (4) casein and its compounds; (5) chemistry of the souring of milk; (6) kumyss and carbonated milk. Some unsolved problems that still called urgently for attention in the way of rigid chemical investigation were (1) the action of rennet or pepsin upon the casein of milk, (2) the chemistry of casein, especially in relation to inorganic salts in milk; (3) the chemistry of paracasein, the product formed by rennet coagulation; (4) the relation between the casein of human milk and the casein of cows' milk. In concluding his remarks, the speaker said he had tried to indicate in his paper (1) that there were positive errors in literature regarding the composition of milk, which needed correction; (2) that work had been done and was being done in other connections which found practical application to some of the problems of medical practice, and (3) that there yet remained for solution problems of profound and far-reaching importance.

Municipal Regulation of the Milk Supply.—Dr. GEORGE W. GOLER, Health Officer of the City of Rochester, N. Y., presented this paper. The speaker first emphasized the importance of milk as an article of diet, and said that before taking up the question of its municipal control, he wished to present the milkman's view of the case. Of the several millions of milch cattle kept in this country, 50 per cent. were said to be kept at a loss, 25 per cent. returned no profit, and only 25 per cent. were profitable to their owners. The business of milk production and distribution was not generally, save by the large concerns, conducted in a systematic manner. However practical the men engaged in the work might be, they were not scientifically trained in the different steps of tillage, planting, storing, and feeding, nor in properly housing and caring for cattle, nor in handling and transporting milk. The men were all engaged in handling the most perishable of foods; the only one that did not rise and fall in price with the demand for it, and the cost of its production. Men in the milk business worked every day in the year, in the heat and in the cold, on Sundays and holidays. The demands of the public compelled work and delivery at early and unusual hours, so that fresh (?) milk might be on hand for breakfast. The speaker then discussed in detail the municipal regulation of the milk supply, beginning with the inspection and control of the dairy, the proper method of the transportation and delivery of the milk, and the strict enforcement of the city milk ordinances. The latter, he said, required a sufficient number of inspectors to really inspect, and to collect from each wagon at least one monthly sample for bacteriological and chemical examination, with at least a bimonthly sample from each store offering milk for sale. There should be a daily inspection of the incoming milk at each railroad station for (a) condition of and housing of cans and bottles of milk in shipment; (b) condition of empty cans reshipped; (c) temperature of milk; (d) inspection of railroad samples to guard the retailers against fraud on the part of the wholesalers. Thus the city provided for the bacteriological and chemical examination of the milk supply, the wagons and stores, and inspection. The country end of the work was of even greater importance. The territory from which the city drew its milk supply must be mapped, the dairies plotted, the roads examined, the railroad facilities noted, and the routes laid out so that every farm shipping milk to the city might in the beginning be subjected to systematic bimonthly inspection. No milk must be permitted to enter the city until the seal of inspection had been placed upon it by the inspector.

State Regulation of the Milk Supply.—Dr. E. B. VOORHEES of New Brunswick, N. J., Director of the New Jersey Agricultural Experiment Stations, stated that the objects to be attained by State regulation of milk supplies should be (1) to provide a healthy and wholesome food product and (2) to encourage the producer in his efforts to make a clean and healthful product. This control should be both restrictive and educative; restrictive in prohibiting certain methods of practice which resulted in an unclean product, and educative because the matter of control was reasonable. The laws that had been enacted in the past had not been altogether reasonable, and because many unnecessary, foolish, and impracticable methods of control had been adopted by State and municipal authorities, much misapprehension existed in the minds of both producers and consumers concerning the usefulness of any control, as well as the possibilities and probabilities of danger from the use of milk that had not been subjected to such control. The producer had rights upon which unwise and unjust regulations infringed; he had undoubtedly suffered in the past, and was now suffering from exaggerated notions in reference to the dangers of using milk, and methods of prevention which had been incorporated into law. On the other hand, it was surely right that the State should exercise proper supervision over the possible sources of danger, mainly in the matter of the production and sale of the milk, and along the following lines: (1) The health of the animals; (2) the food and water supply of the animals; (3) the stabling of the animals and care of milk on the farm; (4) the sale of milk of varying composition. In the first three directions the control had reference directly to the conserving of the public health; in the fourth it had reference entirely to the sale of milk as a commodity, and the regulations should not be prohibitive, but permissible. The State should also make such regulations for the retailer as shall guarantee proper care in transporting and storing of the milk and its distribution, as well as the requisite cleansing and return of the vessels in which the milk had been transported, although in all cases the regulations should be so reasonable as to make it possible to have them complied with. Dr. Voorhees, after discussing in detail these various State regulations, said the whole matter of milk control was largely one of education and fair dealing. The State could assist in securing it by limited and reasonable restrictive measures, whose execution was in the hands of intelligent officers.

Milk as a Food.—Dr. HENRY D. CHAPIN said that milk was such a commonplace article of diet that it was somewhat difficult to approach the subject from a purely scientific standpoint. Such an investigation would show that milk was supplied to young animals for a certain period after birth, and that it was a food, because growth and increase in weight occurred when no other form of nourishment was taken. A study of the processes of re-

production would show that milk was not the only form of food supplied by the mother. Before birth occurred three different methods of feeding were employed by the mother and three different kinds of food were supplied, these different methods of feeding gradually passing from one into the other. The young animal, before birth, was continuously changing its form and structure, and the form of the food and the method of supplying it changed as fast as the changes in the young animal took place. Milk was not supplied at birth, but colostrum, which was gradually displaced by milk, and the latter, in turn, was displaced by solid food. Milk was the last of five special forms of food supplied by the mother during a period of very rapid development, and it was especially adapted to young animals just before they were ready to subsist on solid food. Comparative examinations of the milk of different species of animals showed that they were not alike in composition or in their behavior with pepsin and acid. The digestive processes of these different species of animals were also unlike, which led to the conclusion that nature purposely made milks unlike because they were intended to be suitable for animals with different nutritive requirements and different digestive processes. Milk was a special form of food supplied during the period in which the digestive organs were developing; milk was a complete food, but this statement was correct only when applied to mother's milk, for the milk of some species contained so much less of the various ingredients than the milk of other species that it would be a starvation diet for some young animals, even if they had the proper digestive properties. The attention of the medical profession could not be too strongly directed to the fact that pure cow's milk was used as a food only in feeding adults and older children, and here it caused little or no trouble. The feeding of pure, natural, fresh cow's milk to infants was not common, especially when they were young. In feeding infants, mixtures or new compounds derived from cow's milk were generally employed, many of which had none of the digestive properties of cow's milk. The properties of pure cow's milk as a food were pretty well understood. What the practising physician needed to become familiar with was the properties of the derivatives of cow's milk he used in his practice many times more frequently than he used pure milk.

Dr. Ransford E. Van Gieson of Brooklyn said that careful attention to the papers of the evening had only convinced him more strongly of the fact that we had still a great deal to learn concerning the chemistry of the proteids of human and cow's milk. For example, the difference between cow casein and human casein was very great, both in its physical and chemical properties. As regarded the composition of cow's milk, the only figures to depend on were those derived from an average analysis of a large number of animals. While the pasteurization of milk had its drawbacks, it also possessed undeniable advantages, especially during the heated term, and to that extent it might be regarded as a necessary evil.

Dr. Edward F. Brush of Mt. Vernon, N. Y., said he had been interested in the milk question for many years. While much had been written and said regarding the dangers of typhoid and tubercle and other bacilli in milk, they were not the only factors to be considered. During the hot weather, cows were not infrequently tormented by flies or dogs, or all were to feed on poisonous weeds, and under such conditions the milk of these animals might contain toxins which were a potent factor in the causation of diarrheal diseases. The dairy cow was subject to almost all the ailments to which the human being was subject, and the speaker recalled several instances where he had been able to convince himself that epidemics of scarlet fever were conveyed through the medium of cow's milk. Dr. Brush said he did not agree with one of the previous speakers that the cow was naturally a clean animal, but in spite of the fact that we utilized her milk during life and her flesh after death there was no reason why she should not be given preference to the horse as regarded stable care and pasturage, the contrary, however, was quite the rule. In speaking of the tuberculin test in cattle, Dr. Brush said that while he did not doubt its value, the work in the beginning was too often intrusted to inexperienced and at times ignorant men, with little else than a thermometer to guide them, and he knew of instances where excited and nervous, but otherwise healthy cattle were sacrificed as the result of their overzealous efforts. On the other hand, every possible ill which the cow was heir to had been attributed to tuberculosis. This work should be intrusted to skilled veterinarians, who were capable of making a correct diagnosis and instructing the farmer how to breed his cows.

Dr. William H. Park said he did not agree with Prof. Conn that the great majority of bacteria in ordinary milk were harmless. The lactic acid variety covered a multitude of types, including the colon bacillus which was not at all harmless. The bacterial standard of milk, to which several of the speakers had referred, was employed chiefly to detect whether the milk was clean or not, and how long it had been on the market. In the present stage of our knowledge regarding milk bacteriology, it was scarcely possible to pick out the different types of bacteria. The essential features in the proper care of milk were to keep it cold, to keep the dirt out and to keep the time down. The term "commercial pasteurization," which one of the speakers had employed, was a rather indefinite one. One firm, for example, might pasteurize milk by exposing it to a temperature of 160° for one minute, while another might accomplish the same purpose by exposing it to a temperature of 140° for thirty minutes. In connection with pasteurization, the time and temperature must be considered.

Dr. Charles E. North said the problem of the milk supply in New York City was unique and rather peculiar, as he had learned from personal experience. The man who sold the milk in the city did not own either the farm or the cow, and had utterly lost control of the supply. On the other hand, it was difficult to teach the dairy farmer how to produce the kind of milk the public demanded. Clean, raw milk was what the public wanted, but under present conditions it was absolutely impossible for the average producer to supply it. To obtain it, we required a new kind of farmer—men of more intelligence and capital. At present, we were menaced by a flood of dirty and contaminated milk, and in order to protect the public from the disease germs that it contained it was advisable to resort to pasteurization. He believed that a large part of our milk supply would require pasteurization for a long time to come.

Mr. George L. Flanders of Albany, N. Y., an Assistant Commissioner of Agriculture of the State of New York, said he had listened to a number of discussions on the question of pure milk, particularly from a bacteriological standpoint, and they had all impressed him strongly with the view that, in order to obtain pure milk, the proper place to begin was at the source of the supply. In the State of New York there were 1,800,000 milk cows, and much work had been done throughout the State during the past fifteen years by the Department of Agriculture in trying to educate the milk producing farmer how to care for the cows and handle the milk. As a result of this work, the people in the cities of the State to-day were receiving better milk than ever before. One of the great drawbacks, however, in producing the result desired had been that the middleman had been able to manipulate the prices so that the producer could scarcely afford to follow the instructions as to the best methods of producing pure, clean milk. In reply to a criticism made by Dr. Brush that the work of examining cattle had been intrusted to men who were ignorant and inexperienced, Mr. Flanders said that perhaps Dr. Brush was unaware of the fact that these men were all college graduates and experienced veterinarians.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE BOARD OF REGISTRATION AND EXAMINATION.

December 11, 12, *and* 13, 1906.

PHYSIOLOGY.

1. How are foods classified? Describe each class.
2. Where and by what secretions are nitrogenous foods digested?
3. Describe the process of blood coagulation.
4. Describe a heart beat.
5. What part of digestion takes place in the duodenum?
6. What changes does the blood undergo in respiration, and how is it accomplished?
7. What conditions hasten and what retard absorption?
8. Describe a serous membrane, and name its office.
9. What is meant by the term blood pressure?
10. How is the heat of the body maintained?

OBSTETRICS.

1. Name the varieties of ectopic pregnancy. Give briefly the symptoms and signs by which it may be recognized.
2. How determine before labor the presentation and position of fetus without making a vaginal examination?
3. How, during pregnancy, may death of the fetus be recognized?
4. Name some conditions which would warrant the induction of premature labor.
5. How distinguish one shoulder from another when the elbow and hand cannot be reached?
6. What conditions would cause you to make a craniotomy or embryotomy rather than a cesarean section?
7. How should labor be induced at about the seventh or eighth month?
8. Give briefly the pathology of so-called milk leg.
9. In about what period of time should the second stage of labor be concluded? Why?
10. Give briefly the symptoms of rupture of the uterus and outline its management.

DISEASES OF WOMEN.

1. Classify uterine hemorrhage and give some of the causes.
2. Give treatment for nausea and hyperemesis of pregnancy.
3. Give some of the causes and treatment for pruritus vulvæ.
4. Give some of the aids and hindrances to involution.
5. Name three diseases of mammary glands; give their treatment.

DISEASES OF CHILDREN.

1. Symptomatology and treatment of rickets. From what must it be differentiated?
2. How would you treat a child, age two years, who is suffering with vomiting and diarrhea?
3. Diagnosis and management of chorea in children.
4. Diagnosis, prognosis, and treatment of inherited syphilis.
5. Give the period of incubation of whooping cough, measles, scarlet fever, diphtheria, chickenpox, and mumps.

SURGERY.

1. Define surgical diseases; give an example with treatment for same.
2. Classify fractures and dislocations of the shoulder.
3. How do you dress a fractured clavicle?
4. Describe technique of surgical treatment for empyema.
5. Describe technique of cholecystostomy.
6. How frequently should you catheterize an unconscious patient?
7. Describe operation for varicocele.
8. What is the danger of surgical treatment of corns and bunions in old people, and why?
9. Give a simple formula for hypodermoclysis and what conditions call for its use.
10. Give symptoms and treatment of intussusception of bowels.

CHEMISTRY.

1. Define acid, base, and salt.
2. What inorganic salts enter into the formation of bone?
3. What is chemical affinity, cohesion, and adhesion?
4. What are the properties of an acid? of an alkali?
5. What is an oxide?
6. What is chloroform? How made?
7. What is the difference between fermentation and putrefaction?
8. What is the antidote to carbolic acid?
9. Describe a method of preparing oxygen.
10. Name three mineral poisons and give their antidotes.

MATERIA MEDICA AND THERAPEUTICS.

1. Upon what does the activity of hydrogen peroxide depend? How is it employed in medicine?
2. For what purpose is cold employed as a therapeutic agent; how does it produce its effects?
3. In what way may exercise act as a therapeutic agent?
4. What is heroin? Describe its physical properties and physiological action; give some indications for its use.
5. Write a prescription for a patient suffering from cystitis with ammoniacal urine.
6. Describe the lethal effects of hydrocyanic acid.
7. Write a prescription for a patient with broken cardiac compensation.
8. How does quinine produce its effect in malaria?
9. From what is eserine obtained? Describe its action.
10. How graduate the dose of a remedy to the age of a patient?

ANATOMY.

1. What vessels unite to form the inferior vena cava? Describe its course and termination.
2. Give the origin, course, and branches of the axillary artery.
3. Describe the medulla oblongata.
4. Give the distribution of the pneumogastric nerve.
5. Describe the larynx.
6. What are Peyer's glands? Where are they found?
7. Describe the gall-bladder, giving its location and relations.
8. Give the names of five muscles of the shoulder and arm.
9. What is the diaphragm? Where is it situated? Mention the principal opening in the diaphragm.
10. Give the origin, insertion, and action of the deltoid muscle.

PHYSICAL DIAGNOSIS.

1. How discriminate organic from functional murmurs of the heart?
2. Give pathological significance of aortic murmurs.
3. State pathological significance of herpes labialis.
4. State indications suggested by the reflex vomiting.
5. What are the indications suggested by hiccough?
6. State pathological significance of blood in the stools.
7. State physical signs of an effusion in acute pleurisy.
8. Describe the methods of palpation to ascertain the condition of the kidneys.
9. State pathological significance of the general distention of the abdomen.
10. State pathological significance of rigid recti muscles of the abdomen.

PRACTICE AND PATHOLOGY.

1. Name some of the causes of constipation, and give dietetic and hygienic treatment.
2. Describe the changes that follow generalized arterio-sclerosis.
3. Differentiate between catarrhal jaundice, gallstones in the common duct, and malignant growth affecting common duct.
4. Locate the lesion in paralysis of the right arm and leg, and left side of the face.
5. Describe the process of healing by the blood clot dressing, *i.e.* where the cavity is allowed to fill with blood and is then closed.
6. How do carcinoma and sarcoma differ from each other?
7. Diagnose and give treatment of erysipelas.
8. Diagnose and give treatment for dysentery.
9. What is acne? How do you treat it?
10. Give symptoms, diagnosis, and treatment of epilepsy.

***It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.**

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE BOARD OF REGISTRATION AND EXAMINATION.

December 11, 12, *and* 13, 1906.

PHYSIOLOGY.

1. Foods are classified as follows:

I. Inorganic { Water. / Salts

II. Organic { Non-nitrogenous { Carbohydrates / Fats ; Nitrogenous—Proteids.

2. Nitrogenous foods are digested in (1) the stomach, by the pepsin of the gastric juice; and in (2) the small intestine, by the trypsin of the pancreatic juice.

3. When blood is withdrawn from the blood-vessels of the living body, it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats on the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleo-proteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.

5. The proteids are converted into proteoses and peptones, the starches are converted into maltose, fats are emulsified and saponified, and the casein of milk is curdled.

6. The respiratory changes in the blood: (1) In the *lungs,* the blood is changed in color, gains oxygen, loses carbon dioxide, loses heat, and loses watery vapor. (2) In the *capillaries of the body,* the blood loses oxygen and receives carbon dioxide.

7. Substances in a liquid or gaseous state are absorbed more readily than solids. The more dense the fluid the slower the absorption. The more tense and full the blood-vessels the slower the absorption. The more rapid the circulation the quicker the absorption.

8. The pericardium may be taken as an example of a serous membrane. It consists of two layers, a visceral and a parietal. The free surface is covered with a single layer of endothelium, which rests upon a connective tissue stroma. Between the endothelial cells are stomata. Serous membranes are supplied with blood-vessels, lymphatics, and a few nerves. The office of a serous membrane is to secrete a fluid for the lubrication and protection of the organ or organs with which it is in contact.

9. By the term *blood pressure* is meant the pressure on the blood due to (1) the ventricular systole, (2) the elasticity of the walls of the arteries, and (3) the resistance in the capillaries.

10. The heat of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. Heat is *gained* to the body by (1) the muscles, during contraction; (2) the secreting glands; (3) the brain, during mental activity; and (4) by the ingestion of food and hot liquids.

Heat is *lost* to the body by (1) the skin, through evaporation, radiation, and conduction; (2) the lungs; and (3) the excretions (feces and urine).

OBSTETRICS.

1. The varieties of ectopic pregnancy are: (1) Tubal, (2) interstitial, (3) ovarian, and (4) abdominal.

In differentiating this condition from a normal pregnancy, the following signs and symptoms are of most reliance. "When extrauterine pregnancy exists, there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility. Nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy. Pains are often very severe, with marked tenderness within the pelvis. Such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating. This tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 *are positive signs.*" (*American Text-Book of Obstetrics.*)

3. Symptoms of death of fetus are: cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements are absent, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited.

4. Conditions warranting the induction of premature labor: (1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy, (6) hydatidiform mole.

5. "*Diagnosis of one shoulder from the other when the hand and arm are not tangible:* 1. Observe the opening of the axilla: it always points toward the child's feet. If the feet be, therefore, toward the *right* side of the pelvis, the *head* will be toward the *left* side.

"2. The scapula, its spinous process especially, will indicate whether the child's back be toward the pubes or toward the sacral promontory.

"3. A moment's reflection will show that a child lying across the pelvis (let the reader imagine *himself* to be lying across it), with its *head* in the *right* iliac fossa, and its *back* to the *pubes, must* be presenting its *left* shoulder to the pelvic brim—the 'position' of the 'presentation' being, necessarily, right cephalo-iliac (dorso-anterior). If the axillary opening show the head to be in the *left* iliac fossa, and the position of the scapula show the child's back to be toward the mother's sacrum, it will still be the left shoulder presenting, the *position,* however, being left cephalo-iliac (or dorso-posterior).

"The same data and deduction may be used for the right shoulder and its two 'positions.'" (King's *Obstetrics.*)

6. "Embryotomy is indicated to-day in but two conditions: First, in all instances in which the fetus is *dead* and delivery of the unmutilated fetus would increase the danger for the mother. Second, upon the *living* fetus in obstructed labor due to monstrosity; and in exceptional cases in which the mother's condition, from hemorrhage, repeated attempts at delivery, sepsis, or shock, is such as to render embryotomy by far the safer operation." (Edgar's *Obstetrics.*)

8. Milk leg may follow puerperal sepsis in which there is a thrombosis of the iliac or femoral vein. Sometimes it occurs after a uterine phlebitis, in which clots are carried from the uterine sinuses to the hypogastric veins, where they cause obstruction to the blood flow in the crural veins. The trouble may also begin as a crural phlebitis. It is thus due either to cellulitis or to thrombosis.

9. The second stage of labor usually lasts from one and a half to two hours. While this is the average time, the process may be much prolonged. It may last twenty-four hours without serious consequences. No rule can be laid down as to when interference should be permitted. Each case must be taken on its own merits. If labor is unduly prolonged, much damage may be done to the maternal tissues, sloughing, fistulæ, etc., may result; and the fetus may also suffer. Shock, exhaustion, and greater liability to sepsis are also more likely to occur.

DISEASES OF WOMEN.

1. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of uterine hemorrhages, and also gives the causes of the same:

1. *Hemorrhages Complicating Pregnancy, Labor, or the Puerperium:*

A. Hemorrhages of Pregnancy: caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of Labor: caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the Puerperium: caused by (1) retained secundines; (2) displaced uterus;

(3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

II. *Hemorrhages Occurring in the Non-Pregnant Woman:*

A. In Virgins Before the Age of Thirty: caused by (1) uterine congestion, the result of cold or exposure; (2) endometritis; (3) polypi and fibroid tumors.

B. In Married Women Before the Age of Thirty: caused by (1) subinvolution; (2) laceration of the cervix; (3) endometritis; (4) retrodisplacements of the uterus; (5) polypi and fibroid tumors.

C. In Women After the Age of Thirty: caused by (1) carcinoma of the cervix; (2) carcinoma of the body of the uterus; (3) sarcoma of the uterus.

3. Pruritus vulva may be *caused by:*—parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin, or idiopathic.

Treatment consists in removing the cause, if possible; cleanliness, fresh air, tonics, and general attention to hygiene; local applications of solution of biehloride of mercury, 1:2,000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

4. The following are some of the *aids to involution:*—good health before labor; a labor not too long or fatiguing; absence of inflammation, sepsis, or laceration; a sufficient amount of rest after the confinement; neither too early rising after the labor, nor too long lying constantly upon the back; nursing the baby; and the administration of ergot. The opposite conditions are *hindrances to involution.*

DISEASES OF CHILDREN.

5. The period of incubation of whooping cough is from three to fourteen days; of measles, ten to fourteen days; of scarlet fever, a few hours to seven days; diphtheria, a few hours to seven days; chickenpox, about fourteen days; mumps, fourteen to twenty-one days.

SURGERY.

1. A surgical disease is a disease that is amenable to surgical treatment, *e.g.* a boil.

6. Every four to six hours.

8. Gangrene may ensue; due to the enfeebled circulation.

CHEMISTRY.

1. An *acid* is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element, without the formation of a base.

A *base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water.

A *salt* is a substance formed by the substitution of an electro-positive element for part or all of the replaceable hydrogen of an acid.

2. Calcium phosphate, calcium carbonate, calcium fluoride, magnesium phosphate, and sodium chloride.

3. *Chemical affinity* is that force which holds together the atoms in a molecule.

Cohesion is the force by which molecules of the same kind are held together.

Adhesion is used with two meanings: (1) the force by which unlike molecules are held together. (2) The force which binds together the surfaces of masses when in contact.

4. The properties of an *acid* are: (1) It contains hydrogen; (2) part or all of its hydrogen can be replaced by a metal (or its equivalent), and a salt is thereby formed; (3) it can change the color of many organic substances; (4) when soluble in water it has an acid or sour taste.

The properties of an *alkali* are: (1) It is strongly basic; (2) it is alkaline in reaction; (3) it will saponify fats.

5. An *oxide* is a compound of oxygen with another element.

6. Chloroform is a substitution product of methane. Three of the four hydrogen atoms of methane are replaced by three atoms of chlorine; hence the formula is $CHCl_3$, and the proper name would be Trichlormethane.

Chloroform can be obtained by heating chloral hydrate with an alkali:

$$C_2HCl_3(OH)_2 + KHO = CHCl_3 + HCOOK + H_2O$$

7. *Fermentation* is the decomposition of organic matter containing carbon, hydrogen, and oxygen only. When it also contains nitrogen and sulphur the process is called *Putrefaction.*

8. Alcohol.

9. Oxygen can be prepared by heating potassium chlorate:

$$2KClO_3 = 2KCl + 3O_2$$

10. (1) Arsenic; antidote, freshly prepared ferric hydroxide. (2) Corrosive sublimate; antidote, white of egg in moderation. (3) Phosphorus; antidote (physiological), old French oil of turpentine.

MATERIA MEDICA AND THERAPEUTICS.

1. The activity of hydrogen peroxide depends upon the readiness with which it gives up oxygen to oxidizable substances with which it comes in contact.

It is employed in the form of the solution:—Aqua Hydrogenii Dioxidi, which contains about ten volumes of available oxygen.

2. Cold is employed:—for its local effect on inflammatory processes; for neuralgias; as a local anesthetic; to reduce the body temperature; to relieve cardiac palpitation; in meningitis; for insomnia; by rectal injection in dysentery.

"Cold causes relief of pain in inflammation by producing contraction of the local blood-vessel walls. As a result inflammatory exudates do not occur, congestion is relieved, and as the pressure on the nerve filaments ceases the pulsating pain of inflammation passes away." (Hare's *Practical Therapeutics.*)

3. The following from Parkes' *Practical Hygiene* will answer this question: "The effects of exercise on the body are as follows: (1) Increased force and frequency of the heart's action, and the increased circulation of the blood through all parts of the body. (2) The pulmonary circulation being quickened, more carbonic acid and water are taken to the lungs and eliminated. The amount of air inspired and expired is largely increased, and the oxygenation of the blood is consequently accelerated. (3) The action of the skin is heightened, and perspiration becomes marked, large quantities of sweat being poured out of the sweat glands. The evaporation of the sweat from the surface of the body regulates the temperature and prevents any rise above the normal. (4) The water and salt of the urine are decreased owing to the large cutaneous secretion, but the nitrogen (in the form of urea, uric acid, and extractives) is unaffected. In the period of rest following excessive exercise, the nitrogen elimination may be slightly increased. (5) The voluntary muscles are brought into active play; the circulation of the blood through them is accelerated; waste products are rapidly carried away for excretion; while the material for new tissue is brought to them."

4. Heroin is a derivative of morphine; it is formed from morphine by substituting acetyl for its two hydroxyls. It is a colorless, odorless powder; crystalline, with a somewhat bitter taste, and is insoluble in water. The hydrochloride, however, is soluble in water.

Its action is to quiet the respiratory centers; and it is used chiefly for quieting cough.

5. ℞ Hexamethylenaminæ ʒij.
Aquæ destillatæ q. s. ad ʒiv. M.
Sig.:—One teaspoonful every three hours.

9. Eserine is *obtained* from Physostigma.

Its *action* is:—(1) to contract the pupil; (2) to stimulate involuntary muscle fibers; (3) a mild nervous sedative; (4) it increases peristalsis.

10. Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

PHYSICAL DIAGNOSIS.

1. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

2. *Aortic murmurs* may signify: (1) aortic stenosis; (2) aneurysm of the arch of the aorta; (3) aortic regurgitation. In the latter case the murmur is diastolic; in the two former, it is systolic.

3. *Herpes labialis* may signify:—(1) slight feverishness; (2) coryza; (3) bronchitis; (4) pneumonia; (5) digestive disturbances; (6) cerebrospinal fever; (7) approaching menstruation; and (8) it may be a neurosis.

4. *Reflex vomiting* may indicate:—meningitis; pregnancy; astigmatism; irritation of the fauces; worms; uterine, tubal, or ovarian disease.

5. *Hiccough* may indicate:—several of the gastrointestinal disorders; epilepsy, hysteria, meningitis, cerebral tumors; gout; diabetes; typhoid; alcoholism; nephritis.

6. *Blood in the stools* may indicate:—(1) traumatism; (2) acute inflammation of the bowels, as in enteritis and dysentery; (3) chronic heart or liver disease; (4) scurvy, purpura or infectious fevers; (5) rupture of an aneurysm; (6) ulcers in the intestine; (7) intussusception; (8) the passage of blood from the stomach in hematemesis; (9) hemorrhagic infarction of the bowel from embolism or thrombosis of the mesenteric artery; (10) piles, fissure, or fistula. (From Steven's *Practice of Medicine*.)

9. *General distention of the abdomen* may signify:—Tumors, ascites, pregnancy, tympanites, peritonitis, cretinism, enlarged mesenteric glands.

10. *Rigid recti muscles* may signify:—appendicitis or peritonitis.

PRACTICE AND PATHOLOGY.

2. In the smaller blood-vessels the lumen may become nearly obliterated (endarteritis obliterans). There may be cardiac hypertrophy; thrombosis may occur; the thrombi may become organized, or emboli may be formed; connective tissue hyperplasia is apt to occur.

4. The lower part of the pons, on the left side.

6. *Carcinoma* is derived from the epiblast or the hypoblast; possesses a stroma, in which are both blood-vessels and lymphatics; metastasis occurs by the lymphatics.

Sarcoma is derived from the mesoblast; it has no stroma and no lymphatics; metastasis occurs by the blood-vessels which are in contact with the cells.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.

THE PHYSIOLOGICAL ACTION OF THE PANCREATIC ENZYMES, WITH SPECIAL REFERENCE TO HEMATOLOGY, URINOLOGY, AND CLINICAL PATHOLOGY.

By MARGARET A. CLEAVES, M.D.,

NEW YORK.

Digestive ferments should not be regarded therapeutically in any way other than medicinal agents. To that end a study of their action upon the blood and urine is not only of great importance, but of the first consideration.

In trypsin we have a drug possessed of great potentialities, and one which should not be allowed to remain an unchartered derelict on the sea of therapeutics, a perpetual menace, a veritable danger. I have no desire to enter the arena already strewn with eminent pathologists and surgeons, nor do I wish to advance or discuss "cancer cures"; but because of my experience in the enzymic treatment of cancer, supplemented by careful laboratory observation, it is daily enforced on me by those seeking my assistance in an advisory way that many are using the pancreatic ferments, with an impunity that can only be accounted for by a lack of concrete knowledge. The fatal results which are chronicled are not always due to cancer, but often to uremic poisoning from faulty therapeutic technique.

My reason for this paper is not to discuss the merits or demerits of the treatment advanced by Dr. John Beard, but to call attention to the dangers and discouragements of the treatment. That the seeming advantages of the treatment outweigh these dangers, from my point of view, goes without saying, or I would have discarded the pancreatic ferments as therapeutic agents. A secondary and very considerable consideration in my mind is that trypsin opens up a new field to the experimental physiologist and clinician in a certain class of diseases hitherto not linked together.

Despite the fact that it is impossible to do otherwise than to leave many gaps, it seems but logical to embody my clinical experience in a tentative report on the physiological action of the pancreatic ferments.

Enzymes.—Before entering upon a consideration of the physiological action and reaction induced by the trypsin treatment, it is first necessary to take up in detail the occurrence, nature, function, and action of enzymes. The facts cited must of necessity be fragmentary, as the sum total of the knowledge concerning enzymes is still in the stage of debatable theory.

Enzymes, of which trypsin is an example, are in some degree characterized by the following reactions and characteristics: They are exclusively of cell life, and no cell is without them; hence the deduction that enzymes are of necessity an accompaniment of proteid. Practically the only attempt to fix definitely the action of enzymes is that embodied in the theory of Arthus, who ascribed their qualities simply to natural laws. He finds an analogy between the enzymic properties of a cell and magnetism, basing his deduction upon the facts that enzymes and magnetism are both destroyed by heat, dissolved by acid, each impossible of isolation, and both are recognized by deeds rather than by perceptible matter.

The following formulas give the synthetic and general chemical reaction of enzymes:

$$C_3H_5—O—OC—C_3H_7+H_2O=C_2H_5OH+HOOC—C_3H_7$$

Ethyl butyrate + water = ethyl alcohol + butyric acid.

If water be added to ethyl butyrate the above equation takes place. The reverse equation is true, except that the reaction is never complete, but the reaction is so slow in the reverse equation that unless a catalytic agent is present the time required is very long. This is well brought out in Wells' Chemical Pathology,[1] the latest and best authority on the subject.

Synthetically, Taylor[2] was able to build up triolein by the action of lipase upon oleic acid and glycerine, and it is known that the intestinal wall splits proteids, which are rebuilt in other parts of the body. This must be done by enzymes, which reverse their usual action, and synthetically build up complex proteids from simpler bodies.

All enzymic action depends on the fact that the chemical reactions accomplished are everlastingly reversible and tend to an equilibrium. The action is also catalytic, and the tendency to find an equilibrium before a complete chemical reaction takes place must be remembered in connection with the administration of trypsin.

As a classical example of the synthetic action of enzymes the formation of hippuric acid from benzoic acid and glycocoll may be given. It is probable that enzymes can only act as dehydrating agents and oxydizers, or in establishing the reverse of these processes.

There are certain phenomena which enzymes and toxins have in common. Both act on cells to produce immune bodies known as antienzymes and antitoxins respectively; a specific enzyme acting on a suitable cell will produce a specific antienzyme just as surely as diphtheria will produce antidiphtheritic toxin. Toxicity is also a characteristic of the enzyme when injected into a body. Fiquet[3] gives the first action of trypsin as rendering the blood uncoagulable, but afterward the opposite effect is observed. Wells[4] in using trypsin and lipase found an acute inflammatory condition. A marked difference between enzymes and toxins is that strong solutions of enzymes are able to resist the action of the milder

germicides, when a weak solution of the enzyme is rendered inert.

Enzymes exist in the cell as inert bodies, zymogenic in form, and their activities only come after they are discharged from the cell, for example, in the case of trypsinogen, which is acted upon by the enterokinase of the intestinal wall to form active trypsin.

It is probable that enzymes are of stereochemical configuration in their construction; that is, they are built up on a central element having a definite valence, and hence, that all enzymes are capable of entering into chemical action with only those substances that attract and have an opposite isomeric form. Emil Fischer has proved that a different enzyme is needed for example to differentiate and act on two sugars, no matter how closely they are allied.

The pancreas yields three enzymes: Trypsin, amylopsin, and lipase. Of these trypsin is as exclusive in its action on the proteids as lipase is on the action of fats, and the third, amylopsin, acts on the carbohydrates.

Cases.—For the purposes of this paper the conditions treated of will be classified as follows, and a single case from each class will be selected for illustrative purposes: (1) Intestinal surgical interference; (2) postoperative; (3) inoperable; (4) metastases; (5) nonmalignant.

(1) Intestinal Surgical Interference.—Rectal adenocarcinoma. The original operation was performed seven years since and artificial anus formed; microscopical examination made by J. H. Wright of the Massachusetts General Hospital. Two subsequent operations, one to reunite the intestine (failed); the second fourteen to fifteen months since to change the lateral incision in the intestine to a cross cut, on account of the pocketing of the feces in the colon. At that time the mesenteric glands were found enlarged. This enlargement was regarded by the surgeon as malignant. At the time treatment was instituted, ten months since, the entire pelvis was filled with plaster-of-paris-like induration, as is common in the female pelvis. There was an ulcerated area about 1½ inches above the internal sphincter of a ragged nodular feel, the examining finger and irrigating catheter passing to the depth of four inches only. A condition of profound neurasthenia of long standing existed. Morphine had been taken off and on for two years, almost constantly for one year, one to two grains in twenty-four hours. There were obstinate constipation, loss of appetite, strength, and flesh, pain, discharge, odor, sense of weight, bearing down, and a sinking feeling in the pelvis, with inability to stand or walk save for a few moments only, and very short distances. In addition there were more or less constant fluctuations of temperature, exhausting night sweats, and intense sciatic and sacral pain. Length of life was estimated by the surgeon at one year, but the patient grew rapidly worse, leading the family physician to put it at from two to three months.

The enzyme treatment has been kept up for ten months, at first vigorously, later less frequently. At the beginning of treatment continuous irrigation of the cut off sigmoid flexure dislodged old fecal matter which, upon examination, showed tubercle bacilli. The masses are absorbed, there is absence of weight in the pelvis, absence of pain; no opiates have been used in eight months; there is no odor, no discharge, appetite fair, food is taken in sufficient quantities, the functions are normal, sleep good, good mental vigor, better than for over a year; the patient looks after his personal and professional interests and presents no evidence of progressive malignant disease; weight fluctuates, at present gaining.

At intervals of from four to six weeks during past six months there have been discarded from the rectum pieces of tissue, not necrotic, which have been found by Dr. Wm. M. Higgins to be destitute of malignant characteristics and showing the structure of an adenoma. The disused bowel has been carefully irrigated and is now empty of its fecal contents.

(2) Post Operative.—Carcinoma of uterus and bladder wall. Panhysterectomy, January 9, 1907, bladder wall torn and reunited; service of Dr. Louis J. Ladinski, N. Y. Polyclinic Hospital, by whose courtesy I was enabled to supervise the postoperative treatment, which was begun January 19, 1907; twenty days after operation, characteristic tryptoglycogenic reaction. (See Chart No. 1 for temperature curve.)

Result to date: Improved appetite and metabolism, softening of nodular tissues in vagina as in the illustrative rectal case, Class 1. Still under treatment. Odor and pain present at beginning of treatment now in abeyance.

(3) Inoperable.—Uterine. Microscopic examination in service of Dr. Vanderveer of Albany, who curetted one year since for hemorrhage. Adenocarcinoma, infiltration of both broad ligaments. Seen by Drs. Clement Cleveland and Robert T. Morris of New York City and declared inoperable by both. Uterus fixed, hard, cervix indurated, and both broad ligaments infiltrated.

Treatment instituted February 11, 1907. By March 1, induration of broad ligaments was markedly lessened, uterus movable. This case was seen during the eight weeks of treatment four times by Dr. Robert T. Morris, who on April 2 found that improvement had progressed to the point where he was willing to operate. Patient in good condition. Much improved in every way. Operation was arranged for a week later, but patient was called home on account of illness in family and despite the future gravity of the case, decided not to have the operation performed. In addition to the enzyme treatment, vaginal hydroelectric treatments, with the continuous current, were given twice a week. The body superficies was exposed to the action of light and static electricity used pretty constantly. This case showed the characteristic tryptoglycogenic reaction, but followed a very regular course from first to last. The daily range of the temperature was from normal to 99° in the morning, 99° at noon, and 100° at night—occasionally 101° and 102°.

(4) Metastases.—Amputation of right breast was performed in 1903: the patient was seen in 1907. Scirrhus cancer of left breast of extreme malignancy; microscopic examination by Dr. Wm. M. Higgins. One year in duration; metastatic involvement. Operable stage had been devoted to Christian Science. Growth absolutely fixed, involvement of cervical, axillary, mediastinal, subcutaneous, inframammary region, and inguinal glands. An invalid for thirty years. Digestive disturbances of years standing; insufficiency of hepatic and pancreatic function. Under treatment for three months. Pain in breast entirely relieved last four weeks of life save night preceding death, no breaking down of tissue, nutrition improved. Seen by Dr. Graeme M. Hammond of New York City three days before death, who pronounced it the

most healthy looking scirrhus cancer of the breast he had ever seen.

Patient died of exhaustion probably referable to action of toxins on vagus. Consciousness and mental activity to the last. No uremic symptoms.

(5) Nonmalignant.—Abdominal hysterectomy, October 18, 1906, by Dr. J. Riddle Goffe. Through his courtesy I had charge of the postoperative treatment. The indications for treatment were based upon the report of the pathologist, who gave a diagnosis of carcinoma. Later examination by another pathologist showed the section furnished to be benign in character. There was no tryptoglycogenic reaction. (See Chart No. 2 for temperature curve in contrast with Chart No. 1, of temperature in case illustrating Class 2.) Metabolism greatly improved and a gain of twenty pounds in weight.

Preparations.—Of the pancreatic ferments (Fairchild) two are used in every case, viz., an injection of trypsin which is prepared directly from the fresh pancreas gland especially for hypodermic use. It contains the trypsin in its normal association with the other soluble enzymes and constituents of the pancreas secretions. The second—amyolpsin—is a solution of pancreatic diastase (amylopsin) devoid of the proteolytic (trypsin) and fat-splitting (lipase) ferments. It is also especially prepared for hypodermic use.

Methods of administration: (1) Hypodermic, (*a*) into the subcutaneous tissues, (*b*) into the tumor mass; (2) by rectum; (3) by mouth. The administration of the pancreatic ferments is almost exclusively by hypodermic injections, combined with the local application of a pancreatic lotion and a trypsin powder in suitable localities. According to Graves,[4] unless the ferments are directly injected into the growth, no results are obtained. This is in direct opposition to my own observations.

In cases where there is very severe local reaction at the site of injection, rather than discontinue the use of trypsin, I have given it occasionally per rectum diluted in twice to three times its volume of sterilized water. In this way I have secured evidence of the action of the ferments, but not in the same degree as when used hypodermically. There has been slight chill, rise of temperature, tension and rigidity of diseased glands, and a slight but insufficient increase of the eosinophiles.

Macafee[5] reports a case of adenocarcinoma, uterine primary, rectal secondary, in which he gave the enzymic ferments (1) by mouth (2) in the colonic opening. No reaction was noted save once there were nausea, vomiting, and a rash which were controlled by letting up on the oral administration. The patient was markedly improved.

E. v. Leyden and P. Bergell[6] report that injections made directly into a carcinoma in man were

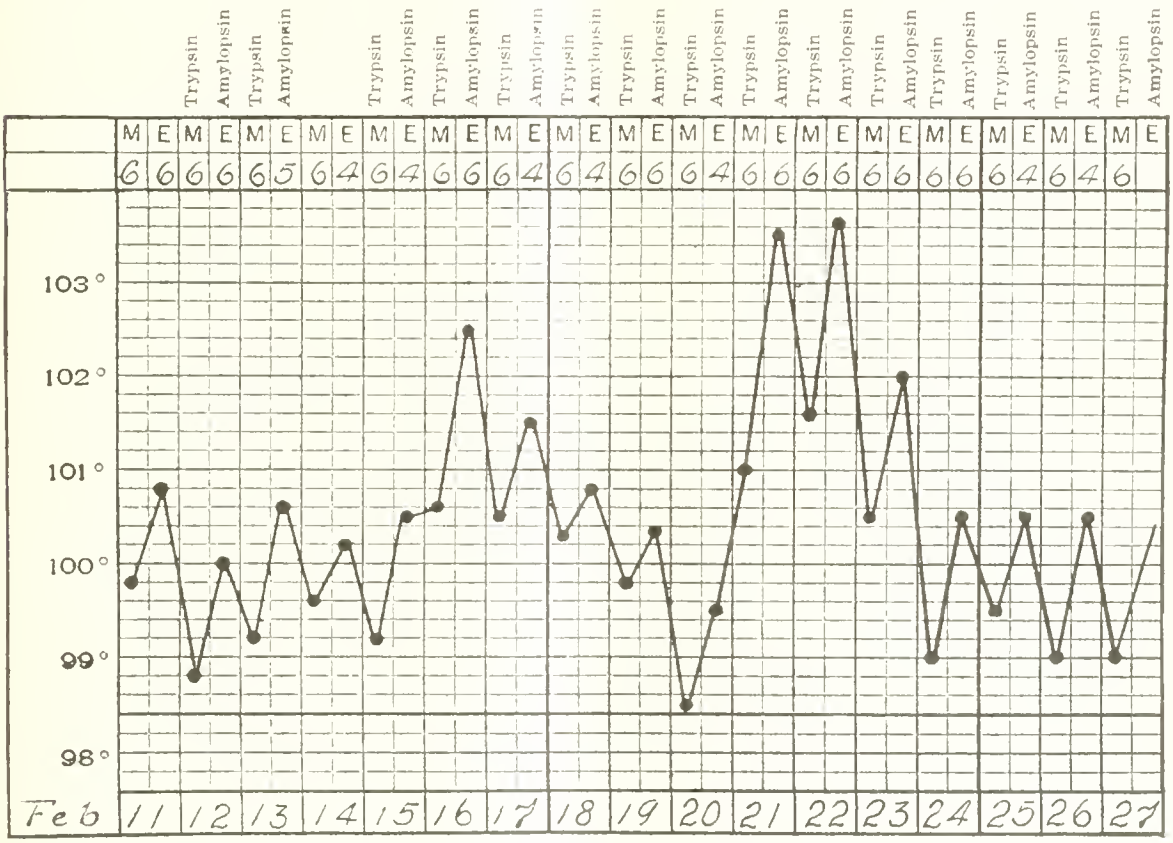

Chart 1. Illustrative Case, Class 2, Carcinoma of the Uterus. The treatment was instituted January 28, 1907; the chart shows the temperature during the third and fourth weeks of treatment; the doses of trypsin and amylopsin were 38 minims each.

disappointing and that their experimental experience with trypsin shows that larger amounts pass into the blood when it is given by the mouth than when it is injected subcutaneously. In the direct injection into the cancerous tissue, the result was always circumscribed. Given internally in large amounts and over long periods of time, no decisive influence could be demonstrated in cases of inaccessible internal carcinoma. On the other hand, an unmistakable favorable reaction was noted in nearly every case of carcinoma of the stomach not too far advanced and still free from metastases. They also found that a tumor whose cells have been digested by the trypsin in some circumscribed area never reacts to this interference with increased growth either locally or in general. This is justly regarded as significant and is believed by von Leyden to show an actual specific destructive process, even if it is only temporary.

The *dose* of *trypsin* hypodermically varies and is governed by (1) the pathological condition and (2) by the condition of the kidneys before and after treatment is instituted.

In nonmalignant conditions large and long continued doses are well borne, as there is no reaction other than the local one at the site of the injection. This is well shown in illustrative case of Class 5, and also in the experiments of Pinkus[7] upon healthy dogs. In the latter as much as six ampoules of the original strength was given, with the result of improving nutrition and increasing the body weight. The same result was obtained in nonmalignant case of Class 5. This patient was given injections of trypsin of special strength daily for four weeks, in the first week from one-third to one-half ampoule, and afterward from one to two ampoules without rule was followed, and two ampoules were given first daily, and then on alternate days. Again in case illustrating Class 3, from one-half an ampoule to three ampoules of the trypsin injection (special strength) was given daily excepting Sundays and the few days on which amylopsin was given.

If given by rectum, the dose should be twice that of the customary hypodermic dose, and it should be diluted in from two to three times its volume of cold sterilized water. The rectal tube should be carried high up into the bowel for at least nine to twelve inches.

There is no evidence of any localized inflammation within the intestinal tract as with puncture. The method, however, is not advocated save where the discomfort, pain, swelling, and induration following upon hypodermic use is very badly borne

CHART 2 Illustrative Case, Class 5, non-malignant. Teatment was instituted December 2[illegible] 1906, the chart shows the temperature from the seventeenth to the thirty-fourth days of treatment.

any amylopsin, without any reaction, and with steady nutritive gain. This was evidenced by the urine analysis as well as by the patient's appearance and condition of improved metabolism, and her gain in weight from December 2, 1906, to February 15, 1907, of twenty pounds. She never had a rise of temperature, nor any save local reaction from the punctures.

In patients suffering from malignant conditions the doses must vary according to the patient's ability to take care of them. Small and infrequent doses seem to bear a definite relation to long and protracted toxic conditions.

In illustrative case of Class 1 the original strength of trypsin injection was used, beginning with five minims and rapidly increasing to two ampoules.

In a rectal case belonging to Class 3, the same and the administration of trypsin and amylopsin is imperative.

Amylopsin.—This, in the present state of our knowledge should be administered in doses of from one to two ampoules from the beginning of treatment to control any bad symptoms, such as nausea, vomiting, pain in the back, drowsiness, high arterial tension, albuminuria, and edema generally. The position of amylopsin is a difficult one to define. There is practically no literature on the subject nor are there any laboratory experiments dealing with amylopsin isolated from other ferments. It is, therefore, difficult to trace how far amylopsin acts as a physiological antidote to trypsin. It does seem to increase the urea output and apparently relieves the distressing symptoms associated with the action

of trypsin, and until further studies and experiments have been made as to its physiological role, it should be administered as indicated, and later in the treatment alternate with the use of trypsin, while still further on it may be given alone. At all times the blood must be regarded as the index, and careful observations must be made of the urine as well as the clinical picture to determine the indications for injections of trypsin, their frequency and strength.

Site of Puncture.—This in my experience has invariably been into the subcutaneous tissues of the back from the infrascapular region, and including the buttocks, keeping well away from the vertebral column and avoiding the use of both sides of the body simultaneously in order that the patient may lie on one side or the other without pain. In ambulant patients the buttocks are not used save exceptionally. On the other hand, where patients are obliged to be in bed, the buttocks may be used as well as the back. In case illustrating Class 1, where collapse occurred in thirty seconds after the injection, the puncture was made by my colleague very near the spinal column, and about the third dorsal vertebra. The explanation seems to be the same as that governing surgical shock. Graves[4] reports a serious state of collapse, following upon and two hours after the first injection of ten minims into a rapidly proliferating squamous cell carcinoma of the cervix uteri which for a time was alarming. He states that the reaction resembled in general character that which sometimes follows the injections of Coley's serum, but was more severe. The explanation in both cases is undoubtedly the same.

Care in Administration.—The greatest care and cleanliness should obtain of (1) the operator's hands, (2) the syringe, and (3) the patient's skin.

Local Reaction.—The hypodermic administration of trypsin in contradistinction to amyolpsin is accompanied by severe local reaction, not dissimilar to that following deep-seated injection of mercury. This varies in different patients.

Absorption of the Ferments.—This seems to take place rather slowly, and patients complain bitterly if the whole back is used indiscriminately for hypodermic injections.

Trypsin *vs.* Amylopsin.—Subjectively there is quickly acquired by patients an ability to differentiate between trypsin and amylopsin (1) at site of injection, (2) in systemic reaction.

With the former the burning sensation at site of injection is intense and inflammatory reaction marked, while with the latter there is very little sensory disturbance following upon the introduction of the ferment into the subcutaneous tissues, so little that patients will say when amylopsin is given: "Oh! put it anywhere; it does not matter." With trypsin it is a matter of grave consideration if the patient's point of view receives the consideration it should. Graves[4] injects directly into the tumor masses and states that there is no evidence in these cases to show that trypsin affects cancer cells by circulating in the blood or that it affects them in any way excepting by direct contact. My experience and laboratory work justify the reverse of this statement.

Tryptoglycogenic Reaction.—The marked eosinophilia of each case treated by the pancreatic ferments, with the exception of illustrative case of Class 5, suggests a comparison of the conditions in which eosinophilia is found. The following conditions are given by Wood[8] as being associated with eosinophilia: (1) Bronchial asthma, (2) skin diseases, (3) intestinal parasites, (4) trichinosis, (5) malignant diseases, especially bone marrow, (6) postfebrile eosinophilia, (7) toxic eosinophilia (tuberculin, cinnamic acid, camphor), (8) hydatid cysts, (9) gonorrhea (occasional), (10) scarlet fever.

To this list now may be added the administration of trypsin. Nos. 3, 4, 5, and 8 are possessed of a common factor in that glycogen is present in pathological quantities as a concurrent element. To trace the connection between the occurrence of eosinophilia in some of the conditions mentioned by Wood[8] would lead too far into the field of speculation, but in view of the fact that malignant tumors are rich in glycogen, and that under the enzymic treatment there is established an eosinophilia, it is logical to conclude that the classical eosinophilia of intestinal parasites is due to the glycogen contained in the epi-

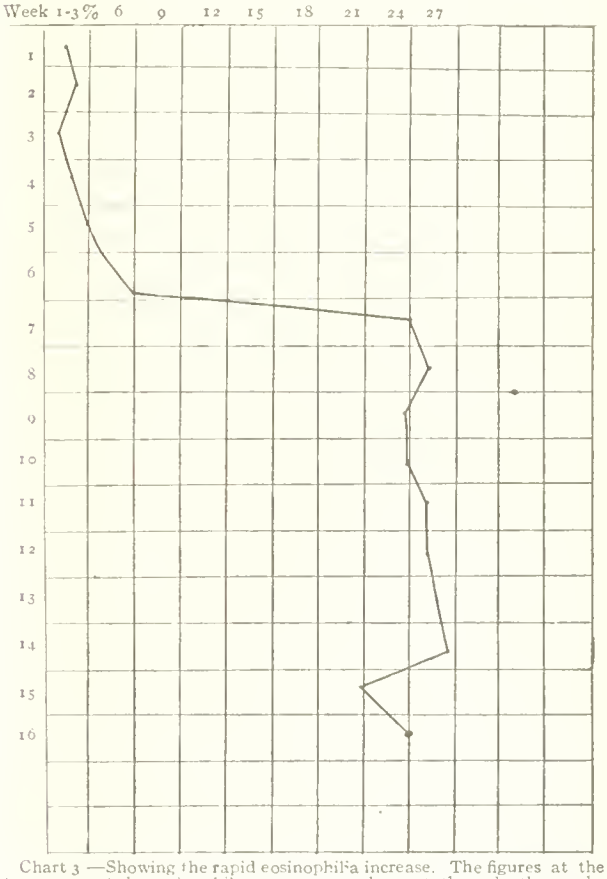

Chart 3.—Showing the rapid eosinophilia increase. The figures at the top represent the eosinophile percentages; those at the side the weeks of treatment. The white cells numbered 14,000 per c.m. approximately throughout the treatment; the red cells, over 4,000,000; the hemoglobin percentage was 90.

There is present a sufficient glycogenic potential to cause the reaction to be exhibited, for example, where a panhysterectomy has been had as an illustrative case under Class 2. The temperature chart of this patient graphically shows the characteristic dermis of these parasites. It is of equal interest to mention here that in hydatid cysts,[9] a cyst very rich in glycogen, as high as 50 per cent. of eosinophilia has been found. Glycogen is also present in all newly proliferating tissues. For example, Bernard[10] has shown it to be present in nails, feathers, etc., and in moulting animals. This is suggestive in view of the fact that in many skin diseases a proliferation of the cutis vera is exhibited.

Systemic Reaction.—In a consideration of the systemic reaction following upon the administration of trypsin, it is necessary to differentiate between those patients having pathoglycogenic accumulations and those without. It is necessary also that the former condition should exist in order that a "tryptoglycogenic" reaction should be obtained.

temperature reaction in a condition characterized by pathoglycogenic accumulations, while the illustrative case of Class 5 shows no such reaction. This latter postoperative case was submitted to me for the enzyme treatment by Dr. J. Riddle Goffe, with the diagnosis of carcinoma, the diagnosis being based on the microscopical pathological findings as reported to him by the pathologist.

In view of previous experience, the absence of systemic reaction caused me to question the pathological findings. I reported this to Dr. Goffe and asked for confirmation of the diagnosis of carcinoma. He kindly sent me the pathologist's report,

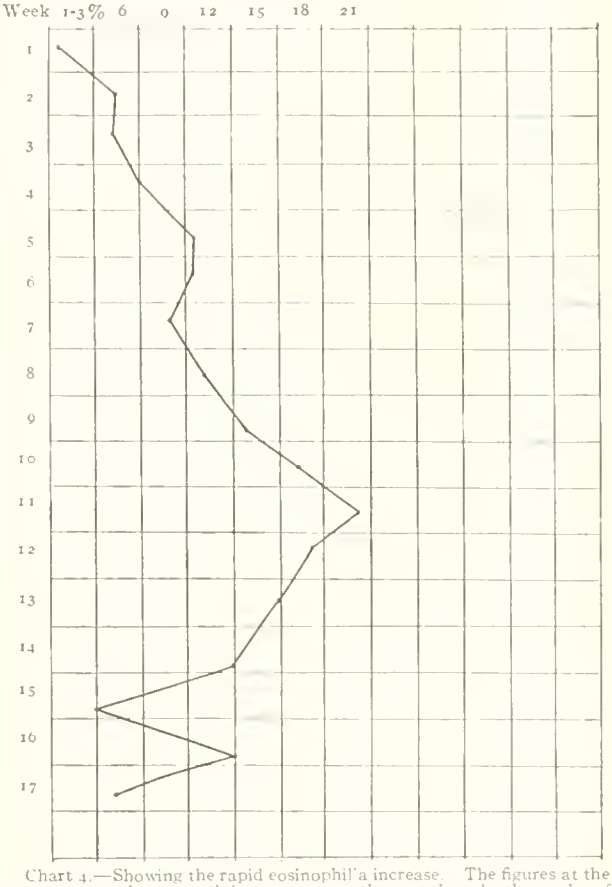

Chart 4.—Showing the rapid eosinophil a increase. The figures at the top represent the eosinophile percentages; those at the side the weeks of treatment. The white cells numbered before treatment, 5,100; during treatment, 12,000; the day before death, 18,000; the red cells, before treatment, 4,312,000; during treatment, 4,864,000; the day before death, 4,000,000; hemoglobin percentage, before treatment, 62, during treatment, 92; the day before death, 95.

which stated that the section taken was a carcinoma. In the continued absence of any tryptoglycogenic reaction, and continued nutritive gain, I asked Dr. Goffe if he could secure me a section, which he promptly did. This upon examination Dr. Wm. M. Higgins diagnosed as benign, a diagnosis which was confirmed by several pathologists in New York City, by the State Cancer Laboratory at Buffalo, and by Dr. John Beard of Edinburgh. This is the only case in which the cardinal symptoms of the tryptoglycogenic reaction were not present.

The only symptoms were the usual local ones referable to the hypodermic injections, together with a possible low-grade nephritis. Owing to the fact that there is a possibility of setting up a subacute nephritis, the burden of proving or disproving this interesting confirmation of Dr. Beard's theory, as to the selective action of the pancreatic ferments, must await the appearance of sufficient wrongly diagnosed cases.

Within from one-half to two hours after the injection of trypsin, in the average case, sooner or later in the treatment the patient exhibits many or all the symptoms of a toxemia, *i.e.* chills, fever, temperature ranging from 100° to 102°-103° F., sweating, rapid pulse, increased respiration, and not infrequently the skin is covered with a rash.

Blood.—In cases of cancer cachexia with the moderate loss in hemoglobin, a marked improvement is shown, although the daily deviations are greater than 5 per cent.

A moderate leucocytosis immediately follows the injection of trypsin, the count running from 9,000 to 14,000 per cubic centimeter within the first week. There is no accumulative effect exhibited by the white blood count. The red blood cells follow the hemoglobin curve closely, giving an index approximating 1 throughout. The distinct and very characteristic eosinophilia increase, as shown in Charts Nos. 3 and 4, seems to be a fair and scientific basis for a tentative working hypothesis as regards the effect of trypsin and amylopsin, and is of the greatest value from a clinical-pathological point of view, especially in connection with Habershon's[11] views on the close alliance, if not the identity, of glycogen and eosinophilia granules. The question of glycogen in tumors has been well worked out by Lubarsch[12] and Gierke,[13] stimulated by Brault's false theory that the malignancy of a tumor varied directly as its glycogenic contents. According to Wells, the two factors that govern the presence of glycogen are the embryonic origin of the tumor and local retrogressive changes. Tumors arising from embryonic tissues containing glycogen are in consequence particularly rich in this carbohydrate. Fully 80 per cent. of tumors in their final stages are associated with glycogen in pathological quantities. Is trypsin the catalytic agent that converts the proteid molecule into glycogen? If so, is this a conservative process, or merely a vagrant chemical reaction which takes place without interfering with the pathological metabolism of cancer?

The presence of an intestinal parasite, rich in glycogen, gives the characteristic eosinophilia picture of clinical microscopy. In cases of hydatid cysts as high as 58 per cent. of eosinophiles have been noted.[9] Attention is constantly being directed in the pages of medical literature to the high percentage of eosinophiles in all those conditions in which glycogen is present in pathological quantities. It is a common bond in all pathological conditions associated with glycogen. These facts, combined with Lubarsch's findings, that glycogen is constant in horny degeneration of a squamous cancer, would most strongly suggest that the eosinophile reaction of trypsin is due to a degeneration of cancerous growth, and should not be constant for all tumors, but vary as their embryological basis.

The only possible explanation of the effect of trypsin on pathological conditions capable of giving a tryptic reaction must be that certain proteid molecules, *e.g.* in cancerous conditions, are capable of being attacked by trypsin, because of their special configuration. This configuration allows the trypsin to act on the proteid disturbing the point of equilibrium in the glycogen proteid synthesis, the equilibrium point as a whole being that of a simpler molecule than the complex proteid molecule of perverted cell metabolism met with, for example, in cancer. That is, if a quantity of food represented by 10x would in the ordinary course of metabolism give 9x proteid and 1x of glycogen as the final result in the unfinished synthetic and catalytic reactions, the injections of trypsin in the given pathological condition will result in 1x proteid and 9x

glycogen, and a consequent faulty metabolic functioning of the cell, and perhaps its death.

From these observations a hypothesis may be formulated, namely, that trypsin acts on intercellular matter of a definite configuration, following the selective law of enzymes, and that the result is a pathological quantity of glycogen throughout the body, manifested especially in the eosin granules and to a certain extent probably stored up in the muscles.

As glycogen is not stored up in dead cells, but rather split off from them, and as it is associated in nearly all cases with accumulation in the leucocytes and muscle cells, it would seem fair to imagine that in cases of trypsin reaction the body is saturated with glycogen. Clinically I would note in this connection that the most marked results have been obtained in cases of adenocarcinoma.

Action on the Sympathetic Nervous System.—As the result of the trypsin treatment of cancer there is produced a profound irritation of the sympathetic nervous system. This is markedly evidenced by interference with the circulation in glandular structures—a breast, for example. The gland becomes swollen, is tense and rigid, both to the observer's touch and the patient's sensation. In adenocarcinoma there is great tumefaction, but there does not appear to be the same tenseness and rigidity as in scirrhus. The redness of the superficial structures still further emphasizes the disturbed circulatory conditions. Where there is glandular involvement, as in illustrative case of Class 4, the entire chain of involved glands, in this instance cervical, axillary, mediastinal, and subcutaneous gland of inframammary regions especially, and occasionally the inguinal also, became extremely tense and rigid during the hours following the use of trypsin.

While the daily urine analyses have not established clearly a definite relation between the treatment and the output of urea, there does seem to have been noted a tendency toward the lessening of the urea following the injection of trypsin, which can readily be explained on the ground of the interference of the circulation in the glandular structure due to the irritation of the sympathetic nervous system; while on the other hand, in a number of instances, an increased output of urea has been observed upon the administration of amylopsin. This data, however, is not sufficient to establish the fact that the output of urea is limited by the action of trypsin or increased by the administration of amylopsin. It is simply rational to believe that the circulatory conditions in the kidney (vasomotor constriction) under the influence of trypsin should limit both the secretion of urine and the output of urea. It is noted by all these patients with intelligence, or by their nurses, that following the use of the trypsin the urine is less profuse and of a darker coloring.

Another and invariable evidence of the irritation of the sympathetic nervous system is shown in the complete relaxation of sphincter muscles, for example, the anal sphincter, the urethral, that of the os uteri, according to the site of the disease.

In illustrative case of Class 1 the anal sphincter has been continuously relaxed since the first two weeks of treatment, now ten months since.

In the illustrative case of Class 3 the os uteri was dilated at the end of two weeks and fully open in eighteen days, the examining finger penetrating freely beyond the internal os. So complete was this dilatation that the contour of the proliferating mass within the body of the uterus could be readily outlined.

Eosinophiles in Pulmonary Tuberculosis.—The behavior of eosinophile leucocytes in pulmonary tuberculosis has been studied by J. M. Swan and H. T. Karsner[14] and they present further evidence as to the behavior of the eosinophiles in cases of tuberculosis, with special reference to the prognostic value of these cells found in the peripheral blood. Differential counts of the leucocytes in the blood of thirty-one cases of pulmonary tuberculosis were made. Of this number twenty-six cases were fatal and five were stationary, or were improving under treatment at the time the observations were discontinued. In all the fatal cases except two the eosinophile cells were below 1 per cent. as a rule, at periods from 102 days before death to the day of death. In the cases which remained stationary, or which were improving under treatment, the eosinophiles, while subject to fluctuations, were present in fair proportion, usually over 1 per cent. From their observations the authors conclude that in cases of pulmonary tuberculosis the eosinophile cells tend to disappear from the circulating blood as the progress of the disease brings the fatal termination nearer, and that as the patient improves under treatment and as the disease shows a tendency to become arrested, the eosinophile cells reappear in the circulating blood.

A preliminary study of the same subject has been made by Opie.[15] While the behavior of eosinophile leucocytes has not been studied in the same careful manner in conditions of intestinal tuberculosis, there can be no question but that they must deport themselves in similar fashion.

In illustrative case under Class 1, therefore, the absolute disappearance of tubercle bacilli from the discharge of the disused bowel may then be explained by the increased eosinophilia of the circulating medium, consequent upon the administration of the enzymic treatment. The enzyme treatment was begun by the introduction of injections of trypsin as originally put out, diluted with two volumes of sterilized water introduced into the disused rectum. The fecal discharge from the cut-off bowel—sigmoid flexure—was much more profuse after treatment in this way for a little over a week, and contained, in addition to the semiconsistent old grayish fecal matter, a number of ovoid bodies, the size of an ordinary almond, which, when dried and opened, had a pithlike appearance. This discharge upon examination (August 10, 1906) revealed the presence of tubercle bacilli. Their presence accounted for the fluctuations of temperature, exhausting night sweats, absolutely tubercular in their characteristics, and in part for impaired appetite and loss of flesh and strength.

On August 10, the trypsin was introduced directly into the circulation by hypodermic injections into the subcutaneous tissues of the buttocks. This was carried on daily with relief from night sweats, improved appetite, and steady diminution of the plaster-of-paris-like induration in and about the rectum and bladder. Later on came the characteristic tumefaction of the rectal tissues, which were in a condition of cauliflower excrescence. Within three weeks from the beginning of hypodermic injections my case book records improved appetite, lessened pain, lessened rectal discharge, better appearance of urine, increased vesical capacity with longer intervals between rises of temperature (normal, 99-100), and disappearance of excessive night sweats. The tumor mass of most recent formation, apparently the result of severe attack of illness characterized by fever, sweating, imperfect functioning, excruciating sciatic pain with exquisite sacral sensi-

tiveness, cheek of affected buttock swollen, hot as well as painful, and later on a condition of complete analgesia extending down the leg and to the genitals, the latter part of July, had disappeared, and discharges of September 6, 1906, from unused bowel showed in the granular detritus or well digested matter a few tubercle bacilli present only.

On September 6, the use of amylopsin was begun, alternating in doses of two ampoules (original strength) with injections of trypsin, two ampoules also of original strength. Examination of rectal discharge a week later (September 14, 1906) showed no tubercle bacilli present; nor have repeated examinations since, now ten months, of the discharges from the disused bowel and urine revealed their presence. If the behavior of eosinophile leucocytes in tuberculosis is constant, as per the observations of Swan and Karsner,[14] then in the eosinophilia, established by the hypodermic use of the enzymes, there is very suggestive evidence as to the rationale of the disappearance of the tubercle bacilli and the rapid improvement in this case. The enlarged mesenteric glands in this case were, I believe, tubercular, not malignant. While one case is not sufficient for proof, one case supported by this scientific fact is sufficiently suggestive to induce the careful and systematic use of enzymic treatment in tuberculosis. The fact remains that this illustrative case of Class 1 shows absolutely no evidence of tuberculosis save inability to make any marked gain in weight, and periods when night sweats are slightly in evidence. Experimental medicine must determine the appropriate place of these ferments in the treatment of tuberculosis. Here it is only necessary to say that laboratory experiments are under way to prove or disprove the generalization of the truth of this isolated observation.

For use in tuberculosis, as in cancer, the injections should be an extract, freshly prepared from the pancreas gland direct and containing the ferments, trypsin and amylopsin. The absolute disappearance in this case, followed upon six weeks' use of trypsin, and four injections of amylopsin. The place of the latter does not seem to be conclusive, although Beard believes it to be the important factor. The disappearance of the tubercle bacilli was coincident with the period of treatment, which has been found to be characterized by the highest eosinophilia curve.

Dr. Edwin Lewis[16] has made an experimental study of a preparation of the fresh pancreas gland, not of trypsin alone, but other associated ferments, in tuberculosis. His results, while not negative, were not conclusive.

Excretion.—Trypsin and amylopsin are excreted mainly by the kidneys, producing a nephritis more or less extensive. Granular casts appear in the urine almost immediately after the first doses of the ferments. The nephritis does not seem to be progressive, the casts and albumin remaining pretty constant unless the dosage is increased. A single superposed dose of three ampoules has been seen to produce epithelial casts. It is difficult to disassociate the predisposition toward indicanuria resulting from the ferment treatment from the characteristic indican of cancer.

The presence of indican in pathological quantities is probably due to an increased absorption of indol from the intestine, and not to an increased tryptophan, as the indicanuria may be controlled by administration of 1-100 of a grain of calomel every hour.

In every instance casts have appeared in the following order: (1) Occasional fine granular, then coarsely granular, (2) hyaline, (3) epithelial. Under the regimen which forms a part of the supplementary treatment and hygiene of these cases, this nephritis is kept pretty well under control.

Conclusion.—The justification of this treatment is to be found in: (1) The pathological findings, (2) relief from pain, (3) absence of odor and necrotic discharge, (4) improved metabolism, (*a*) in cases that do well, (*b*) even in those who succumb, (5) increased mental vigor, and (6) by inspiring the patient with hope.

On the other hand, it may result in shortening life by a few months, but that short span of added existence would be characterized by breaking down of tissues, odor, necrotic discharge, pain, imperfect metabolism, loss of mental vigor, and by utter hopelessness on the part of patient and friends.

Treatment should be undertaken early in every instance and should always be an adjunct to surgical interference in every postoperative case.

Metastases should never be allowed to develop. The importance of removing a diseased organ, as in case illustrating Class 3, must never be lost sight of, and the enzyme treatment should be carried on with a full recognition of the value of skilled surgical interference when possible.

The indications are that the use of the enzyme treatment will have to be continued over long periods of time and perhaps at intervals during life, but as the absence of pain is a constant accompaniment, it would seem logical and better to have a patient with the trypsin necessity rather than the morphine habit.

To illustrative case of Class I. there has probably been administered more trypsin than to any other individual patient, yet daily urine analysis shows that the kidneys are functioning to all intents normally.

Significance of Cytodiagnosis and Therapeutic Value of Lumbar Puncture in Tuberculous Meningitis.—Olimpio Cozzolino has made a careful cytological examination of the blood of eleven cases of infantile tuberculous meningitis, some of which he has treated by lumbar puncture. He gives the conclusions at which he has arrived. He believes that the cytological examination of the blood is of value in aiding to establish the diagnosis, but that other means must be used to make the diagnosis absolute. Polynucleosis is not rare in basilar meningitis, both where the tubercle bacilli are many and where they are few in the blood. Lumbar puncture is of no diagnostic value and rarely gives any therapeutic results.—*Rivista di Clinica Pediatrica.*

EYESTRAIN AND OTHER DISEASES DUE TO CROSSING, CROWDING, AND DAMMING OF THE RETINAL VESSELS.

By GEORGE M GOULD, M D.,

PHILADELPHIA

An ophthalmoscopic glance at the fundus of the normal living eye makes it evident that the vascularization and nutrition of the intraocular tissues, especially of the retina, is not only of prime importance, but that it is the first condition of vision. And the best possible vision is the *sine qua non* of the motility, safety, and success of the dependent organism in the struggle for existence. The retinal function is one of amazing delicacy; it is conditioned upon an unexampled complexity and microscopic fineness of structure, and upon a state of the highest instability of equilibrium of molecular substance. The task of nourishing and reestablishing this function, when temporarily exhausted, is of almost incredible difficulty. Phases of this difficulty throng upon the attention. For example, the eye is a closed system, and the dominating structure, the retina, must receive its arterial supply and discharge the venous blood within the million-stranded bundle of nerves called the optic nerve. To make transparent all the ocular structures from the cornea to the pigment layer of the retina has been a unique and next to impossible necessity, and from nonsuccess follow a score of diseases such as leucoma, cataract, etc. There is one difficulty nature could not overcome: the blood supply of the retina had to be carried by vessels made opaque by the red blood corpuscles and coursing in front of the retina. This was a necessity resulting from the condition of the "closed system" of the globe of the eye.

The normal intraocular pressure, moreover, was required to give the globe its stability of form and make the visual act a constant and certain function. The relation of this tonicity of the globe to the entrance and exit of the blood and lymph and to the passage of the blood through the retinal vessels is one of close adjustment. A too soft globe would plainly lessen the reliability of retinal response and impair the all-important image-forming function; a globe too hard would lessen vascularization, nerve function, etc.—would mean all that the word glaucoma means.

Embryologically studied, one sees how easily the retinal vessels may become anomalous. One might, indeed, describe those of each and every eye as anomalous, so unlike is one from another. But the norm, as shown in noncomplaining eyes, and in the pictures of the textbooks, brings it about that the larger trunks of the vessels do not cross over or under each other in their courses, and that a single vessel does not curl or circle so that it passes above or below itself. If such a crossing takes place the established and necessary intraocular pressure will surely tend to, or actually bring about an impaired passage of the blood within one or both the trunks concerned. Whether the impeded circulation will lessen the supply of arterial blood to the portion of the retina it normally feeds, or whether the normal venous outflow is prevented, will, of course, depend upon the facts in each case, the peculiarities of the crossing, the location of the block, the tension of the eyeball, etc.

Ophthalmologists have evidently not been observant of these blockings or dammings, either physiologically or pathologically. Since I first suspected their existence and pathologic significance I have found them far more common than I had supposed. Although they may be so slight as to produce no serious or demonstrable symptoms, I am sure they may be so severe as to produce the greatest and longest suffering and even the life-tragedy of the patient. If the choking is of an artery, and if it is great, and if supplying the macular region, and especially of the right eye of a righthanded (and righteyed) person, the consequences will be the worst. If the impeded venous outflow is from that region the morbid results will probably be as bad, although different. The farther from the macula is the region of the impaired nutrition, the less will be the likelihood of morbid symptoms. It will be apparent that vessels carrying red blood corpuscles must not traverse the macular or perimacular spaces, and hence that here collateral or anastomotic circulation cannot, as elsewhere in the body, take up the nutrition of the part impaired by the blocked vessels.

And it is also equally plain that the blood supply is not, and by the nature of the case cannot be, wholly cut off (as in embolism or thrombosis), but only lessened.

The symptoms may be intensified, varied, multiplied, or masked by the coexistence of ametropic eyestrain.

Of the illustrative cases with certain and distinct and logically consequent symptoms, I briefly epitomize two:

A woman, aged forty-six, for most of her life had suffered intensely from many of the typical symptoms of eyestrain. Her statements and history as related by herself seemed so exaggerated that I was at first suspicious of hysteria and a morbid pleasure in pain, or in the belief that pain existed. Study of her case and observance of the woman's character in time convinced me that there was absolutely no such mental factor present, and that the suffering was most genuinely neurologic and physical. She had been under the care of many famous ophthalmologists, none of whom had been capable of helping her; none could guess the exact nature of the disease. The patient had loyally and faithfully carried out every kind of treatment, and had worn all possible kinds of spectacles, until each physician in turn confessed himself wholly mystified and unable to give relief. Except from one other I never heard a more pitiful and harrowing tale of suffering patiently borne, of hope renewed with each new oculist or physician consulted, of bitter disappointment as no cure followed. I was to be the last!

Since she can remember the patient has had "difficulty in seeing." The closer description of the "difficulty" makes it clear that it consisted in a failure of the right eye to hold the image, or see as plainly or continuously as with the left eye. It is what I have long been accustomed to denominate as "fading image." All her life, also, the woman has had headache. For the past eight years the worst symptom has been constant pain and tenderness across the brow and a "beating" in the right eye, not lessened by any treatment. At the menstrual period there has been no headache, but an intense pain across the eyes, with nausea but no vomiting. There have long been insomnia, indigestion, constipation, "nervousness," "fidgetiness," with the frequently allied coupling of hypertension and depression of spirits. There has been a long and harrowing history of "rheumatism," "neuritis," and an eight-months'-long constriction of the throat during

which only liquids could be swallowed. There have been many other symptoms which may here be omitted.

She was formerly under the care, for five years, of Dr. ——, a famous oculist, and then another man of equal repute treated her for several years. For a number of years again, another most reputable and learned man also failed to give the patient the least relief. In 1902 he ordered:

R. + Sph. 2.25 + Cyl. 0.50 ax. 80°.
L. + Sph. 2.25 + Cyl. 0.25 ax. 100°.

He plainly thought that the slight exorphoria present was a great factor, because with the above prescription he combined 1.5° prisms each eye bases in. When no relief came he at last advised tenotomy, which the woman, with a wisdom greater than that of the doctor, rightly refused. Even without the foolish prisms the glasses were not correct, overcorrecting the error for distance, and undercorrecting it for near. With failure evident, this oculist advised the patient to consult Dr. —— of ——, an ophthalmic surgeon of wide renown, "who," he added, "always makes a point of disagreeing with me in everything." This was done that the patient might have an entirely independent opinion. She added, with a sickly smile, that "he did disagree in every particular." But the disagreement brought no help, and then another oculist was consulted some nine months before coming to me. He ordered:

R. + Sph. 2.00Prism 2° B. I.
L. + Sph. 1.50Prism 1.5° B. D.

This order was as bad as if it had been made by "the leading oculist of the city."

Without a mydriatic I estimated the error of refraction to be:

R. + Sph. 1.62 + Cyl. 0.62 ax. 180° = 20/50+
L. + Sph. 1.37 + Cyl. 0.37 ax. 180° = 20/30?
2° B. I., 1° B. D. L.

There was also evident subnormality of accommodation. With paralyzed accommodation the errors were found to be:

R. + Sph. 2.00 + Cyl. 0.50 ax. 180° = 20/50+
L. + Sph. 2.00 + Cyl. 0.37 ax. 180° = 20/30?

With all the woman's good will to do as advised she could not and would not try bifocal spectacles, because she had by bitter experience demonstrated that they only increased her symptoms. This fact was a hint to my mind, and one which stuck there, that there was in this case an unsolved problem. I gave proper distance glasses with "fronts" for near, but the "unbearable pain" lessened no whit. In a few weeks the error was not different, and I demanded bifocals, to be used at meals, and in the house. She vowed she "could not see with them." I did not then suspect the reason they increased difficulty and pain, but this became apparent when with search and study I found that she closed the right eye when reading and ignored its image for distance, and that she "had done this for years," as she now confessed. I was now on the heels of the mystery.

At the first visit in using the ophthalmoscope I spoke of a curious loop in the superior temporal artery of the right eye. The patient said: "Oh, everybody has noticed that," but adding that it had no significance. The artery close to the disc turned upon itself, forming a circle about 10° in diameter, and passing under itself proceeded onward toward the macula. But in passing beneath the vessel was flattened by the pressure of the vessel above it, and from that point the artery was pale, half collapsed, and evidently carrying but a small quantity of blood. The macula was stippled and somewhat morbid in appearance, but otherwise the eye ground seemed normal. My glasses had given no relief; there was a decided tendency to shut the right—the naturally dominant and important dextral eye—out of function; no device had given hope; the subnormality of accommodation of the right eye was about 1 D. greater than in the left eye—a significant fact; the amblyopia had not bettered under proper glasses; the symptoms, partly those due to eyestrain, were so peculiar as to arouse suspician that more than ametropia was the matter,—such were the conditions which directed attention to the hitherto neglected looping of the upper macular artery, and the plainly lessened blood supply of the retinal area supplied by it. I at once ordered a blinder worn nearly constantly before this eye. A more certain test would have been a bandage, because, according to the physiologic law of imperative function, the right eye must struggle for life and dominancy during all the years it is dying. In a few weeks the report was that while there was not by any means complete comfort, there had been a decided lessening of the severity of the pain, etc. The most significant fact was this: While the blinder was worn there was comparative freedom from pain, etc., but when it was removed a throbbing pain came on, which did not disappear until the blinder had been worn again for an hour. I then knew my theory was correct and that there was nothing left but to exclude the ailing eye from function. A large black lens was provided to be worn absolutely constantly, and progressive relief is being secured. I do not look for entire happiness in this case, because too great injury has been done, and the exclusion of the right eye from function can never be complete; it must still desire or be forced to partial life and function because it is the right eye, and because its exclusion comes so late in life. The less of two tragedies is chosen, and that is often the command of practical medicine or ethics.

The moral of the tale is that knowledge of the nature and cause of an incurable disease is infinitely better than blind groping in the darkness and false, mischosen, and misapplied methods of cure.

My second case was that of a healthy strong young man of twenty, who began having "inability to use his eyes" when he was about eight years of ago. Since this time there has been a continued blepharospasm, a rapid closing and opening of the lids; the lids are nipped down tight and held almost as long as they are kept open. He has not had any of the usual reflexes such as headache, dyspepsia, "migraine," etc., and no amount of questioning is able to elicit any more definite or satisfying details as to the nature of his troubles than that "things disappear," "fade out," etc., and he could not an cannot read, write, or study. Do what he would he could not use his eyes for constant or near work. From ten to fifteen he went to school for about two months at the beginning of the year, but after that had to stay at home or travel. At fifteen he kept at school for a year, but since then has lost every other year, "not on account of health, but because of impossibility of using his eyes."

Oculist No. 1 was consulted at the age of nine, and his glasses were worn for six months, with no relief.

Oculist No. 2 changed his glasses, and these were

worn two years, but without aiding the patient to study.

Oculist No. 3 was consulted at the age of twelve with some benefit.

Oculist No. 4 changed the prescription, and these glasses were worn for but a little while. He now went two years before consulting

Oculist No. 5, who told him nothing was the matter with his eyes. But on attempting to resume study he was at once compelled to stop.

Oculist No. 6 "tried and tried" to make it possible for the patient to study. Failing, he sent him off to "the leading oculist" of a distant city, who in 1906 ordered:

R. + Sph. 0.75 + Cyl. 0.37 ax. 60° } Distance.
L. + Sph. 1.00 + Cyl. 0.25 ax. 90° }

L. + S. 1.37 and Cyl. } Near.
R. + S. 1.12 and Cyl. }

For a few weeks these felt comfortable, but then the old symptoms returned despite the diagnosis, antique, antiquarian, and though dead never buried, of "gout and rheumatism of the eye."

Oculist No. 7, myself, under cycloplegia diagnosed:

R. + Sph. 0.87 + Cyl. 0.37 ax. 70° = 20/20?
L. + Sph. 1.00 + Cyl. 0.25 ax. 90° = 20/20

with perfect muscular balance.

His greatest complaint, upon persistent questioning, is that he becomes suddenly blind, or nearly so, when looking at anything. Things fade out and become nearly or wholly invisible. Even in the street, in looking at a person, the bodily figure grows dim or invisible; when playing baseball, and watching the course of the ball in the air, it will disappear for a second or more and then again become visible. In order to see anything plainly he has to rub his eyes. In near vision it is more impossible to hold the image. The peculiar and persistent blepharospasm for twelve years, with the rapid fading of the image, seems to point to difficult holding of the retinal function due to faulty blood supply. Competent general physicians have examined him and pronounce him free from all recognizable systemic or organic disease.

Having in mind the case above described, I was quick to recognize the existence in this man's eyes of the anomalies of the network of the retinal veins and arteries. From the point of emergence or entrance at the disc they curled about each other, crossed and recrossed each other, in a manner to strike immediate attention. Description would be almost impossible. The upper temporal artery of the right eye crosses over the vein on the disc, and crosses under the vein twice after leaving the disc. The lower temporal artery crosses over the vein on the disc and does not recover full size and color for 30° below the disc. The upper temporal artery of the left eye passes over the vein on the disc, again passes under the vein on the disc, and once more passes under the vein about 40° from the disc. The lower temporal artery passes beneath the vein on the disc, passes over the vein 20° from the disc, and again over the vein 40° from the disc. The arteries are smaller and thinner and lighter in color on the disc than toward the periphery, whereas the veins are turgid and swollen as they approach the disc. There was noteworthy general venous stasis, and venous pulsation was present. Both eyes were affected in the same way, but the right possibly in a more decided manner. I felt justified in ordering correct lenses, in explaining what I thought the cause of his symptoms, their incurability, and in urging a life-time renunciation of nearly all reading, writing, or near-work occupations.

It seems probable that in such intercrossing of blocked and choked vessels lessening the supply of arterial blood and serum, or preventing the normal out-passing of venous blood and lymph, we have the distinct cause of a new type of ocular disease, and especially of its results, another kind of incurable eyestrain. The same or a similar result may be due to crowding of the vessels at the disc, as they turn, or within the optic nerve sheath itself, with venous pulsation, stasis, impaired nutrition, etc. Is it also not possible that such blocking and crowding may account for the rise of other retinal and intraocular diseases, the etiology of which is at present not clear? Such, *e.g.* as degenerative, pigmentary and atrophic macular diseases, the enlargement of the globe and the lessening of hyperopia, its passage into myopia, the change, during presbyopia, of 90° axes to 180° axes of astigmatism, all of which and more, are possible consequences of the lessened outflow and disturbed nutrition which would follow crossing and crowding of the vessels. Would not such causes constitute precisely the factors needed to clear up the etiology of the mysterious and terrible disease, glaucoma? It appears highly significant that the several greatest ocular diseases, glaucoma, cataract, presbyopia, the reversal of the astigmatic axes, etc., should all be coincidental and fall upon the time of failing life-powers and lowered blood pressure. It is presumable that, etiologically, they may often depend upon the want of vascularization or full nutrition of the intraocular tissues, a process that even in the young has been of most difficult biologic accomplishment.

Even the greatest of all ocular diseases, astigmatism, and other forms of ametropia, with all the morbid results of eyestrain upon the general system, upon education, and social evolution, even these indirectly depend upon the shape of the eyeball, *i.e.* upon its tonicity, blood pressure, and nutrition. Astigmatism is largely dependent upon the pressure of the upper lid, which must rest upon the cornea at the upper border of the pupil, in order to shade the retina and thus aid in the reinstatement of its unstable equilibrium when impaired by every visual act. A greater tonicity would prevent the indentation by the lid, but it would prevent also the transmission of the nerve impulses and the currents of the blood, lymph, and serum; that is, a greater tonicity would be glaucoma.

ACID INTOXICATION OR ACIDOSIS: A FACTOR IN DISEASE.

By EUGENE S. TALBOT, M.S., D.D.S., M.D., LL.D.,
CHICAGO.

More than twenty years ago, visiting the different public and private institutions in this country and Europe and private patients, pursuing my studies in degeneracy, I was struck with the fact that the teeth of diabetics, tabetics, and paretic dements were badly worn away. Destruction of the alveolar process was likewise very marked. Destruction of the teeth in healthy, normal individuals was occasionally noticed. An endeavor was made fifteen years ago to ascertain the cause of this destruction designated as interstitial gingivitis or so-called pyorrhea alveolaris.

In a paper on "Pyorrhea Alveolaris,"[1] I mentioned that the disease had two origins, "local and constitutional." The constitutional form was the re-

sult of faulty metabolism or autointoxication. Since this, further researches have shown acid autointoxication to be a great factor in erosion, abrasion, and interstitial gingivitis.

Figures 1 and 2, the models of the jaws and teeth of two physicians respectively thirty-eight and forty-two years of age, show the destruction of the

Fig. 1

alveolar process. In men at these ages in apparent perfect health, interstitial gingivitis has made rapid progress. Figure 3 shows the condition of the teeth and jaws of a diabetic fifty-five years of age. Figure 4 shows the jaws in their original position. The crowns of the teeth are worn away. The alveolar process is almost entirely destroyed. Some of the teeth have already dropped out and others are loose. The relation of acid autointoxication and mouth acidity is very intimate. The acids taken into the body and those produced by chemical changes within, such as hydrochloric, lactic, acetic, diacetic, β-oxybutyric, uric, and other acids circulate in the system, passing out through kidneys, lungs, skin, and mucous membrane especially of the mouth. If the kidneys do not carry off the surplus acidity, a greater strain is put upon the lungs, skin, and mucous membranes of the mouth. The alveolar process and gums, being doubly transitory, as well as end organs, contain excretive and secretive glands. The gums are the first structure of the body which indicate systemic defects particularly noticeable in mercurial, lead, and brass poisoning, scurvy, etc. The mucous glands normally secrete acid fluid, while the salivary glands excrete alkaline fluid. It not rarely happens, however, that the kidneys fail in their function and the system becomes so saturated with acid that the salivary glands secrete acid saliva. The acid secretion from the gums soon sets up inflammation which causes absorption of bone and the teeth in time fall out. The acid from the glands of the gums and the salivary glands continues to cause destruction of the teeth.

Friction from the lips, teeth, and foreign bodies assist greatly in tooth destruction. Teeth softened by faulty nutrition and acid states are easily destroyed by acids and friction.

Researches into the cause of erosion and abrasion of the teeth and interstitial gingivitis causing destruction of the alveolar process from which all suffered resulted as follows:

1. *Uranalysis of Diabetic Patients.*—Uranalysis by the Columbian Medical Laboratories of three hundred and ninety-four diabetics showed specific gravity, one 1.003, one 1.005, one 1.007, one 1.010, one 1.011, eight 1.012, one 1.013, six 1.014, six 1.015, four 1.016, five 1.017, seven 1.018, six 1.019, seven 1.020, five 1.021, thirteen 1.022, fifteen 1.023, ten 1.024, twenty 1.025, thirteen 1.026, thirteen 1.027, eighteen 1.028, nineteen 1.029, twenty-five 1.030, twelve 1.031, fifteen 1.032, twenty-eight 1.033, sixteen 1.034, twenty 1.035, seventeen 1.036, eighteen 1.037, nine 1.038, twelve 1.039, ten 1.040, eight 1.041, eight 1.042, two 1.043, seven 1.044, two 1.045, two 1.046.

Percentage of Sugar.—Twelve had 0.1 per cent., eighteen 0.2, three 0.3, eleven 0.4, seven 0.5, seven 0.6, one 0.7, four 0.8, eight 0.9, ten 1, one 1.1, eight 1.2, seventeen 1.3, six 1.4, one 1.5, thirteen 1.6, seven 1.7, four 1.8, one 1.9, five 2, three 2.1, six 2.2, three 2.3, seven 2.4, three 2.5, five 2.6 one 2.7, three 2.8, three 2.9, four 3, one 3.1, five 3.2, six 3.3, one 3.4, two 3.5, ten 3.6, five 3.7, five 3.8, fifteen 4, four 4.1, five 4.2, two 4.3, two 4.4, three 4.5, eight 4.6, four 4.7, five 4.8, five 4.9, five 5, two 5.2, ten 5.3, five 5.4, one 5.5 nine 5.6 seven 5.7, five 5.8, one 5.9, nine 6, five 6.1, ten 6.2, ten 6.4, one 6.5, five 6.6, one 6.7, three 6.8, five 6.9, three 7, one 7.1, two 7.2, two 7.3, two 7.4, one 7.6, one 7.7, three 7.8, one 7.9, one 8, one 8.2, one 8.5, one 8.7, one 9, one 9.1.

Degree of Acidity.—Two passed 4 degrees, two 6, one 7, two 8, six 10, five 12, sixteen 14, one 15, fifteen 16, one 17, thirteen 18, twenty 20, one 21, twelve 22, one 23, ten 24, two 25, fourteen 26, sixteen 28, one 29, twenty-one 30, seventeen 32, thirteen 34, four 35, twenty 36, two 37, eleven 38, two 39, thirteen 40, one 41, eight 42, seven 44, two 45, eight 46, two 47, five 48, five 50, five 52, one 54, twelve 56, one 57, four 58, five 60, one 62, one 63, three 64, two 66, two 68, two 70, three 72, one 74, one 75, one 100, two 104, one 120, one alkaline, two neutral.

Acetone.—Of this number of cases only nineteen were examined for acetone. In eleven, acetone was present, in eight absent. Thirty-two were examined for diacetic acid; in six it was present and twenty-six absent. Twenty-four were examined for

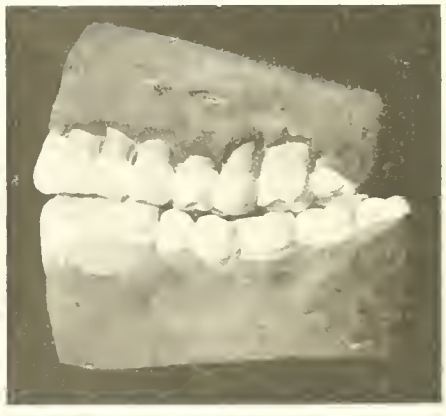

Fig.

β-oxybutyric; in all it was negative. It will be observed that the per cent. of acetone bodies in diabetics is very small.

Uric Acid.—The examination for uric acid of three hundred and seventy patients showed its presence to a greater or less degree in fifty-six and negative in three hundred and fourteen, or about 15 per cent. had uric acid.

Indican.—Of the three hundred and ninety-four examinations, three hundred and twenty showed in-

dican to a greater or less extent. Seventy-four were normal in this respect.

2. *Uranalysis of Tabetic Patients.*—Degree of acidity in thirty-five was as follows: One passed 5 degrees, one 6, one 7, three 9, two 10, one 11, one 14, one 17, two 19, two 20, one 22, one 46, one 48, one 49, one 50, one 56, one 62, one 73, two 76, one 78, one 81, one 82, one 84, one 97, one 99, one 112, four alkaline. Those patients having the alkaline urine had marked erosion of the teeth showing that at some time there had been a high degree of acidity. Cystitis caused the urine to become alkaline. All showed indican to a greater of less extent.

3. *Uranalysis of Paretic Dements.*—Degree of acidity: There were twenty-one males, four females. Three passed 5 degrees, one 7, three 8, two 9, one 10, one 11, one 12, one 13, one 15, two 16, one 17, one 22, one 28, one 34, one 38, one 39, one 44, one 51, one 52, one 70. These patients were in a quiet state. If the urine could have been examined after excitement or an explosion the degree of acidity would have been greater.

4. *Uranalysis of Private Patients.*—Degree of acidity: I examined one hundred and twenty-nine. Three were also sent to me by Dr. J. F. Keefe of Chicago, making in all one hundred and thirty-two. All were from eleven to eighty-four years of age. All showed erosion and abrasion to a greater or less extent. Three passed 2 degrees; three 8, two 10, two 11, seven 12, two 14, two 15, five 16, six 18, two 19, eight 20, five 22, five 24, six 26, four 28, two 29, six 30, two 31, four 32, two 33, three 34, nine 36, two 38, two 40, two 44, five 46, one 47, two 48, two 50, five 52, five 54, four 56, one 58, three 60, two 62, five 70, one 90, one 127, one 132; only four or 3.8 per cent. had uric acid. I quote here from a previous paper, "Interstitial Gingivitis Due to Autointoxication,"[2] my first fifty patients' degree of acidity, one had 11 degrees, two 12, one 14, two 15, one 16, two 17.5, four 20, one 22, one 24, five 30, seven 36, two 40, two 44, one 46, two 56, one 58, one 59, one 60, two 62; 3 per cent. had uric acid, all had indican.

The method of obtaining the degree of acidity of the urine given by Neubauer and Vogel[3] is very simple. The instruments necessary for this work are one burette 50 c.c., one wooden stand, one Barnes dropping bottle, one 10-c.c. graduate, and one small glass. Place the burette in the wooden stand in an upright position; fill the tube with the solution (1-10 normal sodium hydrate) to exactly 0. The degree of acidity is obtained by taking 10 c.c. of urine specimen, measured in the graduate glass, then placed in the small glass; add four drops of phenolphtalien; then add drop by drop NaOH (1-10 normal sodium hydrate) until a slight pinkish color is produced. Having noted on paper the number of c.c. of the NaOH in the burette before and after the pink color is obtained, the number of c.c. displaced multiplied by 10 (in order to find the number of c.c. NaOH necessary to reduce 100 c.c. urine) equals the degree of acidity. Each step in this operation must be carefully performed; each instrument must be kept perfectly clean in order to get good results.

The normal degree of acidity of the urine is from 30 to 40. When the degree is below 30 (the difference between the degree indicated and 30 shows the degree retained in the system), it indicates either renal insufficiency or excessive suboxidation products producing renal strain. In cases in which the degree of acidity exceeds 40, there is excessively imperfect oxidation which, irrespective of the types of acid, underlies, as is now pretty generally recognized, severe constitutional stress allied to that of diabetic acidosis.

The question arises, does the quantity of urine passed in twenty-four hours influence the degree of acidity? Thus, if more than 40 ounces (the normal amount) was passed, the degree of acidity would be low as compared with less than 40 ounces. There is a relationship between the polyuria produced by nerve and other strains in seemingly normal persons. This occurs in students under examination and certain hysterics under excitement. The eliminatory functions of the kidneys are interfered with, but the watery excretory powers are increased. There is real, albeit not nosologic, renal insufficiency producing a condition temporarily analogous to diabetes insipidus. The state is not normal but is not necessarily nosological.

On application of the phenolphtalein, if the urine specimen turns pink, it is alkaline, therefore no degree of acidity can be obtained. Litmus paper (held over ammonia until a deep blue is obtained) is applied to the gums and lips to ascertain if the mucus be acid. Acid mucus was found in every case tested. The circle of evidence, therefore, is complete.

It is not my intention here to discuss the uric acid theory of disease except to point out that modern research has shown that uric acid *per se* is overestimated as a cause of diseases. The theory obtained its impetus through Fothergill, thirty years ago, and reached its climax when Haig[4] of London published his work. Modern research has shown that uric acid is only occasionally found in disease.

Some years ago, uric acid was set forth as a cause of interstitial gingivitis. At that time I instituted a series of experiments in two laboratories.[5] Two hundred and fifteen specimens from mouths with interstitial gingivitis were examined. Only 5.5 per cent. contained uric acid. In three hundred and seventy diabetics, 15 per cent. contained uric acid. Of one hundred and thirty-one private patients suffering with interstitial gingivitis, but 3 per cent had uric acid. In the first fifty patients in another series of experiments, 3 per cent. had uric acid. While the number of patients examined for uric acid is small and covers only a small range of diseases, the statistics may seem to be of little etiological moment to the general practitioner. Since faulty metabolism and autointoxication are associated and since all patients had interstitial gingivitis and many erosion and abrasion, they are of the greatest moment.

Few adult persons have not had an excess of acidity at some period. The slightest change in the action of the liver by which nitrogenous material is not converted into urea and pass out through the kidneys will cause acid excess in the system. Complete oxidation is essential to a normal condition. The organs and tissues of the body act as best they can to bring about this condition. In some systems, the liver has all it can do to care for the waste products of the tissues themselves. That fruit acids may be converted into alkaline substances in the system is true. The liver and tissues become overworked. The acids which are taken into the stomach as food are in excess, they are stored up in the system. The fruit habit (especially grape fruit) so generally indulged in to excess in America is producing havoc with the alveolar process, gums, and teeth.

One case is sufficient illustration of the many

requiring treatment. A twenty-seven-year-old woman had her teeth and mouth put in good condition in January, 1907. February 16, she returned with what she thought a cavity at the cervical margin of the left superior cuspid. Upon examination, I found the gums inflamed and receding, not only at that particular location but about all the teeth. Previous to this, the gums and mucous membrane were in fairly good condition. Litmus test showed the mucus to be very acid. There was no cavity, only sensitive exposed dentine. Much gas was passing from the stomach. Upon interrogation in regard to her food she informed me she had been eating grape fruit every morning for three weeks. Uranalysis of a twenty-four-hour specimen showed the degree of acidity to be fourteen. Sixteen degrees were retained in the system. The recession of the gums and the sensitive dentine were due to the acid retention. The skin, lungs, and mucous membranes try to dispose of the surplus. If these structures are unable to do so, they are expelled as gas, vomit, or fermentative stools. That the acid excess of the system does pass through the mucous and salivary glands of the mouth to produce destruction of tissue, has already been demonstrated. With these illustrations showing destruction of tissue in the mouth the question arises how far does this acidity affect other tissues and diseases of the body? For want of time, merely a few uranalyses in diseases were made.

DISEASE.	DEGREE OF URINARY ACIDITY.
Arthritis (rheumatoid)	One 70.
Backache (severe)	One 10; one 25; two 30; one 35; one 36; one 40; one 50; one 79; one 82; one 87; one 90; one 95; two 100; two 110; one 120.
Bronchitis	One 56; one 58; one 60; one 61; one 67; one 120.

Tuberculosis	One 10; one 20; one 21; one 30; one 44; one 52; one 56; one 78; one 81; one 88; one 102; one 108; one 115; one 142.
Tubercular hip disease	One 80.
Typhoid fever	One 76; one 88; one 90; one 100; one 120.
Urticaria	One 47.

On comparing the office patients of the dentist with those of other specialists and patients ill at home or in a hospital, it is found that the degree of acidity does not vary to any great extent. A constant abnormal degree of urinary acidity, in an individual attending to his affairs, means that sooner or later an organ or structure is bound to give way. This is particularly true at the senile period of stress (about sixty) when the arteries degenerate. The victim of abnormal degree of acidity is more subject to disease than one with normal acidity. Study of the effects of high degree of acidity in an otherwise normal individual whose teeth and alveolar process are being destroyed has exceedingly interesting results. In the evolution of man, the face, nose, jaws, and teeth are being lost for the benefit of the brain under the law of economy of growth. They, therefore, are transitory structures. The alveolar process exists to hold the teeth. If the teeth be not present or if they be lost in the lifetime of the individual, the alveolar process disappears. The bone appears and disappears twice during life, if the second teeth be lost. The alveolar process, then, is a doubly transitory structure. The alveolar process being an end organ, blood-vessels and nerves extend through it as far as the peridental membrane and stop. The tooth so fas as disease of the bone is concerned is a foreign body. The alveolar process, the most sensitive structure in the human, is the first to be involved when acid or other autointoxication or chronic poisoning takes place.

Lessened blood alkalinity affects the whole alveolar process by setting up an irritation and inflammation of the coats of its arterioles and in the tooth pulp (which is also an end organ), producing endarteritis obliterans, arteriosclerosis, and nerve-end degeneration. I have demonstrated those diseases many times. Disease of the terminal nerves and arteries causes absorption of the bone. The inflammatory process has been termed interstitial gingivitis; the bone absorption, osteomalacia, or senile absorption, although it may occur early in life.

May not osteomalacia in other parts of the body be due to the same cause? The change which has taken place in the blood owing to excessive acidity? The change which has taken place in the blood owing to excessive acidity plays a very important part in the action of the heart, producing high tension. It is supposed to act direct upon the subendocardiac ganglia and also by the irritation directly through the coronary arteries and their

branches to those ganglia situated in the muscular tissue.

Acids in the system must also influence the vasomotor supply causing contraction of the arterioles. In the light of my own researches, another factor must enter largely into the cause of the increased action upon the heart for systolic force, namely, endarteritis obliterans, arteriosclerosis (thickening of the arterial walls), and nerve-end degeneration. Greater pressure is required of the heart to force the blood through the arterioles to their extremities. To ascertain the blood pressure in my patients suffering with interstitial gingivitis, I used Cook's modification of the Riva Rocci sphygmomanometer, this instrument being best adapted for my convenience and exceedingly simple. The armlet used was sold with the instrument and consists of a rubber bag 4½ by 40 cm. The patients ranged from twenty-seven to sixty-seven years of age. With this instrument the normal adult female arterial blood pressure is 115 to 125 mm.; adult male, 125 to 135 mm.

In twenty-six females there were three who ranged between 115 mm. Hg. and 125 mm. Hg. and therefore normal. Three ranged below 115 mm. Hg. and twenty from 133 mm. Hg. to 180 mm. Hg.

In twenty-four males there were eight who ranged between 125 mm. Hg. and 135 mm. Hg. and therefore normal. Three ranged below 125 mm. Hg. and thirteen from 135 mm. Hg. and 160 mm. Hg.

When we consider that thirteen of these patients were under forty-five years of age, the high blood pressure is remarkable.

Other end organs and structures of the body, such as the liver, kidney, eye, etc., are obviously predisposed to affection in the same manner, leading up to sclerosis of the liver. Bright's disease of the kidney, and degeneration of arteries in the brain.

Kidney lesions, due to the eruptive fevers in children, are influenced to a great extent by a high degree of acidity in the system. The effects of high degree of acidity in the mother on the fetus in producing arrest of development at the senile or first period of stress, causing deformities of the child, merit investigation. Wild animals in captivity are very susceptible to deformities; no other etiological explanation has, so far, accounted for them.

An abnormal degree of urinary acidity extending over a period of nine months accounts for many of the neuralgias, toothaches, destruction of teeth by erosion, decay of the teeth and wasting of the alveolar process, skin diseases, and many other lesions so common in pregnancy which cease to trouble after birth of the child. Mental strain due to overwork, grief, shock, etc., check the secretions causing an abnormal degree of urinary acidity which eventually results in diabetes, Bright's disease, and arterial degeneration. There are many other lesions traceable to or influenced by a high acidity of the system.

While uranalysis has only been made in few diseases, enough has been demonstrated to show that an excess of acidity is found in the urine of all diseases. It will be noted that a high degree of acidity is found in the more simple ailments, such as head and backache and cold in the head, as well as in the more severe diseases, such as pneumonia and typhoid fever. Especially is this true in pregnancy. The abnormal degree of urinary acidity or reduced alkalinity of the blood must of necessity interfere with nutrition as well as to prevent the proper action of drugs. Enough has been mentioned to show the relation of an abnormal degree of urinary acidity and the necessity of uranalysis in every case to ascertain the degree. The abnormal degree should be restored to normal as part of the treatment.

Lately some very able papers have discussed acetone bodies in the urine (acetone, diacetic, and β-oxybutyric acid) in relation to the anesthetic administration of chloroform. Deaths have occurred without apparent cause within a few days or weeks after a successful operation.

A number of theories have been advanced as to the cause, such as chloroform poisoning, nephritis, acute yellow atrophy of the liver, acetone bodies, etc; the principal one shown by postmortem being fatty degeneration of the liver and occasionally nephritis. Some other primary cause must exist to bring about the changes in the kidney and liver which would not result from chloroform acting upon a healthy organ.

In my diabetics a small per cent. of cases only presented the acetone bodies. There was, however, an abnormal degree of urinary acidity showing that the liver and kidneys were overworked.

In the case of Drs. Bevan and Favill[6] the degree of acidity was 11.6 degrees, or 18.4 degrees retained in the system (30 to 40 being normal). How long this degree of acidity had been in the urine no one knows, probably a long time. Examination of the teeth, gums, and alveolar process by a skillful dentist would have determined. Such a degree of acidity could not have occurred without a decided impression upon these structures as well as upon the liver and kidneys. The diacetic acid which was present gradually diminished until the day before death, when it had disappeared altogether. This, however, could not have been the case with the degree of acidity, since it would require some days to reduce it to normal.

Autopsy showed "chronic nephritis (minimum degree)" which together with the abnormal degree of urinary acidity would indicate renal insufficiency for a long period. Retention of acid in the system, no doubt, caused the nephritis. The lessened alkalinity of the blood, together with other poisons, due to renal insufficiency, was clearly the primary cause of death, administration of chloroform being secondary.

In 1873, the late Prof. Freer sent a fifty-eight-year-old man to me to have his teeth removed. He had recovered from an attack of Bright's disease sufficiently to have this operation performed. The man walked to my office, had twenty-two loose teeth removed under the influence of ether, recovered from the operation, walked home eight blocks, had regular meals, slept well two nights, became restless on the third, and died without any apparent symptoms on the fourth day. Shock from the extraction of the teeth could not have caused death. The alveolar process was entirely destroyed. The teeth were simply held in position by gum tissue. All were loose and could have been removed without forceps. An abnormal degree of urinary acidity must have been present in this patient.

In 1882, I administered nitrous oxide gas to a twenty-eight-year-old man for the extraction of a tooth. The mouth was held open by means of a cork between the teeth. Before I could get the patient under the influence of the gas the face and lips became blue, a spasm of the muscles of the face and jaws occurred, cutting the cork in two. The muscles of the jaws and face became fixed and rigid

as did all the muscles of the body. After three hours' labor, I was able to take the patient home. He was sick in bed for four weeks and finally recovered.

People often have a bluish appearance of the face and lips with spasmodic action of the muscles of the face while going under the influence of nitrous oxide gas. It was formerly supposed to be due to impure gas. This, however, was shown to be untrue after the process of compressing the gas in cylinders, which must of necessity be pure.

Since, as I have shown, many individuals have an abnormal degree of urinary acidity under which destruction of the teeth and alveolar process results, colds are contracted, headache and backache, and many serious lesions develop in pregnancy to be corrected by making the acidity normal, is here not a positive index for prophylaxis? Should not the surgeon, who operates upon a patient first, if time permit, make the acidity normal? In every disease to which the physician is called, should not the degree of acidity of the urine and amount of indican first be obtained to have some definite basis for work? Will not drugs produce better results in diseases if the urinary acidity be normal? Frequently the treatment of these two symptoms alone restores the patient to health.

I am obligated to the following physicians for their assistance: Dr. Sidney Kuh, Cook County Hospital; Dr. S. M. Robin, Cook County Hospital for the Insane and Poorhouse; Dr. Robert Preble, St. Luke's Hospital; Drs. W. A. Evans and Adolph Gehrmann, Columbus Medical Laboratories; Dr. J. F. Keefe, Dr. J. G. Kiernan, Dr. S. S. Bishop, Dr. E. D. Howland, Dr. J. D. McGowan, Dr. J. C. Gill, Dr. W. K. Harrison, Dr. Bertha Bush, Dr. Vida A. Latham, all of Chicago.

A CASE OF INTESTINAL OBSTRUCTION DUE TO PERSISTENCE AND ANOMALY OF THE URACHUS; OPERATION; RECOVERY.

By ANTONIO FANONI, M.D.,

NEW YORK

VISITING SURGEON TO THE ITALIAN HOSPITAL, INSTRUCTOR IN GENITO URINARY SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

On September 20, 1906, I was called to Portchester to see a man, G. D. S., twenty-five years old, single, carpenter. He had come to this country from Italy in June, and had been in perfectly good health until two years ago, when he was seized with an attack of abdominal pain which lasted two or three days, with constipation and vomiting. These symptoms disappeared after three days, when his bowels moved. In the early part of July, after his arrival in America, he had another similar attack of pain in the abdomen, vomiting partly digested food, but his bowels continued to move. The attack again subsided after four or five days.

He remained well until September 14, when he was seized with abdominal pain more violent than in any previous attack, with vomiting of stomach contents. The pain subsided somewhat after the administration of morphine hypodermatically by a local physician. His bowels did not move in spite of the fact that every possible means suggested by three physicians had been applied. On the day following the onset of the attack the vomiting became stercoraceous and remained so for six days.

When I first saw the patient I was struck by the anxious, hollow-eyed, sallow, wax-like, and drawn face, expressing intense suffering and exhaustion from lack of sleep and nourishment. The skin was dry and the tongue dry and coated. There were spasmodic twitchings of the abdominal muscles. The temperature was subnormal, and the pulse 115. The pain, vomiting, and constipation had persisted since the first day. While I was examining the patient he was seized with excruciating pain and piteously begged for morphine. On palpation I found tympany above the umbilical line and dullness below this line.

The diagnosis was intestinal obstruction, and immediate operation was advised. The patient was at once transferred to the Italian Hospital and was operated on the same evening. His pulse before operation was 128, temperature 100.6° F., respiration 28.

First Operation.—An incision was made on the right side along the external border of the rectus to the pubis, revealing one inch below the umbilicus a coil of intestine so large that it looked like an overdistended stomach. This portion of intestine was held between the anterior abdominal wall and a stout fibrous cord the size of the little finger, showing here and there a fine fringe of peritoneum. This cord was followed downward, and was seen to be attached to the fundus of the bladder. It was followed upward where it was attached to the anterior abdominal wall one inch above and two inches to the right of the umbilicus. This cord had no connection with the liver, and its upper end divided into three branches which spread out in the shape of a fan.

The first thought on seeing this cord was that it was either a remnant of an umbilical vessel or of the urachus. Having satisfied myself that it was not a vital structure, it was ligated at both ends and excised. This at once freed the intestine, which was dark and congested in places, but did not show any gangrene. Owing to the patient's desperate condition, no further attempt was made to handle the intestines, although there was a small spot which looked as though it had been considerably damaged. The abdomen was closed in the usual way.

First Pathological Report.—A specimen of the resected urachal tissue from the upper end of the urachus (the lower and longer part resected was unfortunately lost in the operating room) was sent to Dr. H. T. Brooks of the Post Graduate Hospital for histologic examination. The following is Dr. Brooks' report: "The specimen received from you a few days ago was composed of three layers. (1) A thick, dense outer layer of concentrically arranged fibrous connective tissue; (2) an equally thick, perpendicularly arranged fibrous layer which gradually merges with a (3) internal richly cellular layer. This third layer extends to a centrally located lumen, at which point it is markedly infiltrated with round cells and polynuclear leucocytes. Here, also, are a number of small areas of coagulation necrosis near which occasional giant cells are observed. There is no sign of a mucous lining. The general structure of the tissue resembles a

duct, apparently the remains of the urachus. The pathologic condition appears to me to be an acute suppurative infection upon a probable tubercular basis."

The slides were then also sent to Dr. James Ewing of Cornell University Medical College, the following being the report kindly rendered by Dr. Ewing: "The wall of the structure is composed of dense fibrous tissue circularly arranged and containing a moderate supply of large and small vessels, arteries, and veins. There are no definite remnants of muscular tissue. The canal is lined by a dense layer of thick, granulation tissue in which are many round cells and some giant cells. No tubercles are seen. The histological structure is consistent with an origin from a chronically inflamed patent urachus, which is also strongly indicated by the anatomical relations."

The slides were finally taken to Dr. T. M. Prudden of Columbia University, who agreed completely with Dr. Ewing's statements, subscribing to the same in full.

The patient had a spontaneous movement of the bowels two hours after the operation, and had two additional movements during the night.

Owing to the close relations of the urachus and the bladder, it was thought advisable to cystoscope the patient and see whether anything could be detected that might throw light on his condition. The bladder was normal. The left ureteral opening was in the normal position, but about four times larger than normal. The ureteral catheter passed readily to the renal pelvis and there was no evidence of narrowing. The right ureteral orifice was of about normal size and there was some difficulty in finding it. There was nothing to suggest an inflammatory process. The catheter on the right side also easily passed up to the renal pelvis. After three weeks the patient left the hospital in perfect health. He had gained a good deal in weight, especially as he had been kept under general tonics.

The patient remained well until two months after the operation, when I was again informed by telephone, from Portchester, that he could not move his bowels and that he had cramp-like pains in the abdomen. I suggested purgatives, which proved effective and relieved the pain. About two weeks later he came to my office and told me that every two or three days he had a recurrence of pain and constipation. He feared he would not improve and preferred to remain in New York where he could be under my observation.

On examination a swelling was found in the right hypochondriac region, over the side of the stump of the urachus which had been left in the abdomen. It was thought that some inflammatory process existed in the roots of the urachus, as there was some fluctuation in that region, and that a recurrence of the obstruction might be due to adhesions of the stump of the urachus to the intestine. At all events, every means of moving the bowels was tried for several days without success. As the pain was getting worse, it was decided not to lose any valuable time, but to operate at once in order, firstly, to relieve the obstruction, and secondly, to open the abscess.

Second Operation.—Accordingly, an incision was made in the semilunar line, over the tumor. When the structures down to the peritoneum had been cut through, some cheesy material was found and removed, together with the three remnants of the roots of the urachus. After cleansing the field thoroughly, the wound was packed with gauze and closed, leaving sufficient opening for drainage. Then, protecting the drains with gauze, the incision was enlarged downward for three inches, and after having freed numerous small adhesions, it was found that a band of adhesions had formed between the omentum and the urachal stump, and that a loop of small intestine about fifteen inches long had become gradually constricted by this adhesion, so that the lumen at both the distal and proximal ends of the loop permitted the passage only of fluids. The narrowing at the ends of the loop was largely due to hyperplasia of the wall of the gut, caused by the compression of the band.

As there were no signs of necrosis in the gut, and the blood supply was not markedly interfered with, and as the two ends of the gut to be united differed so greatly in caliber, a lateral intestinal anastomosis was made, the coils of the intestine being placed side by side and joined by a continuous, non-penetrating silk suture and finished in the usual way, without removing the loop of intestine.

Owing to the proximity of an infected focus, a cigarette drain was introduced down to the sutured gut and the abdominal cavity closed in three tiers. The drain was removed after four days and the patient made a rapid recovery, gaining nearly twenty pounds in three weeks. He left the hospital four weeks later in excellent condition.

There was no sign of tuberculosis in either the intestines or the peritoneum. The cheesy masses found in the roots of the urachus therefore seemed to be evidence of a localized tuberculous process.

Second Pathological Report.—Specimens of the urachal stump tissue were again submitted to Drs. Brooks, Ewing, and Prudden for examination, and the following are the reports of these pathologists:

"Microscopic examination of the urachus tissue recently received from you showed the typical histologic structure of tuberculosis and also tubercle bacilli."—H. T. Brooks.

"In a small area in the stump of the urachus removed at the second operation there is granulation tissue containing many typical miliary tubercles with characteristic giant cells. A stain for tubercle bacilli would probably render the diagnosis positive."—J. Ewing.

"The second specimen showed a small area of tuberculous inflammation."—T. M. Prudden.

The urachus is the remnant of the allantois of the embryo, and connects the body of the bladder with the umbilicus. It is widest at the bladder and grows thinner as it ascends. In my patient the urachus was abnormal in several respects. It started at the bladder, was free in the abdominal cavity, and instead of ending at the umbilicus it passed two inches to the right side of the navel to a point one inch above the latter, and there divided into three spreading branches, as already described. The free part of the urachus formed the chord of an arc made up by the abdominal wall and the bladder, and in this arc the intestinal loop was caught.

The history of the patient points to the occurrence of an attack of obstruction in Italy two years before I saw him. The intestine, however, succeeded in freeing itself, and he recovered from this attack. The operation performed after his second attack removed the cause of obstruction.

While in all abdominal work a certain degree of speed is most desirable, this is imperative in intestinal obstruction. For this reason I did not cover the stump of the urachus with peritoneum, and this, perhaps, was the cause of the recurrence of obstruction. Such recurrences are frequently

met with, as the result of adhesions without the presence of any stumps. I felt satisfied when I had removed the cause of obstruction and that I had better chances for a good result in this case if I closed the abdomen as soon as this had been done instead of subjecting the frail, exhausted patient, whose resistance was very low, to a more lengthy operation.

As to the tuberculous condition found in the second specimen of urachal tissue, I have every reason to believe that it was purely local, namely, a tuberculous degeneration of the upper end of the urachus. I cannot say this positively, as the longest piece of urachus was lost at the first operation. If the entire urachus had been diseased, probably there would have been more trouble by this time.

This case, so far as I know, is unique in that the cause of obstruction was an abnormally attached, persistent urachus; at least, a search of the literature has failed to reveal a similar instance. The tuberculous condition of the stump and the good recovery after the operations are features which add interest to the case.

A COMMENT ON THE X-RAY AS APPLIED TO PROSTATIC ENLARGEMENT.*

By L. BOLTON BANGS, M.D.,
NEW YORK.

The following case is a typical, uncomplicated one of enlargement of the prostate. It is presented to illustrate a phase of the "*x*-ray" movement.

The patient is a well nourished, vigorous subject of sixty-four years of age, who gave me the following history of his symptoms and treatment prior to coming under my care. Ten years ago he first noticed a slight degree of dysuria and diminution of the stream of urine. The dysuria gradually increased, and frequency of urination developed, till a little over two years ago he was urinating every hour in the daytime and four times in the night. At or about this time vesical tenesmus also began to be a distressing symptom. He then received treatment, which consisted of the systematic use of the catheter and the passage of sounds. Under this treatment there was gradual improvement. The dysuria and frequency lessened and the tenesmus disappeared. The amount of residual urine at first was not stated, but there was a gradual diminution in its amount till in February, 1905, it varied from ¾ oz. to 3 oz., rarely as much as 3 oz., and his nocturnal urination was usually once, occasionally twice. There being no further improvement, the average residual urine remaining at about 1½ oz., it was suggested to him to try the *x*-ray treatment, which was begun in March, 1905. A month later, in April, 1905, he ceased using the catheter, and had received in all sixteen or eighteen treatments. According to his statement the *x*-ray tube was placed a few inches from the perineum. He declares that he was immediately improved, the intervals becoming from three to four hours, but the nocturnal urination remained once and sometimes twice. Also at this time there was occasionally an annoying urgency and, when his mind was occupied, the interval between urinations was longer; but after such an interval the urgency would be distressing and imperative. In the autumn of 1905 he had another course of *x*-ray treatment; but, notwithstanding this, the return of cold weather caused a mild relapse of his difficulties, and he spent the winter of 1905 and 1906 in Egypt, with relief of the symptoms, but with occasionally a little relapse of frequency and tenesmus. In September of 1906 his symptoms returned with full force, the tenesmus especially to such a degree that he had to sit down to urinate, as his bowels would move at the same time.

Toward the end of December, 1906, the *x*-ray treatment was resumed. He experienced some improvement, but after the twelfth treatment dermatitis of the perineum ensued which caused a temporary suspension of the method. Notwithstanding the treatment and his belief that he was being improved, his symptoms persisted, sometimes with marked severity.

He came to me on the 16th of last March, the last *x*-ray treatment having been given on the 12th of March. At this time he had diurnal urination every two or three hours; nocturnal, twice, and slight tenesmus with occasional severe exacerbations. Rectal palpation found the prostate symmetrically enlarged in all directions, say four times normal; the searcher showed a large median and right lobe intravesically and excluded stone, and by catheter were obtained over eight oz. of sterile residual urine. He is now under observation. He still has notable organic enlargement of the prostate; an average of eight oz. of residual urine; and, unless the bladder is relieved by the catheter, he has severe tenesmus which provokes an involuntary emptying of the rectum.

Inasmuch as from time to time I am hearing of, or reading of, cases of prostatic enlargement purporting to be cured by *x*-ray treatment, it seemed advisable to analyze one which has come under my observation. The explanation of his relief is simple and is quite characteristic of many such cases. The systematic use of the catheter relieved an overdistended bladder with restoration of a certain amount of its functional capacity. This restoration persisted for over a year with intercurrent attacks of mild tenesmus and frequency due, no doubt, to some sudden increase in the volume of his urine, which suggested a winter in a mild and equable climate. Finally, there was gradually a refilling of the bladder beyond the ability of its muscular wall to contract upon its contents, with a relapse of all his symptoms. Such cases should be kept steadily under observation in order to determine how much of the bladder function can be restored and maintained. If sufficient bladder function and asepsis cannot be maintained, prostatectomy should be advised.

20 East Forty-sixth Street.

*Read at a meeting of the Practitioners' Society of New York, April 5, 1907.

Alteration of the Liver in the Newborn Accompanied by Incomplete Pulmonary Respiration.—E. Alfieri has examined the livers of twenty-six new-born children who died during labor or soon after birth, from a few minutes to eight days. He found that the cells of the central zone of the liver lobules were swollen and edematous in all those cases in which the infant died without having respired freely, or from prematurity, or from severe intrauterine asphyxia. Adding to these facts the observations that have been made in animals, the author believes that we are justified in thinking that the retardation of the circulation in the umbilical veins, and its cessation without the establishment of respiration and active pulmonary circulation caused the alterations in the liver. The swelling and edema of the liver cells is an expression of the suffering of the infant in the womb, whether death occurred within the uterus, or the circulation was disturbed after delivery by obstruction of pulmonary respiration.—*La Riforma Medica*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 1, 1907.

THE MANAGEMENT OF THE AMERICAN MEDICAL ASSOCIATION.

DURING the past year the MEDICAL RECORD has on several occasions called attention to certain abuses in the management of the American Medical Association and has insisted upon the necessity of reform in the plan of organization of the Association in order that those who have arrogated to themselves the absolute control of this great body may be shorn of some of their powers. The President-elect of the Association, Dr. Joseph D. Bryant, has also expressed himself indirectly as strongly opposed to this misuse of authority on the part of certain of the officers, and in his annual address before the Medical Society of the State of New York in January of this year took occasion to warn his fellow members of the danger of allowing such abuses to creep into the management of their own organization.

In the May issue of *American Medicine*, a journal whose loyalty to the Association is as firm as our own, appears a temperate but scathing criticism of the management of this afflicted body which should be read and pondered by every member and friend of the Association. The editor says that the defects in the plan of organization of the Association are now becoming apparent and that it is a sorry blunder on the part of the rulers to oppose discussion of its weakness and to attempt to stifle criticism of the manner in which they exercise the power which this plan gives them. The evils of too much officialism, he says, are generally recognized throughout the profession and he quotes the admonition of President-elect Bryant regarding what the latter called "the grave perils begotten by the spirit of paternalism which, not infrequently, is a pernicious by-product of organized power." As an illustration of the lust for power which some of the rulers of the Association have conceived, the writer cites the case of a certain trustee who "is said to have spent in visiting delegates much of the three months preceding the meeting at which his re-election or the election of his successor was due—'mending fences' is the political phrase." It is possible this man was inspired with the belief that his continuance in office was essential to the welfare of the Association, but the uncharitable will be inclined to think that he wanted to continue in power in order to work, rather than work for, the Association.

The encroachment upon the liberty of the individual members of the Association, resulting from "the increasing tendency of the 'leaders' toward mere money-getting, monopoly, and trades-unionism," is dwelt upon, and in this connection President-elect Bryant is again quoted where he says: "If on our part, a spirit of fraternal oppression of any kind should develop as the outcome of organized strength, then indeed will the day of consolidation become one of mourning for the loss in fraternal fellowship and in professional station." In noting further the danger inherent in the plenary powers conferred upon the trustees under the present plan of organization, it is said: "These nine men (with the President and Secretary) may divert portions of the vast accumulations possible under the present policies to ends not in accord with the original aims of the Association nor thoroughly representative of the great body of the profession. One may instance such steps as entering into competition with publishers of books or with the manufacturers of drugs in the name of the Association and by use of its funds. The real aims in such measures may be masked by a specious plea for purity and professionalism." Another evil, one might almost say *the* evil, arising from the enslavement of the great body of members of the Association, whose vocation is science, not politics, is the concentration of power in five officers, four of whom are not elected by the members of the Association or even by the representatives of the State societies in the House of Delegates, but are appointed by the trustees. Two of these officials, the Organizer and the Advertising Manager, hold each but one office. The other lucrative offices, those of General Business Manager, Secretary, and Editor, are held by one man, and it is stated "that the incumbent of these offices is present at all the meetings in an attitude of practically determining all decisions!" It is contended that this triple function cannot be satisfactorily discharged by the present incumbent, for "no one man can by any gifts of nature or acquirement properly perform these diverse duties."

The reforms demanded in the interests of progress by a large and increasing body of the profession, among whom are many members of the Association, and not a few of its officers, including, if his address before the New York State Society had any meaning whatever, the President-elect, are summarized by *American Medicine* as follows:

(1) Verbatim reports of the proceedings of legislative and governing bodies. (2) Itemization and utmost publicity of financial matters. (3) Proper representation in the offices of Secretary, of Editor, and of Business Manager by separate individuals, with proper compensation. (4) Nondiscretionary power of the Editor, with government by the Sections of the published proceedings. (5) The rendering impossible of trades-unionism and monopolistic methods. (6) Provision for general secret ballots upon important questions of policy by means of the machinery of the Association and its journal, through district and county societies. (7) The extension of the referendum and initiative from the optional legislative to the popular and obligatory form. (8) In order to protect apparent minorities, placing the vote necessary for both referendum and initiative upon a reasonable basis. (9) The rights

of individual members must be held inviolate from attack by those in power. (10) The Association and its journal must be enjoined from entering into purely commercial competition to the detriment of its professional rivals. (11) No paid agent of the Association should be permitted to be a member of, or take part in the deliberations of, the bodies governing or directing his actions or compensation.

THE PROGRESS OF THE ANTITUBERCULOSIS MOVEMENT IN NEW YORK.

Since tuberculosis has come to be regarded as a preventable and in most instances a curable disease, the crusade against its spread has become a world-wide movement. In every civilized community it has become an institution, which no longer assumes the character of a visionary dream, but rather the aspect of a practical every-day problem. This modern movement dates back to the year when the germ of the disease was discovered by Robert Koch, although the full meaning of this knowledge was slow to be grasped and fully utilized. In this city a signal advance may be ascribed to the action of the local health board in 1897 in declaring tuberculosis to be an infectious and communicable disease, and requiring a compulsory report of all cases. In a recent article J. A. Miller (*Columbia University Quarterly*, March, 1907) calls attention to the further advances which have been made by the authorities in their sanitary control of the disease, which includes not only a complete register of all the cases of tuberculosis in the city, but also an inspection of the homes of all those who do not come under the care of a private physician. This is part of an educational campaign, which also includes the distribution of circulars and pamphlets in several languages, the regular disinfection after every death from tuberculosis and after every change of residence, and special prohibition in the sanitary code against spitting in public places.

The work of the special committee of the Charity Organization Society on the prevention of tuberculosis has also been a potent factor in the education of the laity. This body has arranged public lectures and stereopticon exhibits, has distributed cards and circulars of information, and by means of a traveling exhibit it has shown in a graphic manner the various aspects of the tuberculosis problem. The sanatorium idea has in recent years been largely developed, and so important has this matter become that both municipal and state institutions have been established for the care and treatment of the incipient cases. These institutions exert a tremendous influence, and their efforts in curing those in the early stages of the disease have been crowned with great success. Under the most favorable circumstances, however, it is quite evident that by this means only a comparatively limited number of patients can be placed under treatment and, among the poor particularly, the vast majority must stay, be it to live or to die. A fight against the disease in these quarters is surrounded with many difficulties, and until a few years ago was considered impracticable, general inspection and occasional disinfection by the health department being all that was attempted. But now we find that special clinics have been established by the larger public hospitals of which the main feature consists in teaching the patient afflicted with tuberculosis how to live and to care for himself. It means practically the application of sanatorium treatment to the unpromising conditions associated with life in the tenements. This advice is reiterated in the homes by the visiting nurse, so that a more or less constant supervision is attained. The results obtained can be characterized only as remarkable, and show the value of concerted effort instead of the desultory advice formerly given. Proper food and air are prescribed instead of medicines, and as even these are a luxury among the poorer classes, the other charitable institutions have combined with the special tuberculosis clinics to supply the deficiency whenever possible. Common sense and humanity are now made the principles of the treatment of this disease, and as these are effective only when co-operation exists between the properly constituted institutions, which strive to furnish this relief, it is a matter of general congratulation that the object has been attained.

THE ANESTHETIST.

In this age of specialists there has been developed a field of work which although of limited application is of extreme importance. Not so very long ago the anesthetist as he now exists was unknown. The administration of an anesthetic in a surgical operation was relegated to the junior staff in the hospitals or to anybody who was willing to undertake the task in private practice. With the advent of the newer anesthetics and the more complicated methods of administering the old, either alone or in combination, the specialist in anesthesia came to the fore, and, although many consider that his days are numbered, he did succeed in instilling into the minds of surgeons the necessity for a more careful administration of the means without which their operations could not be executed. In hospital practice particularly instruction in anesthetics is now regularly provided for, and the junior on the house staff no longer receives his instruction from his predecessor, who is only too anxious to give up the work, but is taught the proper use of anesthetics and their importance by one especially appointed for that purpose. The responsibilities of the anesthetist should be fully appreciated, and in a recent edition of his book on Anesthesia (London, 1907) Hewitt refers to the necessity of legislative enactments to control the administration of anesthetics. As the law now stands in England, and it is probably the same in this country, the legal responsibility in case of accident lies with the operator, and not with the anesthetist. The conditions of half a century ago permitted this, but in the surgery of to-day the rôle played by the anesthetist may be of even greater importance than that played by the operator, and the responsibility should therefore be shifted. In order that this may be done, the anesthetist must be properly qualified.

In order that this important subject may be properly appreciated more attention should be given to instruction on the administration of anesthetics in our medical colleges. A special course of lectures supplemented by appropriate physiological experi-

ments on animals and practical clinical applications should be made part of the curriculum. There are many fads taught which could well be omitted or reduced and a practical branch of this kind substituted. A practical working knowledge of anesthesia should form part of the equipment of every medical graduate, for, as Hewitt very aptly says in his book, "there is just as great a scope for professional skill and judgment when the respiratory, the circulatory, and the nervous functions of a patient are being profoundly modified by a general anesthetic as there is during enteric fever or some other ailment for which the services of an experienced physician are regarded as essential."

Thoracic Injuries and Abdominal Rigidity.

The value of unilateral or double rigidity of the abdominal muscles, the *défense musculaire* of the French writers, as an indication of injury to or inflammation of the abdominal contents is beyond dispute, and some surgeons go so far in doubtful cases as to make its sole presence the indication for laparotomy. Like most clinical signs, however, it requires judgment for its interpretation and it may exist in most pronounced forms entirely independently of any trauma to the structures below the diaphragm. Hildebrand (*Berliner klinische Wochenschrift*, May 6, 1907) reports a number of cases of gunshot wounds of the thorax, in which pronounced unilateral rigidity of the abdominal muscles and even abdominal pain were present without there being any implication of the abdomen in the injury. In order to explain this misleading state of affairs he points out that the abdominal muscles are supplied by the lower intercostal nerves and that a bullet entering the thorax, even though the wound of entrance is high up, very often finds a resting place in the posterior thoracic wall at a much lower point and in close proximity to the intercostal nerves, so that injury or irritation of these readily results. Under these conditions it is easy to understand that reflex rigidity of the abdominal musculature might be produced and also that the abdomen might be the site of referred pains. It therefore behooves the surgeon to keep this possibility in mind in dealing with such injuries, and to remember that abdominal rigidity may easily be present without the slightest damage to this region.

Joint Mice.

While the diagnosis of the presence of detached portions of cartilage free in the knee joint is usually not difficult and the results of the operations for removal of such movable bodies are usually excellent, it is possible in such cases to fall into an error which if not serious in its consequences is at least unpleasant. This consists in removing the offending particle and considering the operation completed without a careful search for other movable bodies. Ewald (*Deutsche medizinische Wochenschrift*, May 2, 1907) reports such a case in which, after easily removing one bit of cartilage from the knee joint of an athlete, when the dressings were for the first time removed on the ninth day the operator was unpleasantly astonished to find another joint mouse plainly palpable at the side of the joint opposite to the incision. This was removed with equal ease and the patient's subsequent complete freedom from symptoms seems to prove that the conditions in the joint had been restored to the normal. In order to avoid such embarrassing contretemps as this Büdinger has recently recommended that in all cases the knee joint be fully explored through a large incision, but the risks attending such a method of operating are so much greater that it would seem preferable to rely on careful palpation at several sessions, combined with radiography, and to extract any body or bodies that can be detected through small incisions that involve practically no danger of subsequent impairment of function.

A New Method for Examining the Heart.

The difficulties in mapping out the heart by percussion are universally recognized and even experienced clinicians are likely to differ somewhat in the results they obtain. This is true particularly of the relative cardiac dullness, and any procedure by means of which the determination of the cardiac outlines is facilitated is to be welcomed. Such a suggestion is made by Stern in the *Münchener medizinische Wochenschrift*, April 30, 1907, who states that he has derived much advantage from examining the heart of his patients in the elevated pelvis position. The right border especially can be determined with greater ease, since the right heart in this position comes more closely into contact with the anterior thoracic wall and the edge of the right lung is pushed somewhat outward. In answer to the objection that this method of examination yields results due only to an abnormal displacement of the organ, Stern avers that since it is possible by this means to obtain more definite outlines for the organ than in the usual positions the procedure affords a useful means of checking up the results obtained by the ordinary method. He also recommends auscultation in this position, and states that the difference in the character of murmurs, or the appearance of sounds previously not audible resulting in this way, may suffice to clear up an otherwise difficult diagnosis. The procedure is also to be recommended in studying venous pulsation in the neck.

News of the Week.

Washington Milk Committee's Report.—The report of the Committee on the Sanitary Relation of the Milk Supply of the District of Columbia embodies the opinion that the advantages of the pasteurization of milk outweigh its disadvantages, and it is recommended that a central pasteurizing plant be established and maintained under the supervision of the Health Department. The committee states that it is so strongly impressed with the manifold dangers connected with the milk supply that until the needful reforms in dairy methods are accomplished it recommends to the public the following as immediate safeguards: 1. Do not patronize a milk dealer at any price whose milk after standing for two hours reveals a visible sediment at the bottom of the bottle. It is evidence of dirty habits, extremely suggestive of danger, and entirely preventable by clean, decent methods without greatly increasing the cost. 2. Subject all your milk to home pasteurization, by simply bringing it to the boiling point, and after cooling keep the milk on ice; this will destroy germ life and reduce the chances of milk-borne diseases to a minimum. 3. Your committee recommends that the result of the recent investigations into the milk supply conducted by the

Bureau of Public Health and Marine Hospital Service, the Bureau of Animal Industry, and the Bureau of Chemistry of the Agriculture Department, with a view of supplementing the work of the Health Department, which on account of its limited force and laboratory facilities could not possibly conduct such an exhaustive investigation, be placed at the disposal of the Commissioners of the District. 4. In conclusion your committee recommends that, until the Health Department shall be in control of a bacteriological laboratory, and a sufficient number of inspectors, the Health Officer request the continuance of the cooperation of the Bureau of Public Health and Marine Hospital Service and the Department of Agriculture for improving the local milk supply. The members of the committee are as follows: George M. Kober (chairman), Emile Berliner, Dr. G. L. Magruder, Dr. C. F. Mason, U. S. Army; Dr. A. D. Melvin, Chief Bureau of Animal Industry; Dr. J. R. Mohler, Bureau of Animal Industry; Dr. M. J. Rosenau, Director Hygienic Laboratory, Public Health Service; Col. R. G. Smith, E. H. Webster, Chief Dairy Division, Department of Agriculture.

The New York City Milk Commission.—The report of the commission consisting of Drs. L. E. Holt, A. Jacobi, Joseph D. Bryant, T. Mitchell Prudden, and Rowland G. Freeman, appointed by Mayor McClellan to investigate the conditions under which milk is sold in this city, has submitted its report, which is based on an investigation of every stage in the passage of the milk from the cow to the consumer. While admitting the advisability of pasteurizing all milk which is open to suspicion, the committee expresses the opinion that what is primarily needed is the extension of the system of inspection at the dairies and milk shipping centers. It is stated that in order to have efficient inspection of the milk business at least one hundred inspectors for the country districts from which the supply is drawn, in addition to the fifteen now available, should be employed.

Result of the Bilibid Prison Inquiry.—Both the committee of scientists and the committee of Filipinos that have been investigating the inoculation of prisoners at Bilibid prison with contaminated anticholera serum have made reports exonerating Dr. R. R. Strong of the Bureau of Science, under whose direction the experiments were being conducted, from all personal responsibility and the Attorney-General has found that there was no negligence on the part of those concerned in the work. Last November thirteen out of twenty-four prisoners who were inoculated with the serum died, as the result, it was afterwards discovered, of contamination of the serum with attenuated plague cultures. Much excitement over the incident was caused among the Filipino population, but the members of the native committee express themselves as satisfied that no one was responsible for the accident and specifically exonerate Dr. Strong. The families of the victims will be provided for by the Philippine Commission.

Plague in India.—The efforts of the British sanitary authorities in India are being greatly hampered in their efforts to restrict the spread of the plague by a story that has been circulated among the natives in the Punjab to the effect that there is no such disease as the plague, but that the recent mortality is all due to the fact that the government has been despatching emissaries throughout the country to poison the wells for the purpose of exterminating the population. The author of the story, who is a Hindu, has been captured by the police and sentenced to two years imprisonment. Thirty-three of his accomplices, who actually dropped mysterious balls into wells, alleging that they did so by the government's order, have been sentenced to eighteen months' imprisonment. The deaths by plague in India during the six weeks ending May 11 were 451,802. In the Punjab alone there were 286,777.

To Systematize the Treatment of the Tuberculous Poor.—The Committee on the Prevention of Tuberculosis of the Charity Organization Society announces that plans have been perfected for the division of New York City into districts with a special tuberculosis dispensary in each district to take care of all consumptives applying for treatment. Under this arrangement the patients are able to obtain more individual care from the visiting nurses, which each dispensary employs, and more regular attendance of the patients is secured. The following dispensaries have entered into the plan: Department of Health, Bellevue Hospital Dispensary, Gouverneur Hospital Dispensary, Presbyterian Hospital Dispensary, Harlem Hospital Dispensary, Vanderbilt Clinic, New York Dispensary, New York Hospital Dispensary, and Health Department, the Bronx. Patients are expected to apply to the dispensary nearest their homes.

Health Conditions in the Isthmus.—The report of the Sanitary Department of the Isthmian Canal Commission shows a decrease in the death rate for the month of April among the employees in the Canal Zone. Among 5,484 white Americans connected with the commission there were only four deaths in April, which gave a death rate of 8.7 per thousand. The decrease in mortality is due chiefly to the falling off of the cases of pneumonia. From this disease there were forty deaths in April, as against fifty-three in March, thirty-nine of the forty being among negroes. There were twenty-one deaths from typhoid, nineteen among the negroes and one among the whites. The number of hospital cases in April was about three-fourths the number in March, while the sick rate is only twenty-one a thousand.

Smallpox.—According to the reports of the Public Health and Marine Hospital Service, in 1906 there were in the United States 12,503 cases of smallpox and ninety deaths, while in 1902 there were 55,857 cases, with 1,852 deaths. In Germany, where vaccination is compulsory and universal, during 1906 there were only twenty-six cases, with five deaths, in the whole empire.

Famine in China.—Owing to the approaching ripening of the new crops the famine in China is said to be broken and the National Red Cross announces that further contributions of money and supplies are no longer needed. The organization has received in money contributions for Chinese famine relief since the work was begun on December 24 last, $320,000, and has received, besides, a large quantity of seed wheat and flour.

Illinois Optometry Bill Vetoed.—Governor Deneen recently vetoed the optometry bill establishing a State Board of Optometry and requiring examination and licensing of opticians. The bill was vigorously opposed by members of the medical profession, and notwithstanding delegations of optometrists and members of the Chicago Optical Society, who were given a hearing before the Governor, he vetoed it.

The Optometry Bill.—The New York Senate has passed the Optometry Bill creating an examin-

ing board for opticians, which really gives to them the right to practise in a limited way a specialty in medicine, as medicine is defined in our new medical law. Year after year the Medical Society of the County of New York has had a Committee on Legislation which has successfully fought these efforts to create new boards, and it was hoped that the law creating a single board for all sorts of practitioners would do away with the need for such effort, but the refracting opticians seem not to be satisfied. The bill now goes to the Assembly for concurrence and an objection on the part of any member of the Assembly will place it in the hands of the Committee on Rules. The physicians of the State are urged to write to the members of this committee asking them to defeat this bill, and also to the Governor, asking him to withhold his signature if the Committee on Rules fail to control it. The following is a list of the persons to whom letters are to be addressed: Hon. Charles E. Hughes, Executive Chamber, Albany; Hon. James W. Wadsworth, Jr., Hon. Ezra P. Prentice, Hon. Edwin A. Merritt, Jr., Hon. Sherman Moreland, Hon. James Oliver, Hon. William A. Burns, Assembly Chamber, Albany, N. Y.

Purchase of Property of Chicago College of Physicians and Surgeons.—A committee was appointed at the meeting of the Illinois State Medical Society, consisting of Drs. C. S. Bacon, J. W. Pettit, and J. Whitfield Smith, to ask Governor Deneen to sign the bill for the purchase of the property of the College of Physicians and Surgeons by the University of Illinois.

Nurses Needed for the Poor.—The New York Association for Improving the Condition of the Poor calls for twenty trained nurses who will volunteer for moderate compensation for its summer work. Some are needed on the staff at Sea Breeze hospitals for children and some for district work in tenement homes. Applications should be addressed to William H. Allen, General Agent, 105 East Twenty-second Street, New York City.

Reception to Professor Killian.—A reception at which Professor Gustav Killian of Freiburg i. B. was the guest of honor was given by Dr. Wolff Freudenthal on last Tuesday evening.

Dr. Follen Cabot, Jr., was elected Professor of Genitourinary Surgery at the last meeting of the faculty of the New York Post-Graduate Medical School and Hospital.

Professor August Bier of Bonn has accepted a call to the Chair of Surgery in the University of Berlin left vacant by the death of Professor von Bergmann. The names of Professor Garrè of Breslau and Professor von Eiselsberg of Vienna had also been mentioned in connection with the position.

Association of Medical Librarians.—The tenth annual meeting of this association will be held at the Marlborough-Blenheim Hotel in Atlantic City on June 3, 1907, under the presidency of Dr. George Dock of Ann Arbor. The secretary is Dr. Albert T. Huntington of Brooklyn.

American Proctologic Society.—The ninth annual meeting of this organization will be held in Atlantic City at the Seaside House on June 3 and 4, 1907, under the presidency of Dr. Samuel G. Gant of this city. The secretary is Dr. A. B. Cooke of Nashville, Tenn.

National Confederation of State Medical Examining and Licensing Boards.—This organization will hold its seventeenth annual meeting in Atlantic City at the Hotel Traymore on June 4, 1907. The president is Dr. Edwin B. Harvey of Boston and the secretary Dr. Murray Galt Motter of Washington, D. C.

Iowa State Medical Society.—Officers as follows were elected at the meeting of this society held in Cedar Falls, Ia., on May 17: *President*, Dr. W. L. Biering of Iowa City; *Vice-President*, Dr. A. G. Shellito of Independence and Dr. H. B. Jennings of Council Bluffs; *Secretary*, Dr. V. L. Treynor of Council Bluffs, reelected; *Treasurer*, Dr. W. B. Small of Waterloo, reelected. The next meeting will be held in Des Moines.

The North Dakota State Medical Association.—At its annual meeting held in Minot on May 15 officers for this association were elected as follows: *President*, Dr. Laughlin of New Rockford; *Vice-Presidents*, Dr. Campbell of Grand Forks, Dr. Countryman of Grafton, Dr. H. A. Beaudoux of Fargo, and Dr. H. W. Phillips of Hope; *Secretary*, Dr. J. H. Rowe of Castleton; *Treasurer*, Dr. J. D. Taylor of Minot.

West Virginia State Medical Association.—At the fortieth session of this society held in Huntington on May 17 officers were elected as follows: *President*, Dr. Flemming Howell; *Vice-Presidents*, Dr. C. O. Henry, Dr. Rader, and Dr. J. Schwinn; *Secretary*, Dr. L. W. Moore; *Treasurer*, Dr. H. K. Owens.

New Mexico Medical Association.—Officers as follows were elected at the meeting of this association held at Las Cruces on May 11: *President*, Dr. R. E. McBride of Las Cruces; *Vice-Presidents*, Dr. Angle of Silver City and Dr. P. M. Steed of Deming; *Secretary*, Dr. G. S. McLandress of Albuquerque and Dr. C. E. Duncan of Socorro.

New Hampshire State Medical Society.—At the annual meeting of this organization held on May 17 in Concord officers were elected as follows: *President*, Dr. John H. Neal of Rochester; *Vice-President*, Dr. John M. Gile of Hanover; *Secretary*, Dr. D. E. Sullivan of Concord; *Treasurer*, Dr. D. M. Currier of Newport.

Polk County (Ark.) Medical Society.—At the recent meeting of this society officers were elected as follows: *President*, Dr. C. Cochran; *Vice-President*, Dr. J. F. Rhodes; *Secretary*, Dr. C. C. Gunnels; *Treasurer*, Dr. D. W. Connelly.

Donation to Chicago Tuberculosis Institute.—Mrs. Keith Spalding of Chicago recently gave to the Chicago Tuberculosis Institute the Edward Tuberculosis Sanitarium at Naperville, Ill., which she founded in November, 1906. She has also promised to give this institution six thousand dollars a year.

Illinois State Medical Society.—The fifty-seventh annual meeting of this Association was held at Rockford, May 21, 22, and 23, 1907. The following officers were elected for the ensuing year: *President*, Dr. Wm. L. Baum of Chicago; *First Vice-President*, Dr. C. W. Lillie of East St. Louis; *Second Vice-President*, Dr. T. H. Culhane of Rockford; *Secretary*, Dr. E. W. Weis, Ottawa, reelected; *Treasurer*, Dr. E. J. Brown, Decatur, reelected. *Delegates to the American Medical Association*, Drs. Frank Billings of Chicago, J. R. Hollowbush of Rock Island, and C. S. Bacon of Chicago. *Alternates*, Dr. G. D. Smith of Elizabeth, Dr. C. B. Horrell of Galesburg, Dr. Robert T. Gilmore of Chicago, Dr. E. B. Montgomery of Quincy, Dr. C. M. Jack of Decatur, Dr. Wm. L. Ballenger of Chicago, and Dr. S. C. Stremmel of Macomb. Peoria was selected as the next place of meeting; time, third Tuesday in May, 1908.

Obituary Notes.—Brig.-Gen. Henry S. Turrill,

U. S. A., retired, of New Milford, Conn., died suddenly of heart disease on May 24 in this city while dictating material for a book he was about to publish. General Turril was born in New Milford in 1842 and was graduated from the Yale Medical School twenty-two years later. He was appointed assistant surgeon to the Seventeenth Connecticut Volunteer Infantry and served through the later part of the Civil War. In 1875 he was appointed assistant surgeon in the regular army and served through the Indian Wars under General A. R. Chaffee. He received the rank of Captain in 1880, that of Major in 1883, Lieutenant-Colonel in 1892, and Brigadier-General about a year ago, just before his retirement.

Dr. Charles Samson Féré, for many years physician to l'Hospice de Bicêtre in Paris, died on April 22 at the age of fifty-four years.

Sir Joseph Fayrer, formerly physician to Queen Victoria and since 1901 physician extraordinary to King Edward, died at Falmouth on May 21 at the age of eighty-three years. In the middle of the preceding century he served in a medical capacity both in the army and the navy and was for a time Professor of Surgery in the medical college at Bengal, President of the Medical Faculty of Calcutta University, and successively Vice-President and President of the Bengal Asiatic Society. He was created a baronet in 1896. He was the author of numerous works on medical topics and of a volume of "Recollections" of his life and times.

Dr. Clarence Tripp Gardner died of nephritis on May 23 at his home in Seaconet, R. I., after an illness of several months. He was born in Providence in 1844 and after having served in the First Rhode Island Infantry as First Lieutenant he was graduated from Harvard Medical School in 1866.

Dr. Guy Davenport Lombard of this city died on May 22 at the age of thirty-five years. He was born in Northampton, Mass., and was graduated from the New York University Medical School in 1896. He served on the Bellevue Hospital interne staff and since 1898 has been Instructor in Histology in the Cornell Medical School.

Dr. Augustus Charles Bernays of St. Louis died suddenly of apoplexy on May 22. Dr. Bernays was born in Highland, Ill., in 1854 and received his medical degree from the University of Heidelberg in 1876. A year later he was made a member of the Royal College of Surgeons in London, and in 1878 he began practice in St. Louis. He was the author of several works on surgery and was active in introducing antiseptic methods into this country.

Dr. Charles Simpson of Minneapolis died on May 16 at the age of sixty-four years. He was born in Scotland, was graduated from the Columbia College of Medicine in 1871, and shortly afterward began practice in Minneapolis. He was Health Commissioner of the city in 1875 and 1876, was the fourth President of the Hennepin County Medical Society, and a member of the State Board of Medical Examiners from 1895 to 1898.

Dr. John W. Suggs of Thomaston, Ga., died on May 17 at the age of seventy-nine years. He had practised in Thomaston for over fifty years.

Dr. Jordan Johnson, lately of Yoakum, died at Taylor, Tex., on May 17 at the age of eighty-four years. He had practised in Yoakum for many years, but retired from active work some time ago.

Dr. George H. Watson of Brooklyn died on May 26 at the age of sixty years. He was born in Sedgewick, Me., and was graduated from Amherst College in 1870. After receiving his medical education in New York and Philadelphia he practised for many years in Bridgewater, Mass. He retired from active work in 1900 and since then had resided in Brooklyn.

Dr. John Hooker Packard of Philadelphia died at Atlantic City on May 20 at the age of seventy-five years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1853. He was for many years one of the surgeons to the Pennsylvania Hospital, but he withdrew from active practice some ten years ago.

Correspondence.

A NEW PLAN OF SUTURING IN PERINEORRHAPHY.

To the Editor of the Medical Record:

Sir:—To overcome the cutting of silk-worm gut sutures in perineorrhaphy, the following plan has given excellent results. Each needle which is ordinarily threaded with one silk-worm gut suture is threaded with two strands of silk-worm gut. When all the sutures have been introduced there will therefore be two strands through each suture line. Select one strand out of each pair and mark them for identification by catching the ends in forceps.

Before tying said strands, by means of a needle "set back" in sound skin the remaining strands for a distance of about one-eighth of an inch from the edge of wound. This may be easily and quickly done by threading an end of each suture on a needle, introducing the needle through the needle puncture in the skin and passing the needle subcutaneously beneath the skin until it emerges a short distance from the original opening. The sutures in the grasp of the forceps are now tied in the usual way and the other set, or those which include a trifle more of skin surface, are not tied at this time. In four or five days, or at any time when the tied sutures begin to "cut" and become "buried," they are removed and the untied sutures are now tied. It is important that as soon as one suture is cut and removed the one that is to take its place should be immediately tied. This will prevent the strain on freshly-adhered surfaces, which would occur if all the stitches were removed before any of the new set were tied. The second set may be removed at the end of ten or twelve days from the date of operation.

The results from this plan have been excellent and the patients have been far more comfortable. The infection, which often starts along the suture line when the suture begins to cut, is avoided by this plan.

William H. Bishop, M.D.

667 Madison Avenue.

OUR LONDON LETTER.

(From Our Special Correspondent

PROBLEMS OF THE REORGANIZED UNIVERSITY—GARMENTS FOR THE TROPICS—ALCOHOL MANIFESTO—CHEMISTS' EXPEDITION—LIVERPOOL TROPICAL SCHOOL.

London, May 10, 1907.

The reorganization of the London University seems to have given satisfaction to no one. The public has not endowed it as liberally as its friends anticipated; its own alumni are torn by dissension as to the results of the change and what they wish for the future, and much the same may be said about outsiders concerned with education in general. With regard to the medical faculty, there are several points of dispute, and discussion has become acrimonious, and personalities have been introduced. All these I pass over, and will refer only to points of general medical interest. First of all, the position as to students, for pupillage must precede graduation—indeed, without a supply of students there would be no graduates. It was hoped that the medical students of London would be able to graduate in the reorganized university as fully and, so to say, as naturally as those of other university centers. But no such result has followed the changes, and while many lament the fact, others rather rejoice, protesting that the obstacle they have leaped ever shall not be diminished, forgetting or unconscious of the fact that some of those obstacles were absurd hindrances to their intellectual development, and merely matters of regulation. It is really pitiable to hear a man who has taken a degree object to a change in regulations which have been shown to be useless hindrances, and to cry out that such changes would lower the value of his degree. The truth seems to

be that many of the defects of the old constitution inhere in the University, and it may be long before all are removed. The University was established as an Examining Board, and promised a degree to all who were able to pass the tests. A person privately educated within the walls of a school or college was promised equality with those taught in academical institutions. The promise was broken by regulations incompatible with the medical curriculum. The most important of these was the insistence of matriculation prior to entering a medical school and making the standard of the matriculation examination that of a minor degree. The student who began hospital work before he had found out this strictly enforced rule, discovered too late that he must sacrifice the time and money he had spent on the hospital school, as none of that could count, because he had not previously passed the matriculation. Here and there such a student made the sacrifice, turned again to his earlier subjects of instruction, and, after passing, came back to the hospital and began again his first session's work in order to secure certificates of attendance on first year's lectures, etc. Thus much money and time was wasted, and few could afford it; for one who could, dozens could not. I know this from long experience as a teacher. The difficulty of the examination, so much complained of, arose from two causes, the first being the subjects were numerous and must all be passed at the same time, rejection in one being fatal in all; the second, the constant effort of examiners to keep up the standard, each examiner holding his own subject as most important, and the constant change of examiners exposing the student to new assessors of his marks. The crotchets of examiners became a study for crammers, who were so successful that the majority of candidates called in their aid. The medical degrees of the University attained a high reputation on the ground that each stage the examination was difficult, but it was to so great an extent merely book work and cramming that succeeded that the defects of young graduates in clinical experience and practical knowledge became proverbial.

Now about the proposed Institute of the Medical Sciences. You will remember that I wrote to you about it at its inception. The Royal Commission recommended the early subjects of the curriculum to be concentrated in one or more centers. University College, as I reported to you, is now such a center, and King's will soon complete its arrangements. The third center was to be the Institute. An appeal for its endowment was issued, a site at South Kensington was granted, estimated as worth about £150,000, while nearly half as much cash was subscribed, and the King and the Prince of Wales approved the scheme. The medical faculty was understood to be satisfied with the prospect of a magnificent institution which would serve as the third center, but lately differences have arisen, and after acrimonious discussion the faculty has voted the rejection of the scheme, the blame being cast upon the hospital schools, which, it is said, cannot compare their differences or, as some say, their jealousies.

The manifesto or joint testimonial to the value of alcohol, which, as I told you some weeks since, was signed and sent to the *Lancet* by sixteen physicians and surgeons, as if they represented the profession or could modify the former declarations signed by thousands, has already begun to produce evil fruit. It is issued by the Licensed Victuallers Central Protection Association and can be seen in many a publican's bar. The *Medical Press and Circular* has issued a countermanifesto, and is satisfied with the response so far, but it will take some time to see what comes of it. Men may be tired of manifesting and shun entrance to the controversy.

The Chemists' Exhibition was opened on Monday and closes this evening. It seems to have been as successful as usual. Of course, it includes much that is of only secondary interest to the medical profession, but a very large part demands and receives its close attention and is well worth seeing.

The Liverpool Tropical School has spent £80,000 on its expeditions, with most important results. Sir A. Jones, president, gave a farewell banquet to the new expedition on sleeping sickness. The next step will be one for blackwater fever, and will probably start in August.

Tertiary Syphilitic Fever.—Luigi D'Amato publishes three cases of tertiary syphilitic fever with the results of treatment and gives us the results of his observations and a review of the work of other authors. He states that syphilitic fever may begin in the early secondary period and last into the tertiary period. It may or may not be accompanied by visceral manifestations, especially in the liver, but the fever does not seem to be dependent on these lesions. It may fall spontaneously without specific treatment, but easily returns. When specific treatment is given it falls by lysis.—*La Riforma Medica*

THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

FOURTH ANNUAL MEETING.

(From Our Special Correspondent.)

At the fourth session of the Philippine Islands Medical Association, held March 1, the first paper read was entitled "The Transmission of Leprosy to Apes," by Moses T. Clegg, Biological Laboratory, Bureau of Science. The experiments recorded were entirely negative, but it was interesting to observe that at intervals of two weeks for a period of three months acid-fast bacilli were found in the adjacent glands near the site of the inoculation in the monkey which was used for the experiments, and further work with this particular animal was interrupted on account of its death from an intercurrent disease. He also stated that organisms injected in symbiosis disappeared from the site of the inoculation a few days afterward, but those injected in pure cultures could be recovered from three weeks to three months afterward.

The next paper, entitled "The Fate of the Agglutinins Upon Filtering an Immune Serum," was read by Dr. Ralph T. Edwards, Biological Laboratory, Bureau of Science. This paper will be published in the Philippine *Journal of Science*.

A paper entitled "On Cultivation of the Piroplasma" was then read by Dr. Kanosuke Miyajima, of the Institute of Infectious Diseases at Tokio, Delegate from His Imperial Japanese Majesty's Government. He stated that whatever success he had had in accomplishing this was due to the information he obtained from the work which has been accomplished by Novey and McNeil in cultivating the *Trypanosoma lewisii*. He took for his investigation the bovine piroplasma, which is very common in Japan. He stated the parasites found were in apparently healthy animals, were mostly of small bacillary forms, while the larger piroforms were ring formed bodies and were only seen occasionally. Upon the full-grown state of the organism being reached, its length is found to be more than three times the diameter of a red blood corpuscle. The organism possesses a well-defined undulating membrane and long, flat flagella; moreover, the position of the nucleus and blepharoplast of the body of the flagella renders it impossible to distinguish the organism from typical trypanosomata. The infected blood was taken from the jugular vein and quickly defibrinated under strict precautions to avoid bacterial contamination. The blood thus obtained is mixed with ordinary nutrient bouillon in proportions varying from one-fifth to one-tenth, and kept in sterile test tubes at a temperature of 20° to 30° C. The development of the parasite occurs as follows: On the first day no motile form was seen in the culture; second day there occurred a certain number of peculiar cells, which occupied the upper layer of the sedimented corpuscles and appeared macroscopically as whitish dots. After these cells were found, motile forms resembling typical trypanosoma were visible, upon the third day after inoculation. Thereafter the organisms multiplied vigorously, and reached the maximum number somewhere between ten and fourteen days. The culture contained motile trypanosomata at room temperature for at least forty-five days, after which most of them underwent deterioration and resulted in irregular granular globular cells. In cultures preserved at a lower temperature, ranging from ten to twenty degrees C., the organsims remained alive for three months. Sub-cultures were readily obtained by inoculating from the original strain. The number of native cattle in Japan which have so far been examined microscopically already amounts to 200, but in not one of these could trypanosomata be found. He also invites attention to the fact that, so far, trypanosomiasis is entirely unknown in Japan. He gave the following conclusions: 1. That the kind of hemacryptozoa known as *Piroplasma parvum* can readily be cultivated outside of the living body. 2. The parasites undergo a developmental change in the bouillon and finally have the typical form of trypanosomata, which cannot be detected in the blood of the infected animals. 3. That a simple mixture of blood and bouillon is the most suitable medium for the cultivation of these parasites, *Piroplasma parvum*, and *Trypanosoma lewisii*. In the preliminary experiments with the cultivation of piroplasma different, culture media were tested, namely, blood agar, sodium citrate, broth in acidulated and unacidulated condition, beef broth, peptone, calf serum, physiological salt solution, and common bouillon. On the 4th of July, 1906, he found motile organisms in one test tube, which contained a small amount of infected blood mixed with sodium citrate solution, prepared after Rogers' method. The entire series of cultures were then subjected to a careful examination, but no motile organisms could be found except in the bouillon.

The next paper, entitled "The Filtration of Antiserums," was read by Dr. E. H. Ruediger, Biological Laboratory, Bureau of Science. He stated that on account of the difficulties met with in endeavoring to obtain antiserums for prophylactic purposes, free from corpuscles, precipitate, and bacteria, it was thought advisable to study the effect of passing the serums through a Berkfelt filter. This had previously been attempted by Woolley, of the Bureau of Science, with rinderpest serum, but had been abandoned because the serum would not pass through the filter. Recently, however, the method was again attempted, and it was found that such serum would readily pass through, provided the blood is free from blood corpuscles, precipitate, and other extraneous matter which would clog the filter. These substances were easily removed by centrifugation for thirty minutes with a speed of 3,000 revolutions per minute. The serum thus obtained was perfectly pure, free from bacteria, and apparently has lost none of its efficacy. At the same time it reduces the danger by filtering the bacteria with which it may have become contaminated during the process of handling. He laid great stress upon the fact that the filter must be cleaned immediately after it has been used, otherwise the filter would become clogged by the accumulation which necessarily takes place during autoclaving. The best method of cleaning the filter has been found to scrub it with a brush in running water and then passing through it a liter or more of distilled water, and, before using it again, the filter should be boiled for at least five minutes in distilled water and then washed out by passing distilled water through it.

A paper on "An Experimental Investigation of the Causation of Beriberi," by Dr. W. V. N. Koch, Medical Officer in Charge of the Infectious Disease Hospital, Hongkong, was then read by Dr. J. M. Atkinson. He stated that those observers who claimed to have found the micrococcus which was the cause of the disease were unquestionably wrong in their views. In order to exclude the possibility of the existence of microorganisms, the following work was undertaken: 1. An examination of blood films made from several hundred cases, stained by different methods; also by 10 to 20 c.c. being withdrawn from patients and different culture methods used, and also by the blood being transferred directly from patients to animals. 2. Spleen punctures were made in nearly 100 cases, and the blood treated as above. 3. Drops of fluids from the subcutaneous tissues were examined culturally. 4. Cerebrospinal fluid drawn by lumbar puncture. 5. Smears and cultures from from organs and tissues of fresh cadavers were made especially from gastroduodenal mucous membrane. In all of the foregoing experiments he failed to find any specific pathogenic organism. After the failure of the above series of investigations, efforts were made to demonstrate the possibility of infecting monkeys by natural means. The rooms in an institution at which an epidemic of beriberi broke out, which were occupied by the inmates who had contracted the disease, were allowed to remain exactly as they had been during occupation, and the conditions maintained as near to normal as possible, except that shutters were closed and the doors made fast. In each of the four rooms two monkeys were turned loose and were kept incarcerated for nearly five months, and were subsequently kept under observation for one year. None of them, after most careful examination, showed signs of beriberi. Associated with these monkeys, rabbits were also placed in the same rooms. After this, some feeding experiments were undertaken. Monkeys were fed from freshly drawn defibrinated blood from beriberi cases, from 30 to 40 c.c. being used, the dose being repeated a number of times. An emulsion of the medulla and pons varolli from recently fatal cases of beriberi were fed to a monkey. Afterward the monkey was inoculated subcutaneously with blood freshly drawn from a case of acute beriberi, probably 5 c.c. were transferred directly from the arm of the patient to the animal. This caused a slight rise of temperature, which subsided, and the animal appeared none the worse. He also inoculated spleen blood and an injection of cerebrospinal fluid. Practically the same experiments were repeated in pigs, sheep, calves, rabbits, fowls, and horses, all with negative results. The conclusions were as follows: 1. Beriberi could not be conveyed to any of the animals used for experiments. 2. It would appear that transference of beriberi infection from man to animals is impossible. 3. In beriberi we are dealing with an infectious disease, but with one of an entirely different etiology.

The next paper was entitled "Leprosy in the Philippine Islands and the Present Methods of Combating the Disease," by Dr. Victor G. Heiser, Director of Health, P. A. Surgeon U. S. P. H. and M. H. Service. This paper will be published in full in the MEDICAL RECORD.

The next paper, "The Habitual Use of Opium as a Factor in the Production of Disease Among Chinese," by Dr. Tee Han Kee, Municipal Physician, City of Manila. He stated more particularly that since the opium law in the Philippines went into effect the Chinese had taken more and more to the hypodermic use of the drug, and that in his opinion the opium habit caused by the hypodermic use was more difficult to cure than that of any other form.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

DEATH OF MOSETIG MOORHOF—A SYMPTOM OF SCIATICA—THE DIFFERENTIAL DIAGNOSIS OF NEURALGIA AND TOOTHACHE—THE ERUPTION OF SMALLPOX—EPIDEMIC CEREBROSPINAL MENINGITIS.

VIENNA, May 1, 1907.

THE tragic death of Prof. Albert Mosetig von Moorhof occurred through accidental drowning in the Danube on April 26. In him the faculty of Vienna loses a scientist whose name has been an ornament to science. Hofrat von Mosetig was one of the most prominent and popular Viennese surgeons and was particularly renowned for the advances he had brought about in military surgery. He gathered rich experiences in the Franco-Prussian war, in the Bosnian campaign of 1878, and in the Servian war of 1885, which he utilized in numerous contributions to medical literature. He introduced iodoform into surgical practice in Vienna and was the inventor of the method of filling bone cavities with an iodoform paraffin mixture. He was born in Triest in 1838 and in 1861 received his medical degree from the University of Vienna. After serving for a time as assistant to Dumreicher, he was, in 1874, appointed Professor of Surgery. In 1871 he was made Chief Surgeon in the Wiedener Hospital, and twenty years later received a similar appointment in the General Hospital.

Sigmund Gara has described a hitherto unknown symptom of sciatica. He observed that patients frequently complained that the onset of the sciatica had been preceded for days or weeks by more or less severe backache, and it was only on the subsidence of this that the pain appeared in the lower extremities. He therefore examined the spine in such cases and observed that on pressure over the spinous process of the last lumbar vertebra very severe pain was occasioned, which was less both above and below. Patients who did not complain of backache also exhibited this symptom. Gara also treated a series of cases supposed to be of sciatica in which there was carcinoma, fracture of the neck of the femur, tumor of the prostate, etc., and in these the above mentioned symptom was either absent or a number of spinous processes were painful. He accordingly claims that the painful point over the spinous process of the last lumbar vertebra is to be regarded as a sign of sciatica only when no other vertebræ are painful.

Franz Berger has studied the problem of the differentiation of neuralgia and toothache. He has found that the faradic current offers an excellent means of detecting diseased teeth. The faradic current, when applied to the well-dried teeth, if they are healthy, causes only a tingling sensation, but if the teeth are diseased severe pain is occasioned. In the case of a woman whose teeth were handsome and appeared healthy, severe and intractable neuralgic pains had persisted for more than a year. By means of the method just described it was discovered that two teeth were diseased and on devitalizing their nerves the pain promptly disappeared.

Carl von Pirquet has described a theory of the smallpox eruption in a communication presented before the Association of Physicians. He believes that in the early vaccinial eruption occurring within twenty-four hours the inflammation is caused through the contact of the lymph with bacteriolytic antibodies present in the previously vaccinated body. The inflammatory symptoms attending the first vaccination, which appear in from eight to ten days, such as the areola and fever, are also to be regarded as caused by toxic products formed through the action of newly developed antibodies. The antibodies which go to the formation of the eruption may be agglutinins through which the causative agents of the disease circulating in the blood are clumped together in the capillaries. This is also indicated by the histological reports of Weigert, who found in the blood-vessels under fresh papules and in the internal organs tubular zoogloea-like masses. Measles resembles smallpox not only in its incubation period, prodromal fever, and leucocyte curve, but also in the fact that in cachectic individuals the exanthem is reduced in intensity and is more pronounced the greater the powers of resistance of the patient.

For some weeks numerous cases of cerebrospinal meningitis have been reported in Vienna. The cases are fre-

quently atypical or abortive and occur in all quarters of the city. Most of them are severe, but under suitable treatment—lumbar puncture and serum injections—give a good prognosis. In one of the southern Austrian provinces an investigation has lately been held for the purpose of determining the necessary prophylactic measures. One of the most important of these is said to be the examination of all persons coming in contact with the patient and who are suffering from nasal catarrh, as many of these are found to have meningococci in the nasopharynx. When these are found, suitable disinfecting sprays are to be used, and disinfection of the body and bed linen of the patients is also recommended.

Progress of Medical Science.

New York Medical Journal, May 18, 1907

Backward and Defective Children.—H. Shoemaker has examined many pupils during the last three years in public and parochial schools and considers that the greatest possible relief would come to them by the adoption of the following rules: First, the relief of all physical defects so far as possible. Second, placing a teacher in charge of a limited number of children. Third, in compelling a home report, from personal observation of the teacher in charge of the actual work, in order that cruelties and neglect may receive proper investigation, or that a teacher may not unwittingly be trying to force an infant mind. Fourth, in making the session shorter. Fifth, in demanding a concession from the parents, which may be implied by admission to the special class, for the correction of all physical defects in their children. Sixth, the employment of manual training, which may create dexterity, even though the power to originate is lacking. Seventh, physical culture and outdoor gymnastics, when possible.

External Hemorrhage with Ectopic Pregnancy.—J. Oliver describes the customary cause and features of ectopic pregnancy, noting that when the oosperm is arrested permanently outside the uterus, especially in the Fallopian tube, it experiences during the full six weeks of its existence so much difficulty in obtaining nutrition by osmosis that it is compelled to unduly hasten not only the vascularization of the chorionic villi, but also the transmutation of those structures which is the prelude to the evolution of the true placenta. The acceleration of these embryonic changes arouses unduly and hastens the activity of the maternal tissues, hence the capillaries located in the lining of an ectopic gestation sac begin to enlarge earlier and are therefore prone to rupture much earlier than the enlarging endometrial vessels of a normal pregnancy. Thus influenced these capillaries become greatly dilated, and if their extrinsic support is weakened the capillaries may rupture. A portion of this blood may find its way to the external genitals. At other times, by a process of vital thinning, a tubal gestation may invade the broad ligament. The placenta may not be disturbed by this invasion and the gestation proceeds uninterruptedly to maturity in the tube and ligament conjointly. Under such circumstances any external hemorrhage noted will come solely from the vessels of the endometrium. The author has already operated in five cases of full time ectopic gestation, extracting the child in each by abdominal section. In two of these patients there was complete amenorrhea during a period of nine months, in the remaining three external hemorrhage was not an important symptom; it was of infrequent occurrence and of short duration, seldom lasting longer than a few hours.

Surgical Treatment of Fibroid Tumors of the Uterus Complicated by Pregnancy.—J. Vance refers to the statistics of this condition, analyzing seventy-two cases collected from literature, reporting one personal case. His general conclusions are thus summarized: (1) All cases of fibroids complicated by pregnancy should be treated surgically and not obstetrically. (2) Myomectomy should be performed only in such cases found suitable for this operation. It is otherwise dangerous. (3) Cesarean section should be done for all cases of fibroids complicated by pregnancy at term. (4) All cases of abortion or miscarriage which cannot be stopped should be immediately submitted to hysterectomy. (5) All cases in which the size of the tumor, pressure symptoms, or any other cause endangers the life of the mother, should have hysterectomy performed. (6) Craniotomy is bad practice at any time and never justifiable on a viable child. (7) All these cases should be sent to the hospital for observation when threatened with abortion or miscarriage, and likewise all full term cases a short time before term, so that surgical procedure can be undertaken with all the care and deliberation of every day major operations. When the above rules are conformed to, many mothers and children will be saved who are now lost.

Drainage in Operations upon the Biliary System.—H. Lilienthal reports four cases, one recovering. He believes that in chronic, profound obstructive jaundice we should secure gradual drainage and be careful not to too suddenly relieve hepatic tension. If the size and condition of the gall-bladder permits, a simple cholecystostomy should be performed as a temporary measure, making the stoma very small so as to prevent the too sudden relief of tension. The operation for radical cure by whatever means may be necessary should be postponed until the conditions have become favorable. In accomplishing this temporary relief great precautions should be taken to prevent the formation of adhesions which might embarrass the operator at the subsequent step. Gauze packings should be dispensed with, and there should be as little handling of the viscera as possible, using the rubber gloved hand *without* gauze during the manipulations. In infectious cholangitis, drainage as early and complete as possible should be the rule. Here we have to do with an active spreading infection and quick removal of as much of the harmful material as rapidly as possible is desirable. In noninfectious and acute (short of six weeks) jaundice drainage by the natural channel into the bowel with suture of the wound in the duct is the most desirable course to follow. In acute obstruction of the cystic duct with no antecedent jaundice, the removal of the cause will often suffice. If the gall-bladder is distinctly diseased or if there is stricture of the cystic duct cholecystectomy with ordinary wound drainage is the best procedure. When there is a history of jaundice, however, one should continue the incision into the common duct in order to be as certain as possible that the way into the duodenum is clear. Drainage will not be required if there has been obstruction by a solitary non-facetted stone, but if the calculus was soft and friable, perhaps a mass of bile sand, very long continued drainage should be the rule. In chronic jaundice with a small, thick gall-bladder containing no bile, it is best to perform cholecystectomy, explore, and drain. In cholemia from obstructing new growth external drainage of the gall-bladder is the correct procedure for the relief of the icterus. In pancreatitis, even without jaundice, drainage by way of the gall-bladder will often effect an apparent cure.

Journal of the American Medical Association, May 25, 1907.

Medical Legislators of Two Republics.—C. A. L. Reed draws a striking contrast between the proportions of medical men in the legislative bodies of France and the United States. There are ninety-two physicians in the two houses of the present French Congress, the Ninth, elected last year, while in our last Congress, the Fifty-ninth, that has just adjourned, there were only four, one in the Senate and three in the House. The contrast is the more striking when we consider the respective populations of the two countries. France, 38,000,000 in 1900, and the United States, estimating on the basis of the census of 1900, approximately 85,000,000, and still more so when we take into account the number of physicians in the two countries—122,000 in the United States and in France hardly one-fourth of that number. Dr. Reed goes over the list of French deputies and senators and shows how many professionally prominent men it includes and how high they stand in public estimation, judging from the honors they have received. Special notice is given to Drs. Clemenceau and Combes. Our present medical representation in our own Congress, while eminently respectable in quality, makes a very poor showing in quantity as compared with that in France. It would seem, as Dr. Reed says, that the medical profession in the United States is not doing its full duty in these higher activities of American citizenship. A partial list of members in State legislatures is also appended.

Isoagglutination of Human Corpuscles.—L. Hektoen describes the phenomena of human isoagglutination, or the clumping of the corpuscles of one person by the serum of another person. Three classes of persons exist as regards isoagglutination: (1) Those whose corpuscles are not agglutinated by the sera of groups 2 and 3, but whose sera agglutinate the corpuscles of groups 2 and 3; (2) those whose corpuscles are agglutinated by the sera of group 3 (and group 1) and whose sera agglutinate the corpuscles of group 3; (3) those whose corpuscles are agglutinated by the sera of group 2 (and group 1), and whose sera agglutinate the corpuscles of group 2. There are the

three corresponding agglutinins, and others no doubt occur occasionally. Of 76 persons whose blood was studied by Hektoen, 36 belonged to group 1, 26 to group 2, and 14 to group 3. Of the 14 persons in group 3, 6 were without any agglutinin, hence it appears that about 90 per cent. of all persons possess isoagglutinin of one kind or another. There is no striking alteration in the agglutinative grouping of persons with various disease, more particularly pneumonia, typhoid fever, scarlet fever, and advanced pulmonary tuberculosis. That human isoagglutinins are bodies with special affinities for the corpuscles on which they act is evident because corpuscles absorb only the agglutinins by which they are agglutinated. The amount of agglutinin varies considerably in sera from different persons, and corpuscles of the same group vary in their agglutinability by the same serum. Human agglutinins are stable bodies; they resist heating to 60° C. for thirty minutes, pass through porcelain filters, and persist for months in serum kept in the icebox. They are distinct from the isohemopsonins of human serum. Their practical importance is in connection with the determination of the opsonic index and the transfusion of blood. The occurrence of isoagglutinins in human blood suggests a danger in homologous transfusion by causing erythrocytic agglutination within the vessels of the subject transfused. The possible danger can be avoided by selecting a donor whose corpuscles are not agglutinated by the serum of the recipient and whose serum does not agglutinate the corpuscles of the latter; that is, the donor and recipient should belong to the same group and preferably to group 1 or 2.

Typhoid Fever from Infected Milk.—J. V. Shoemaker reports an epidemic of typhoid fever occurring in Philadelphia from infected milk. Over twenty patients from one apartment house were taken with the disease within two weeks. The board of health officials made a thorough investigation of the premises and the sanitary conditions. Inquiries concerning the drinking water were made, and it was found that all the patients used either filtered or boiled water. The food and milk supply was then considered. A culture made from the milk showed the presence of typhoid bacilli. It was found that the same milkman supplied all the apartment and boarding houses from which typhoid cases had been reported. The proprietor and one of his servants were both ill with typhoid; the son was convalescing and was filling the milk bottles from a tank by siphonage, starting the flow by sucking with the mouth at one end of the tube. A culture made from one end of this tube revealed typhoid bacilli. Shoemaker states that he does not know of any other case in which typhoid was transmitted through the saliva.

Thymic Tracheostenosis.—Chevalier Jackson reports the seventh case on record of the cure of "thymic asthma" by thymectomy, the first demonstrated radiographically, and the only one, he claims, in which the mechanical compression pathology was proved by direct tracheoscopic observation during life. He gives his conclusions, in substance, as follows: 1. Friedleben's dictum that there is no thymic asthma is an error. The thymus in this case did compress the trachea sufficiently to diminish and to obliterate momentarily its lumen. Thymic tracheostenosis seems a better name for these cases. 2. The dyspnea in this condition is worse in the erect position, and it is expiratory, as might be expected from the increased intrathoracic expiratory pressure and as demonstrated tracheoscopically in this case. The mechanism of this was demonstrated by the flopping out and in of the elevated gland before it was severed. 3. A radiograph is a valuable diagnostic aid. 4. An absolutely positive diagnosis can be made with the tracheoscope. Upper tracheostomy is probably not safe in these cases. Tracheostomy should be done under infiltration anesthesia and should be high, so as to be as far away as possible from the thymectomy wound. 5. A long tracheal cannula, reaching to within a centimeter of the bifurcation, renders the breathing free and the operation of thymectomy safe from risk of asphyxia. 6. The thymectomy is indicated and is best done by the insertion of the little finger from above downward, behind the sternum through a transverse incision, after double sternocleidomastoid tenotomy. The insertion of the finger should be of brief duration, as, though there is no danger of asphyxia, there seems to be serious cardiac inhibition, probably from compression of nerves about the esophagus. Care should be taken not to injure the pleura. 7. An almost complete thymectomy is without effect on either the blood or nutrition. The article is illustrated.

The Lancet, May 11, 1907.

Paratyphoid Fever Following Removal of an Ovarian Cyst.—A case is reported by W. Thyne whose patient was a woman of 38 years, from whom an ovarian cyst was removed, the pedicle being doubly twisted and there being omental adhesions. About two weeks after operation her temperature began to rise and she entered on what was apparently a typhoid stage, there being pea-soup stools and rose-colored spots. No enlargement of the spleen could be detected. No cause for these symptoms could be traced to the operation. The serum did not show the reaction characteristic of typhoid fever, but with certain strains of paratyphoid cultures (though not with all the strains employed), reaction was sufficiently definite to lead to the diagnosis stated above. The author says that if in such cases a diagnosis of typhoid is positive, and the treatment is as customary, no harm results, but when reaction to the Widal test is repeatedly found to be negative, and the case runs a mild course, the diet may be less restricted than it should be, disinfection may be neglected, and disastrous results may follow. He adds that it is only by a bacteriological examination of the blood that typhoid and paratyphoid can be distinguished.

Perforation in Typhoid Fever in Relation to Blood Pressure.—Five cases are summarized by A. L. Sheppard, who tabulates the prominent symptoms. It appears that the pulse rose in 4, and in one was the only marked feature. Peritoneal symptoms were diagnostic in one, while some pain was present in all. The temperature rose in 3, but fell later. Leucocytosis was marked in one, but other signs made the diagnosis of perforation unmistakable. The blood pressure was in no instance the only sign. The author's general conclusions are that the rise of blood pressure is not as certain a diagnostic guide, as some authors have claimed. The signs of perforation, however, are notoriously uncertain, and in no case of typhoid fever, with fairly sudden abdominal pain, combined with any one well-recognized sign (providing there is no other ascertainable cause), should we hesitate to diagnose a perforation. Among these signs should certainly be placed a rise of blood pressure. It seems quite as constant as leucocytosis, and is certainly more easy to observe and chart throughout the course of the disease. A disadvantage that may arise is that owing to restlessness it may be impossible to make an accurate estimation. It will not be common to meet with cases in which violent hemorrhage occurring with perforation renders the pulse imperceptible. In any such case, however, the seriousness of the condition is obvious and the loss of the knowledge of the blood pressure immaterial. All the author's estimates were taken with Martin's modification of a Riva-Rocci sphygmomanometer. In the diagnosis of perforation we must remember that the signs are nearly always most marked about two hours after the accident has occurred, after which they are usually found to return to their previous conditions, and consequently impressions likely to be made on those who see the case at a later stage are often liable to be misleading. The change in blood pressure is no exception to this rule, as the tendency seems for it to fall again to its original level as rapidly as it has risen. In conclusion, one may generally regard, says the author, a rise in blood pressure as positive evidence of perforation, although a stationary pressure is no sign that the perforation has not occurred.

Status Lymphaticus.—L. Vintras discusses the history of this symptom-complex in medical literature. The lymphatic diathesis is not easy to determine. It occurs mostly among tall, rather sparsely built subjects, with fair, clear skins, rather pale, but not with the dead-white pallor of anemia. These patients are of a slow sedentary habit of life, are highly intelligent, self-concentrated, and retiring among strangers. They are very sensitive to climatic influences and they feel the cold keenly. In appearance they are listless and careless, and give the impression of being indifferent to things in which inwardly they are greatly interested. They are emotional, but suppress their emotions. Their fits of anger are concentrated and they are still and turn to a death-like pallor, where others flush red and fly into a passion. There is nothing about them of the spasmodic excitability of the nervous temperament, nor of the hopefulness of the tuberculous temperament. Their pulse is usually slow, sometimes very slow, averaging as low as 45 to 50; but under the stress of worry or emotion their pulse-rate will rise to above 100 and remain so for days and even weeks without any apparent ill effects. It is the same with the heart beats, and it is this which constitutes one of the chief dangers of this condition. Under some strong emotion, but often without any cause, the ratio of the heart beats will double or treble, not in the irregular way, typical of nervous palpitations, but with a steady rise, the heart maintaining a perfectly regular but highly accelerated action. The author believes that in these cases the flabby walls of the heart become suddenly dilated and as suddenly return to their former state. It is quite comprehensible that during

such a paroxysm any interference with the nerve centers may cause the dilated walls of the heart to cease contracting. He thinks that this accounts for many cases of sudden death where no adequate pathological lesion seems to exist. In such patients all catarrhal inflammations are apt to drag on for weeks. Gonorrhea degenerates into gleet and after a long time may clear up or eventuate in joint troubles. Pleurisies are obstinate and the pleuræ exudate will return again and again. Slight injuries may lead to cold abscesses of a size out of all proportion to the cause. Such patients are, on the other hand, less liable to neurotic and tuberculous affections. They have a distinct tendency to improve with advancing years.

The Opsonic Index to Various Organisms in the Sane and Insane.—This subject is discussed by C. J. Shaw, who considers the question with special reference to the results produced by injecting tuberculin. After detailing his experiments, he offers the following conclusions: (1) As the insane are particularly liable to tuberculous infection a comparison of the average indices recorded in the sane and insane and also in the various classes of insane patients would indicate that the opsonic power of the blood serum can be used as a measure of liability to infection and that a low opsonic index precedes infection. (2) The injection of a small dose of tuberculin T. R. in healthy persons produces no negative phase to the tubercle bacillus and therefore may be used as a method of diagnosis. A smaller dose of tuberculin will, however, produce a negative phase in a predisposed person than in one less liable to tuberculous infection. (3) To determine the value of a negative phase after injection the daily variation in opsonic power as well as its level at the time of injection must be estimated. For this reason a number of consecutive observations are necessary; a single, or a number of isolated observations is not sufficient. (4) The average opsonic indices of healthy individuals vary little in different organisms. (5) The injection of a large dose of tuberculin even in healthy individuals causes a fall in opsonic power to other organisms than the tubercle bacillus. This explains the liability of tuberculous cases to secondary infection. For purposes of differential diagnosis by the production of a negative phase a very small dose must be administered. (6) Large doses of tuberculin can be injected into healthy persons without producing constitutional symptoms. Amount of dose may therefore be a matter of diagnostic significance, as a small dose causes a reaction in infected cases.

British Medical Journal, May 11, 1907.

Vicious Circles.—J. B. Hurry defines a vicious circle as a morbid condition in which cause and effect are so correlated that cause becomes effect and effect cause. Morbid processes are often but exaggerations of physiological ones. A healthy cycle is shown in the processes of hemogenesis and hemolysis by which the adjustment between the birth and destruction of the blood cells is effected. Vicious circles are grouped, according to the author, into 1. Organic: An example is seen in acute pneumonia. Dilatation and consequent heart failure are one of the chief dangers, being caused by the increased resistance in the solidified lung. This retards the circulation through the lung, hence throwing more work on the heart, which is already impaired. 2. Symptomatic: *e.g.* pulmonary hemorrhage sets up coughing; result of cough is increased hemorrhage. 3 Infective: Frequently in pulmonary tuberculosis the patient inoculates himself afresh with sputa from the primary tuberculous lesion. 4. Neurotic: In neurasthenia protracted and uncontrolled repose may set up a vicious circle by so deranging the digestive system and affecting the general health that all inclination for physical and mental exertion vanishes. 5. Chemical: A chemical vicious circle occurs in diabetes mellitus, in reference to the two important conditions of polydipsia and polyuria. The polydipsia leads to dilution of the patient's blood, and thus promotes the excretion of sugar and the associated polyuria. The polyuria, on the other hand (by depriving the system of a large quantity of fluid), leads to greater concentration of the blood, and consequently to thirst and polydipsia. 6. Mechanical: A retroverted gravid uterus becomes so impacted in the pelvis as to press on the urethra and cause retention of urine. The distended bladder increases the retroversion and the impaction; the retroversion increases the retention. Similar effects may be produced by myomata or other pelvic tumors. In ascites pressure on the renal veins may lead to ischuria, which in turn aggravates the ascites. 7. Artificial: Alcoholism frequently induces anorexia. This is followed by exhaustion and tempts the victim to seek relief in further indulgence. Again, a miserable home drives a laborer to the public house and to alcoholism, with the result that he has less money than before to maintain his home, which consequently becomes still more miserable. In the case of chronic poisoning of infants by opiates, the child, when not under the influence of the sedative, is irritable and sleepless. Hence the mother finds an excuse for continuing the drug, and the vicious circle is complete. 8. Spurious: A so-called vicious circle is occasionally met with after the operation of gastroenterostomy, when the contents of the afferent end of the jejunum (that is, the segment above the artificial opening), instead of passing into the efferent segment, return through the artificial opening into the stomach and set up regurgitant vomiting. Or the contents of the stomach may pass into the afferent loop and back into the stomach instead of escaping through the efferent loop. A "short-circuiting," in fact, takes place, leading to grave difficulties for which a complementary enteroenterostomy may be required.

Differential Diagnosis Between Ménière's Disease and Other Cases Exhibiting Ménière's Complex of Symptoms.—This subject is considered by T. W. Parry who makes some observations on the practical value of the seton in both conditions and reports one case illustrating the excellent results following the use of the seton in the latter condition. True Ménière's disease occurs in subjects with a normal auditory apparatus, has a sudden onset of symptoms, and auditory nerve deafness. Simulating states occur in patients with previously affected auditory apparatus, and have a gradual onset of symptoms, while deafness is not essential and, if present, is not at the outset of nerve origin. Both states present vertigo, tinnitus, and vomiting. Differential diagnosis, therefore, is established on two points: (1) Examination of the history of the case (whether onset of symptoms is sudden or gradual), and (2) by the tuning fork (whether deafness is of nerve origin or otherwise). The author would make two classes of the causes giving rise to Ménière's symptoms: Class I. Primary Labyrinthine Lesion or Irritation.—(a) An acute exudation or sudden hemorrhage into the labyrinth. This is the "(true) Ménière's disease" of all authors. (b) Chronic labyrinthine lesion, not due to the above causes. The causes of the cases of this class are usually obscure. This is the "Ménière's disease" of some authors and the "Ménière's symptoms" of others. Class II. Secondary Labyrinthine Source of Irritation.—In this class of cases labyrinthine disturbance is produced by extralabyrinthine causes. They are chiefly tympanic in origin. This is the "Ménière's symptoms" of all writers. The use of the seton is highly commended by the author.

Carbolic Acid Gangrene.—Nine cases are summarized by D. Wallace, all following common injuries with carbolic dressings, generally one in twenty strength of solution. In all the original injury or sepsis was trivial in degree. The appearance of the gangrenous part in such cases is characteristic. The skin at first is dry, wrinkled, and grayish-white in color; later it becomes darked and more shriveled. At the junction of the living and dead tissue there is some hyperemia, and eventually a line of demarcation forms. As it is difficult to tell how much is actually destroyed, it is proper to wait for the line of demarcation before amputation is performed. In no one of the cases the author has seen has there been any swelling of the proximal part, but such swelling has been described in some cases. The condition is, as a rule, similar to a typical case of dry gangrene. Various explanations have been given as to the occurrence of gangrene under the conditions mentioned. It may follow the use of solutions as weak as one or two per cent strength. It has been suggested that some individuals have an idiosyncrasy, and are locally much more susceptible to the hurtful action of carbolic acid than others, and that in them stasis followed by thrombosis occurs more readily, and gangrene results. It is the fact that the portion which becomes gangrenous is generally a terminal part of the body—for example, a finger or a toe. That age, sex, or the physical condition of patients do not apparently influence the production of the condition is seen when we note that it occurs at any age, in either sex, and in those who are in perfect health. Patients should always be warned that carbolic acid is a dangerous substance and personally the author deprecates its application of such a dressing to a finger under any circumstances.

Berliner klinische Wochenschrift, May 6, 1907.

Streptococcus Erythema and Its Relation to Scarlet Fever.—Gabritschewsky, who has been experimenting with vaccines prepared from streptococci from cases of

erysipelas and scarlatina, believes that a good deal of evidence exists in favor of the view that the streptococcus is the specific causative agent in scarlatina. He has found that in septic infections streptococci produce scarlatina like rashes and that vaccines prepared from scarlatina streptococci are also able to evoke similar scarlatina-like exanthematous eruptions. The punctate rashes in scarlatina and those resulting from the streptococcus vaccines may be regarded as belonging to the class of infectious, toxic dermatides and as being identical in nature. He also is of the opinion that the fact that in man punctate eruptions with all the other symptoms characteristic of scarlatina may be evoked by vaccines made from the scarlatina streptococcus forms an important and decisive factor in favor of considering the streptococcus as the causative agent of the disease. Accordingly he recommends a further application of streptococcus serum therapy and streptococcus vaccination not only for the complications, but also for the underlying process in scarlatina.

Münchener medizinische Wochenschrift, April 30, 1907.

Observations on the Excretion in the Urine of the Agglutinins in Typhoid Fever.—Hoesslin, in an attempt to gain some information regarding the source of manufacture of the agglutinins, investigated the agglutinating power of the urine in a number of typhoid patients. In fourteen cases the kidneys of the patients appeared to be intact, while in ten others there were complications referable to disorder of these organs. As a result of the tests of the agglutinating power of the urines obtained from these two sets of patients it appeared that healthy kidneys are impervious to agglutinins, for the urines that contained no albumin were found to be without agglutinating power. On the other hand, agglutinins seemed to pass through the diseased kidneys together with the albumin, for the two were found associated in approximately relative proportions. These clinical results were substantiated by animal experiments in which artificial nephritis was induced in immunized rabbits. The author further concludes that the excretion of agglutinin is without effect on the quantity remaining in the body and that the amount lost in this way is constantly replaced. It also appears that the gradual disappearance of the agglutinins occurs within the body itself.

The Interrelationship of the Diazo Reaction, Bacteriemia, and the Widal Reaction in Typhoid Fever.—Genken contributes an article in which he discusses the significance of the chronological element in the occurrence of these three phenomena in the course of typhoid fever, and bases his conclusions on a series of cases which were investigated with this end in view. He concludes that the diazo reaction and bactericmia run a parallel course in cases of typhoid in which no drugs have been used that conflict with the appearance of the diazo reaction. This reaction occurs only in that period of the disease during which bacilli are present in the blood. The elimination of the bacilli from the blood or their complete agglutination leads to a decrease in the diazo reaction and its ultimate complete disappearance in spite of the fact that the fever continues and the patient exhibits the picture of the typhoid state. At the same time the Widal reaction, which represents antagonism to the bacteriemia, is increasing in intensity. If such drugs as salol or calomel are used the occurrence of this parallelism between the diazo reaction and the bacteriemia is not noted since these agents interfere with the development of the reaction. The author suggests that these considerations may lead to an advance in our knowledge of the nature of the diazo reaction, which at present is very fragmentary.

Deutsche medizinische Wochenschrift, May 2, 1907.

The Diagnosis of Subphrenic Abscess.—Determann says that in spite of the efforts that numerous clinicians, such as Leyden, have made to facilitate the diagnosis of this condition, cases occur in which the means at our disposal do not suffice and errors in differential diagnosis are made. He relates one such case in which the diagnosis of right sided empyema was made and at a thoracotomy a large amount of pus was evacuated. The patient died of gradually increasing prostration, and at the autopsy it was discovered that the operation wound had really been carried through the diaphragm and a large subphrenic abscess communicating with an abscess of the liver had been opened. Determann, in view of this experience, recommends that in every case in which the percussion sound undergoes a very gradual transition from pulmonary resonance to extreme dullness or flatness, or in which exudate is obtained from exploratory puncture only in the lower part of the thorax and at a relatively great depth, the possibility of a subphrenic collection of pus must be considered. If this doubt exists the position of the diaphragm should be ascertained by means of a radiograph, and the conical form of the diaphragm shadow observed in cases of subphrenic abscess through the pushing upward of the diaphragm be looked for.

Anguillula Intestinalis Associated with Chronic Diarrhea.—Trappe discusses at length the characteristics of this parasite as well as the views that have been held concerning its pathogenicity. Formerly regarded as the cause of the so-called Cochin-China diarrhea from which the French soldiery suffered, it was later considered to be a harmless parasite. More recently, however, the tendency seems to be once more to accord to it a certain degree of pathogenicity, though the question is still in an unsettled state. In Trapne's own case the patient was a man of thirty years, a native and resident of Silesia, who had always been well until about six months previously, when he developed an obstinate diarrhea which was refractory to all treatment. The stools contained large numbers of *Anguillula intestinalis,* but no other cases of the disease had been reported in the district. Under the administration of astringents the number of parasites in the stools gradually diminished and the stools themselves became less frequent until the patient was enabled to return to work. While even in this case there is no definite proof of the pathogenicity of the parasite, the author considers that it is justifiable to regard it as the cause of the patient's intestinal disorder.

French and Italian Journals.

Colopexy.—Ch. Lenormant considers colopexy the best operation for restoring a prolapsed rectum to its normal position and function. The rectal prolapse must be reducible, otherwise resection will be necessary. The operation consists of reducing the prolapse and then fixing the intestine to the abdominal wall or side of the pelvis. In some cases the intestine is opened to allow of entire rest to the rectum, at the same time that it is fixed, and the artificial anus is afterward closed. Two of the principal factors in the descent of the intestine are the insufficiency of the perineum and abnormal depth of Douglas' cul-de-sac. To make the operation successful the adhesions created with the abdominal wall must be strong and durable. When attached to the side of the pelvis the position of the rectum is more natural and the adhesions are stronger. A long incision is made in the left iliac fossa parallel to the crural arch, the intestine is drawn up so as to reduce the prolapsus; the lower portion is brought up to the incision and fixed to the sides of the wound, including the aponeurosis of the iliac muscles. The peritoneum is opened so as to attach the intestine to the inner side of the ileum. The wound is then closed. In the female with prolapsus of the uterus hysteropexy must be done at the same time. The immediate results of the operation are excellent, it is easy to execute, and mortality is nil. There is recurrence in about twenty-five per cent. of the cases.—*Revue de Chirurgie,* February 12, 1907.

Experiments with Colloidal Mercury.—G. Astolfoni has experimented to ascertain the toxic action of colloidal mercury, its mode of elimination, and localization in various organs. The author finds that the poisonous dose is less than for the other forms of mercury. In whatever way it is administered it is eliminated by the feces and in small quantities by the urine. It is very soon found in the feces and appears for from six to eighteen days after administration. Post mortem the metal is found localized in the liver, kidneys, intestinal walls, spleen, heart, and lungs. There is little difference due to the different modes of administration. It is not found in the bones.—*La Riforma Medica,* February 16, 1907.

Catalysis of Hydrogen Dioxide in the Presence of Blood.—Eduardo Filippi opposes the belief that the action of the hydrogen dioxide on the blood of different animals may be used as a means of distinguishing the blood of different animals when found on fabrics. He has made extensive experiments with reference to the value of such tests and finds them valueless. Human blood is a little more active in decomposing hydrogen dioxide than that of the lower animals, but the differences are so slight and inconstant that no reliable information can be obtained in this way. Fresh blood is a little more active than defibrinated blood, or that taken post mortem. Fibrin preserves the decomposing power for a long time, as does serum. Hemoglobin has no such effect. Heating destroys this power in blood and all its solutions. Diluting blood with distilled water and evaporating it gives a material that has the same activity as fresh blood. If mixed with common salt before evaporation the decomposing power is lost. Any piece of cloth will decompose hydrogen dioxide as easily as blood itself, and for that reason the test with cloths is valueless. It is useless to attach any medico-legal value to these tests.—*Archivio di Farmacologia Sperimentale e Scienze Affini,* December, 1906.

Book Reviews.

THE PRACTICAL MEDICINE SERIES. Under the General Editorial Charge of GUSTAVUS P. HEAD, M.D. Volume IX. ANATOMY, PHYSIOLOGY, PATHOLOGY, DICTIONARY. Edited by W. A. EVANS, M.S., M.D., ADOLPH GEHRMANN, M.D., and WILLIAM HEALY, A.B., M.D. Series 1906. Chicago: The Yearbook Publishers, 1906.

THE chief attraction in this present volume is the section on pathology and bacteriology. This part of the book is full of most interesting and practical information as to recent advances in these fields. The general practitioner can do nothing better, if he wishes to be up to date on these themes, than read this very concise summary. Here will be found much information concerning the newest methods of examining the blood, the urine, etc., and concerning Wright's opsonic index. The sections on antitoxin and physiology and the list of new words are also valuable. Altogether this volume forms one of the most interesting of this excellent series.

PLASTER-OF-PARIS AND HOW TO USE IT. By MARTIN H. WARE, M.D., Surgeon to the Good Samaritan Dispensary, etc. Surgery Publishing Co., N. Y., 1906.

THIS is an excellent little book which contains within a limited number of pages all that is necessary to know about the use of plaster-of-Paris. There are many uses to which this medium may be put, but the references to its use are scattered throughout the literature and not available for reference. The entire subject is discussed from the making of the plaster bandage, a most important item, to the construction of every form of splint, corset, or dressing. There is also a chapter on the use of plaster in dentistry. The illustrations have been specially made in most instances and are on the whole excellent.

THE PRACTICAL MEDICINE SERIES. Under the General Editorial Management of GUSTAVUS P. HEAD, M.D. Vol. X. SKIN AND VENEREAL DISEASES. NERVOUS AND MENTAL DISEASES. Edited by W. L. BAUM, M.D., HUGH T. PATRICK, M.D., and WILLIAM HEALY, A.B., M.D. Chicago: Year Book Publishers, 1906.

IN this, the last of the series of ten volumes comprising this annual publication, the reader will find an abundance of material on the specialties indicated in the title. In the first part of the book much space is devoted to urethritis and to syphilis. In the second part, devoted to neurology, the general practitioner will find much that he could get otherwise only by consulting the special journals and monographs devoted to this line of work. Barring some misprints and some necessary inelegancies of diction which have crept in as the result of the effort to condense the matter into the space of this volume, the book is an excellent example of a short and useful summary of a year's progress in two very distinct lines of medical science.

A TEXTBOOK OF DISEASES OF WOMEN. By J. CLARENCE WEBSTER, B.A., M.D. (Edin.), F.R.C.P.E., F.R.S.E., Professor of Obstetrics and Gynecology in Rush Medical College, in Affiliation with the University of Chicago; Gynecologist to the Presbyterian Hospital and Central Free Dispensary; Consulting Gynecologist to the Passavant and St. Anthony's Hospitals, Chicago. Philadelphia and London: W. B. Saunders Company, 1907.

THIS is a very large book, too large to be used with any comfort unless one has a conveniently-placed book-rest to support it. It is of large octavo size, with 712 pages of thick paper and ten plates of thicker paper. It is too bad the book could not have been divided into two volumes of convenient and portable size, for it contains so much of value that it is a pity for readers to be frightened away by the bulkiness of the tome. The publishers have also sacrificed the author's text and his illustrations by printing the book on such highly glazed paper that it can be studied, especially at night, only by those whose love for knowledge outweighs a prudent care for vision and ocular comfort. Dr. Webster's part has been done wonderfully well. It may be asked of what use is another book on gynecology, but the same doubt might be expressed regarding the utility of new books in any other branch of medicine; they are all covered and covered well; still it does no harm to get a new point of view. That is what the reader of this volume will get—at the same time that he gets a headache from the glare of its shiny pages. The author protests against the notion that the pelvis constitutes the whole of woman, and insists upon regarding woman and her diseases through a lens of wider dispersion, taking into account various physical and psychical facts independent of the local pelvic conditons. In therapeutics he is conservative, and deprecates a resort to new and untried measures when the recognized and proved methods cure the patient. Dr. Webster writes in a pleasant and readable way, and as one assured of his position and with good reasons for his beliefs. A large portion of the book is given to an introductory section on the anatomy of the female pelvic organs. Although this section is well presented and beautifully illustrated, it is not essential to a treatise on the diseases of these organs, and its omission would have very materially lightened and shortened the book.

The illustrations are numerous and beautiful—372 pictures in the text and 10 colored plates. When one looks at them one almost forgives the publishers for spoiling his pleasure in the text in order to enhance that caused by the soft halftone pictures.

A TEXTBOOK OF PATHOLOGY. By ALFRED STENGEL, M.D., Professor of Clinical Medicine, University of Pennsylvania; Physician to the Pennsylvania University, and Philadelphia Hospitals. Fifth Edition. Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, 1906.

IT is about eighteen months since the fourth edition of Dr. Stengel's work appeared, yet in the present edition the book has undergone quite extensive revision. The chapters on Inflammation in the Diseases due to Bacteria, and in those caused by Animal Parasites having received especial attention. The book is well adapted to the use of students, as it is of convenient size, is well, though not profusely, illustrated, and the text is amply descriptive, the author not taking a positive stand in cases in which opinions differ, preferring to state the case and the arguments in favor of the different views, and not forcing the reader to adopt any of them. In addition to the illustrations in the text, three hundred in number, some printed in colors, there are twelve chromolithographic plates. The book has proved its value as a textbook of pathology—up to date, well written, and interesting.

A MANUAL OF NORMAL HISTOLOGY AND ORGANOGRAPHY. By CHARLES HILL, Ph.D., M.D., Assistant Professor of Histology and Embryology at the Northwestern University Medical School, Chicago; formerly Professor of Zoology, University of Washington. Illustrated. Philadelphia and London: W. B. Saunders Company, 1906

THIS is a handy little volume for the elementary student or for rapid reference in the classroom or laboratory for the beginner. The author has laid especial stress and devoted much space to the teeth and oral cavity. He has, perhaps, carried this feature of the manual so far as to lay undue emphasis upon its importance, and yet the subject is no doubt one which is neglected in most textbooks. Considering the nature of the work, the text is readable and, as the author intended, intelligible even to a beginner.

TROPICAL MEDICINE. With special reference to the West Indies, Central America, Hawaii, and the Philippines. Including a General Consideration of Tropical Hygiene. By THOMAS W. JACKSON, M.D., Lecturer on Tropical Medicine, Jefferson Medical College, Philadelphia; Member of the American Society of Tropical Medicine; Lately Captain and Assistant Surgeon, United States Volunteers. One hundred and six illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

THIS is, so far as we know, the first publication by an American author treating of Tropical Diseases; and it deals with such diseases as are found within the boundaries of the United States and its possessions. The volume commences with an interesting introductory chapter on Tropical Hygiene. This is followed by Part I, in which are discussed the Systemic Diseases—Cholera, Beriberi, Plague, Dengue, Tropical Dysentery, Leprosy, Malarial Disease, Malta or Undulant Fever, and Yellow Fever. Part II treats of Animal Parasitic Diseases, with chapters on Ankylostomiasis, Filariasis, Trypanosomiasis, Bilharzia Disease, and Schistosomum Japonicum, Endemic Hemoptysis, Guinea Worm Disease, Liver and Intestinal Fluke Worms, Intestinal Cestodes, and Nematodes. The last fifty pages are devoted to Diseases of Undetermined or Uncertain Causation, and Skin Diseases. Under this heading will be found short chapters on Acute Febrile Icterus, Febrile Tropical Splenomegaly, Tick Fever, Epidemic Dropsy, Tropical Ulcer, Yaws, Tropical Sloughing Phagedena, Mycetoma, Climatic Bubo, Anthum, Goundou, and Skin Affections. The book contains a useful list of books and papers dealing with the subjects under discussion, and due acknowledgment is made of the author's indebtedness to the writings of previous workers in this field. The work is well written, well printed, and sufficiently illustrated; and it should prove useful to all physicians in the Southern States, Cuba, Porto Rico, and Hawaii, and the Philippine Islands.

Society Reports.

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Third Annual Meeting, Held at Washington, D. C., May 6, 7, and 8, 1907.

(Special Report to the MEDICAL RECORD)

(*Continued from page 834*)

SURGICAL SECTION.

Tuesday, May 7—Second Day.

DR. W. S. HALSTEAD OF BALTIMORE IN THE CHAIR.

The Treatment of Surgical Tuberculosis by Hyperemia (Bier).—Dr. V. SCHMIEDEN of Bonn, Germany, said that he appeared in Dr. Bier's stead, in order to speak about the treatment of surgical tuberculosis by means of hyperemia and to demonstrate the technique. He said that Professor Bier's treatment of inflammatory processes was in marked contrast to that of previous teaching, in that this treatment did not combat the infection, but rather increased the normal reaction of the part. Bier increased artificially the redness, swelling, and heat, and these cardinal symptoms of infection were none other than the natural weapons of the organism. If Bier's teaching was founded upon facts, then must its practical application be brought into surgery. Since Bier's investigations they no longer suppressed the inflammation; rather they increased it. At first Bier found real difficulties only in the technique. He discovered that they must use the blood for increasing the inflammation. Therefore, he augmented the hyperemia and, at the same time, decreased the flow of blood, which was already decreased in every inflammatory process. This was the clear train of thought which gave rise to this treatment by hyperemia. Tuberculosis, especially tuberculosis of joints, was the first disease which Bier treated with his hyperemic band. To-day this band was used in many other diseases. One took a broad (6 cm.) soft rubber bandage, applying it slowly and evenly around the extremity, centralwards from the tuberculous joint, but not too close to it. Each turn overlapped the other. The bandage must not cause pain either at the place of application, or in the diseased joint. The extremity began to swell in a moderate degree and assumed a bluish-red color, it remained warm, at least as warm as the other limb, and the pulse remained entirely unchanged. They had no stoppage of the blood current, but an increase in its volume due to a diminution of its flow. This simple technique was often poorly practised. The hyperemic bandage was applied in tuberculosis only for a few hours per day. They applied it from one to four hours in the following manner. Once for an hour or once for two hours, or twice for two hours. If the skin was tender, its location was changed. During the hyperemia they removed all other bandages and over discharging fistulæ placed sterile gauze or a towel. A pressure bandage of any sort would render the hyperemic treatment impossible. Further, one should not have the joint in fixation. The tuberculous joint must be movable after the disease had healed. Bier stated that a stiff joint following healing of tuberculosis was not a good result. The treatment by hyperemia had a high purpose, the maintenance of mobility, an anatomic healing. It was possible to restore the function of a joint in which the disease had progressed so far as to cause changes in the bone and cartilage with the formation of multiple fistulæ. Properly applied hyperemic treatment resulted first in the abeyance of the pain; this was a certain proof of the proper technique. Inflammatory contractures soon disappeared, and active as well as passive movements were again possible. The old teaching, fixation of tuberculous joints, had been pushed aside by Bier. They believed that it was often not the tuberculosis which caused ankylosis, but the improper and overzealous treatment which prevented movements of the joint. It was evident that Bier had revolutionized the treatment of surgical tuberculosis. Naturally, vigorous movements of the joint should be avoided; the point was, through experience, to find the "happy medium" between rest and action. During the course of the treatment other symptoms and signs disappeared, namely, the swelling subsided and the large fungus masses were transformed into hard connective tissue, which by further hyperemia treatment were absorbed. The contour of the bones also again became distinctly visible. In fact, the mobility of the joint became better and better; also, the tuberculous fistulæ, even though they extended into the joint or bone focus, healed; this proved the healing power of the hypermia. But not always did these cases run such a favorable course; often cold abscesses occurred, and with their evacuation much necrotic tissue came away. The better the technique the less often these abscesses occurred, and when they did occur they should be recognized early. Cold abscesses, according to Bier, were processes by which the organism cast off the tissue incapable of healing. In any case, when they did occur one should not interrupt the treatment. This treatment was applicable to nearly all cases. It was to be regretted that tuberculosis of the hip joint could not be treated by hyperemia, because of technical difficulties. Hyperemia of the shoulder, however, was applicable. Especially favorable results followed in tuberculosis of the ankle, elbow, and wrist. In consequence of treatment almost entirely by hyperemia, Bier very seldom was forced to resect a tuberculous joint. Together with the hyperemia band they frequently used the cupping glasses which Dr. Schmieden demonstrated on an individual. They used them in all cases of beginning softening and of abscesses, which might or might not have fistulous openings. Every abscess occurring in the process of joint tuberculosis, as well as in the tuberculosis of the soft parts, was opened and without any fear of a mixed infection; the proper application of the cupping glasses prevented such an infection in almost every case. The two results obtained by the proper use of the glasses, namely, hyperemia and discharge from the fistula, tended to avoid a mixed infection. The result is that after evacuating the detritus and pus the discharge became serous, gradually became less and less, and finally the fistula healed. In all cases of open tuberculosis of joints they used both forms of hyperemia. In general the hyperemic band twice an hour, and the cupping glasses forty-five minutes upon the fistulæ. Dr. Schmieden hoped that his remarks would help in introducing Bier's method into America. Its goal was none other than that of healing without loss of function. Bier in his fifth edition of his book, "Hyperemie als Heilmittel," said: "Formerly I considered the hyperemia treatment good; now I consider it the best."

Dr. WILLY MEYER of New York said that he had used this method since Bier published his paper fifteen years ago. A well-known pathologist in Vienna had stated that he never had found a tuberculous lung in cases of valvular heart disease which produced a venous stasis in the lungs, and this was the starting point of Bier's studies. It was to be regretted that the hip joint could not be made subject to this treatment. Dr. Meyer emphasized the point already made by Dr. Schmieden that the patient should not have pain when the rubber band was applied. There should be a hot, and not a cold stasis. Bier's treatment should not be considered a panacea; one should not be too enthusiastic and believe that every case of joint or bone tuberculosis could be cured by this method. There should be in the hospitals a special ward set apart for the treatment of these cases. After relating the histories of two cases in which most marked results followed this method of treatment, Dr. Meyer said that the Bier treatment was a most excellent help in surgical endeavors to cure tuberculosis of bone and joint disease, and should be more extensively tried and should be known by physicians and surgeons alike.

Present Status of the Opsonic Theory and the Treatment of Tuberculosis.—Dr. Rufus I. Cole of Baltimore read this paper. He said that a specific treatment for infectious disease must first have some theoretical foundation based upon at least a little experimental evidence, and secondly, its value must finally depend upon clinical results. In order, therefore, to discuss intelligently the present status of the opsonic theory and its application, they should first inquire as to the relation of this theory to what was already known regarding immunity in tuberculosis. Upon this their present conclusion should largely rest, since the collection of clinical data required a great deal of time and labor, and the method under discussion had not yet received a sufficiently wide application to make such data of conclusive importance. In the cure of tuberculosis one might either try to put the body in such a condition that a slight balance in its favor may occur, or one might attempt the production of a very high grade of immunity to the bacillus or its products. The former was what they probably did by rest and fresh air, and possibly by the aid of tuberculin. If they could, however, certainly induce this artificially by the proper use of the bacillus or its products, they would at least have partially solved the tuberculosis problem. This was what Wright claimed to have done by the method which bore his name. The ideal condition, of course, would be the production of a fairly high degree of immunity, sufficient to quickly and unquestionably kill the bacteria and neutralize their effects. In tuberculosis this attempt had been made by the effort to produce active or passive immunization to the bacilli, or to their products. Theoretically, the bacillary emulsion offered the most suitable medium to use in order to produce the most marked grade of immunity to the various activities of the tubercle bacillus. While Koch did not so explicitly state in his paper, he must have had in mind that antitoxic immunity was produced by old tuberculin, bactericidal immunity by new. Being convinced that the opsonins did really represent immune bodies, it was next important to determine (1) whether they played any part in tuberculosis immunity; (2) was the technique for their quantitative estimation sufficiently accurate for them to detect slight grades of difference; (3) what was the clinical value of Wright's method of treatment with T. R. tuberclin; (4) what were probably the best methods for producing a high grade of opsonic immunity in tuberculosis. They might conceive that even if it should be shown that the opsonins played little part in tuberculosis immunity, the opsonic index might form an accurate and suitable guide for controlling other immunization processes. Theoretically the most suitable cases for treatment with tuberculin would seem to be those cases of localized tuberculosis in which the presence of secondary infection was unlikely or even improbable. It seemed that the future studies in opsonic immunity in tuberculosis must be along two lines: (1) Experimental, to discover whether opsonic immunity really plays any considerable rôle in tuberculosis, and (2) whether it was possible in any way to produce a high grade of opsonic immunity in this disease. As most investigators have found, and especially as the experiments of Trudeau have demonstrated, satisfactory immunity in tuberculosis had hitherto been obtained only by the use of living bacilli, and whether they were dealing with opsonic immunity or immunity of whatever kind, the successful method would probably be along this line.

Dr. Nathaniel B. Potter of New York said that the technique was extremely difficult, but that, so far as the preparation of the emulsion was concerned, they had been materially aided in New York through the kindness of Dr. Baldwin. Since they had used the little capsules prepared by Dr. Baldwin the emulsion had been invariably constant and uniform, giving excellent results. The emulsion was made with the bacilli killed by heat. He called attention to the fact that there was a variation even in the normals. It was his belief that the leucocytes were not inert.

Dr. G. B. Webb of Colorado Springs said that no mention had been made of the opsonic index as a diagnostic aid. In cases of tuberculous glands the injection of tuberculin was not necessary; if one took the index before and after massage a diagnosis could readily be made. Dr. Webb had had many instances for using the tuberculosis vaccines without the opsonic index and he could quote many cases of tuberculosis, tuberculous cystitis, tuberculosis of the kidneys, of the joints, etc., which had done well without watching the opsonic index.

Dr. John B. Briggs of Washington, D. C., said that he was rather surprised at the lack of Dr. Cole's results; he had followed Wright's method in about one hundred cases and had had surprising results. In many cases he was enabled to correct an apparent error by a careful study of the opsonic index.

Dr. E. R. Baldwin of Saranac Lake said that his experience had been chiefly with the technique and he had had but little clinical experience. He had worked with Wright for several years and he acknowledged the limitations in the technique, saying they were rather wide, and the results had to be interpreted with a good percentage of error. Wright himself did not rely upon the opsonic index. The emulsion Dr. Potter referred to was not difficult to prepare. It was simply a broth culture, washed and sterilized, rolled in a mould with porcelain balls; this muddy mass was then measured off in glass capsules, in which it was sealed. Formalin was added to insure preservation. At present it did not seem that they were justified in recommending it for diagnosis or for treatment in cases of pulmonary tuberculosis, and even Wright himself was not sanguine regarding this.

Dr. Edward L. Trudeau of Saranac Lake said that he had used none other than the clinical method for fifteen years. There seemed to be a great deal of confusion regarding this subject. In using the tuberculin the dose, the intervals between the doses, the size of the dose, all were governed purely by the opsonic index. The question was, Were they going to be guided by the opsonic index, or the tuberculin immunity? Was there any formation of antibodies in the blood? It was the consensus of opinion that, whether they used the opsonic index, or the clinical method, better results would follow the use of the tuberculin if only they knew how to use it.

Dr. Lawrason Brown of Saranac Lake also discussed the paper.

Dr. Rufus I. Cole of Baltimore closed the discussion.

The Advantages and Limitations of the X-Ray in the Treatment of Surgical Tuberculosis.—Dr. Henry K. Pancoast of Philadelphia read this paper. He said that the success of the *x*-ray treatment of tuberculosis, or any other disease, depended upon the experience, common sense, and good judgment of the Roentgenologist, and the close observation of certain cardinal principles which might be enumerated as follows: 1. A reaction of the tissues of the body to the *x*-ray was manifest in those tissues only in which the rays were absorbed. By the use of a proper tube, together with the correct manipulation of the apparatus, the degree of penetration of the greater number of the rays generated could be recognized and controlled. 2. The first effect of radiation upon normal tissues was stimulation, followed by irritation, inflammation, and finally by cellular destruction. 3. The applications should be so administered as to secure that reaction which was necessary or most efficient in obtaining the desired results in the treatment of any disease. 4. In normal tissues the destructive effect was first manifest in those cells which were most highly specialized, as the epithelium of the glands and hair follicles of the skin, and the spermatogenic cells of the testicles. 5. In diseased structures it was first manifest, usually, in those cells which were distinctly pathological, and of a lower vitality than the normal tissue cells. With the knowledge derived from authentic reports, and from personal observations made by every member of the medical

profession [illegible] be not doubting [illegible] favorable [illegible] curative [illegible] upon tuberculous lesions. In the treatment of some of them they might regard this agent almost as a specific remedy; in some manifestations its influence was much less uniformly favorable, while in some of the lesions cures were exceptional or had never been obtained. In comparing the reactions of lupus vulgaris to light and the *x*-ray Dr. Pancoast assumed that the light had far greater bactericidal properties than the *x*-ray, but the latter made up for this deficiency through the greater inflammatory reaction it induced, to the same end, and also through the possibility of a direct destruction of diseased cells. After considering all points of evidence, he thought the decision was decidedly favorable to the *x*-ray in the treatment of lupus, and that it was gradually but surely replacing the Finsen method. The following conclusions as to the treatment of this disease, lupus vulgaris, referred to the *x*-ray only: 1. It had supplanted surgical measures in the treatment of lupus vulgaris, and the latter were now of value only as adjuncts to the *x*-ray. 2. In the treatment of this disease it acted the part of a specific therapeutic agent. 3. The cosmetic results of *x*-ray treatment were, on the whole, superior to those of surgery. 4. Recurrences were less likely to follow *x*-ray treatment, but if they did they were easily controlled. 5. When ulceration was present the *x*-ray treatment might be considered considerably assisted and shortened by partial excision, curettment, or cauterization. 6. It was not always necessary to produce an ulceration of the tubercles, as they might be destroyed without. Nevertheless, a marked skin reaction was usually necessary, and a second degree dermatitis might rarely be necessary, in order to obtain an inflammatory reaction of sufficient intensity to influence the deeper nodules. 7. The undesirable results which might follow *x*-ray treatment were the so-called "*x*-ray burn," permanent telangiectasis, atrophy, and more or less permanent pigmentation. The action of the *x*-ray upon chronic tubercular ulcerations was identical with that observed in lupus. Tubercular sinuses frequently responded well to *x*-ray applications, provided the cause was also removed by the same or other treatment. According to its relation with surgical measures, they might recognize three stages of adenitis in which the *x*-ray was applicable: 1. When the glands were of relatively small size, and had scarcely reached an operable stage. 2. Cases in which the glands were of large size, and in an operable stage. Here surgery would be given the preference. Such cases could usually be improved, and might be cured by the *x*-ray, but the treatment was long, and the enlargement did not entirely disappear as a rule. 3. Cases in which caseation had occurred with or without sinus. These cases were primarily surgical, but the *x*-ray might be employed to great advantage in hastening the healing of ulcers and sinuses, etc., and in producing better cosmetic effects. Literature did not credit the *x*-ray with as much success in the treatment of tubercular laryngitis as he thought was in accordance with its possibilities. In his own experience with a dozen cases he had not failed in a single instance to observe some favorable results. A large number of cases of pulmonary tuberculosis had been reported as cured by the *x*-ray treatment, but these reports must be looked upon with considerable scepticism. Personally he believed that in some cases the *x*-ray applications were capable of some benefit, in conjunction with the usual therapeutic and hygienic measures. In advanced cases it was questionable whether any benefit whatever was to be derived from their application. Tuberculous peritonitis might be and had been favorably influenced by the *x*-ray treatment. He had never seen any favorable results from the *x*-ray treatment of bone lesions, or in tubercular joint lesions. Judging from reports, there was some likelihood of benefit being derived from the *x*-ray treatment of tuberculous orchitis.

Dr. WILLIAMS of Richmond discussed this paper.

AMERICAN SURGICAL ASSOCIATION.

Twenty-eighth Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 839.*)

Thursday, May 9—Third Day.

End-Results Following Operations for Carcinoma of the Breast.—Dr. F. S. DENNIS of New York read this paper reporting a series of fifty cases that had been well at the end of three years, of which thirty-nine were well, though some had had a second operation; five to twenty-five years had elapsed since the operation. Four cases had died of independent causes after having been well three years or more, and seven had died of metastases. In one case there had been a return in the iliac glands after eight years. He considered a ten-year limit for the time after operation before calling the case cured as better than a three years' limit. In one case he had had a recurrence after eighteen years. In one case he had had a recurrence of carcinoma in the opposite breast after eighteen years, which was removed two years ago, and had not reappeared. Another case had sarcoma at the first operation, and fourteen years later carcinoma in the other breast. In the permanent cures most of the cases had been operated on within six months of the incipiency of the disease. He considered that the more radical the operation, within reason, the better the prognosis. He considered the minimum complete operation to include removal of skin, breast, Cooper's ligament, muscle, fat around breast, and axilla. He did not believe in prolonged operations, but he did not think that complete operations should be withheld from any patient.

Prof. E. KUSTER of Marburg, Germany, opened the discussion on the series of papers. He spoke of the anatomy of the breast region and the spread of the disease by the lymphatics, the pathological classification of the tumors as modifying the end results.

Dr. J. E. MOORE of Minneapolis said that surgeons sometimes censure themselves unjustly for the recurrences at the periphery after complete operations. He cited one case where, after complete operation, there had been a recurrence at the end of two years in the periphery in spite of wide skin removal and covering up of the defect by plastic skin flaps. These recurrences were removed, and seven months later there were again recurrences on the new flaps in skin that at the time of the first operation had been over the abdomen and back, and that later lay over just the same spots as the first recurrences. He believed that there had been a deep focus beneath the superficial tissues which had infected both skin flaps, and that it would have been impossible to remove the deep foci at the primary operation, so that the surgeon was not in need of censure.

Dr. J. B. ROBERTS of Philadelphia thought the operations were too limited, and that more cases needed the sacrifice of the arm in order to get outside of the diseased tissue.

Dr. C. B. G. DE NANCREDE of Ann Arbor wished to warn against too implicit belief in the microscopical diagnosis. In one case he had made a clinical diagnosis of sarcoma, and the pathologist had reported carcinoma. A revision of the pathologist's diagnosis had brought out the fact that there were areas in the mass, some of which were typical sarcoma and others typical carcinoma. He would explain Dr. Dennis' case of recurrence of carcinoma after primary sarcoma as a probable primary mixed sarcoma and carcinoma. He would have more extensive examinations of the tumors made by the pathologists.

Dr. A. H. FERGUSON of Chicago said that he did not see how amputation of the arm would save recurrence from glands in the neck. He had only one case in which he had removed the arm on account of involvement of the axillary artery with extensive edema in a case of recurrence after one and a half years. No glands in the neck were found.

The patient had suddenly died on the tenth day after operation, so that no final result could be determined. All of his neck cases had died within two years. He had removed portions of ribs, lung, and sternum in his efforts to get beyond the seat of disease, but all had died. He had had three cases of cancer of the breast in the male, one of whom was alive at the end of fourteen years. In the extensive operations he believed that the patients would live longer and do better with less radical operations.

Dr. T. W. Huntington of San Francisco spoke of the very extensive operations done by Dr. Rixford of his city, who had done several very severe operations on pleura and lung with improvement in the duration of the patient's life. He had done one case himself of interscapulothoracic amputation, and the patient was alive and well nine months after.

Dr. W. B. Coley of New York had had three cases of combined sarcoma and carcinoma. He cited the work of Ehrlich, who from a simple cancer tumor in mice had later produced mixed sarcoma and carcinoma, and still later pure sarcoma, all from injection of the same strain of mouse tumor, but growing under different unappreciated conditions. He did not regard the amputation of the arm as desirable on account of the bad effect it would have in detering other patients with cancer from operation, especially if the arm amputation cases did not recover completely, as they probably would not.

Dr. W. L. Rodman of Philadelphia said that he did not consider the three-year limit of nonrecurrence sufficient, as 15 per cent. had later recurrences. To show that the late recurrences are true recurrences, he deemed it essential to show a coincidence in the nature of the growth, and in absence of this would call them new infections in a person with a predisposition to cancer. In the prognosis the type of the growth seemed very important. He was surprised that Halsted got better results in medullary than in scirrhus growths. He believed that a most essential point in the technique was the extensive removal of the skin. Only in that way could he explain the good results of Gross' operations. Gross had been noted for his dinner-plate incision that had jestingly been called a cartwheel incision.

Dr. S. H. Weeks of Portland, Maine, said he felt he had done a complete operation when he had removed all the diseased tissue. He removed the axillary glands only when he could feel them through a special incision for that purpose. He felt that the fat and the glands had a function to serve and that they ought not to be removed unnecessarily. He thought his position was backed up by the good statistics of the incomplete operation done by Dr. Warren.

Dr. E. Eliot, Jr., of New York reported two cases of late recurrence. In the first a scirrhus nodule had appeared in the old scar after four years. This had been removed, and there had been no sign of recurrence in the two years since. This case he considered a scirrhus degeneration of an old scar and not a recurrence. The pathological diagnosis of the primary tumor was not recorded. The second case was one where there had been a recurrence of a nodule two inches above the old scar seven years after the primary operation. Here the epitheliomatous tissue had a primary focus in the subcutaneous fat, and as there was no normal epithelial tissue in the fat he considered this a true recurrence. In another case five years after the primary operation there had been a reappearance of swelling in the arm without any external evidence of a tumor. At first the condition had been considered a mediastinal recurrence, but though there had been no operation the swelling had disappeared, and had not appeared again in two years, so that it could not well have been a recurrence. In another case there was some persistent obscure lung trouble after the operation, which had first been called a recurrence, but this cleared up on antirheumatic treatment. He did not think that all apparent recurrences were truly such. Unless there is some definite additional risk he saw no reason for not removing the axillary glands in all cases.

Dr. J. C. Bloodgood of Baltimore thought that the most important factor in determining the final outcome was the character of the tumor. In sixteen cases of adenocarcinoma all the subjects were well three years later, but one had died at the end of five years, and one died fifteen years later. In five cases in which the breast only had been removed, four had died and one was cured. Metastases in the axilla were the most common. Of the scirrhus cases none had been cured. Of the mixed scirrhus and medullary a few had been cured. The only cases where recurrences had appeared, and where there had been a cure, were in the cases of adenocarcinoma. The recurrences had occurred in cases where only a small area of skin had been removed so that the wound could be closed by suture.

Dr. B. F. Curtis of New York said that he believed that cells in distant locations existed which had not grown, and which had even retrogressed, and that these explained the very late recurrences.

Dr. W. H. Carmalt of New Haven said that he believed that there were both sarcoma and carcinoma elements in most growths. He reported a case where, after the removal of a myoma (so reported) of the uterus, there had been a recurrence of a sarcoma of the brain, and he associated the two growths.

Dr. N. B. Carson of St. Louis said that while the surgeons recognized the late recurrences of cancers, yet the laity held to three years as the limit of recurrence. That the three years of suspense for the patient was long enough, and that he did not think it wise to lengthen that period of suspense for them.

Dr. S. J. Mixter of Boston said that he believed in a thorough radical operation and that no mutilation was as bad as the horror of having the disease return.

Subcutaneous Rupture of the Spleen.—Dr. Ellsworth Eliot, Jr., of New York read this paper, reporting two cases. The first was a man twenty-six years of age, who fell five stories, fracturing the ninth rib and rupturing the spleen. He was operated on nine hours later, a splenectomy being done. The second case was a woman thirty-four years of age, who fell nine feet. Splenectomy was done there at the end of six hours. Both cases had serous effusions into the left pleural cavity a few weeks after the accident. Among the symptoms Dr. Eliot placed great stress upon the rigidity of the wall of the thorax on the left side at its lower margin, and over the upper portion of the abdomen on the left side, also on the increasing area of dullness in splenic region, as determined by auscultatory percussion. The costal resistance was of great importance to differentiate between rupture of the spleen and fracture of the ribs, as in fracture of the ribs the eleventh and twelfth ribs, being very rarely fractured, would not be rigid, while in splenic injury they would. In the operative treatment pressure of the spleen against the diaphragm by tampon is not permanent, cautery or suture of the wound is rarely adequate, and splenectomy is the best treatment. The choice of incision is one parallel to the left rectus with a second limb along the lower costal margin, and resection of the ribs if necessary. After removal of the spleen clamps are left *in situ* on the pedicle to act as drainage, not only for the splenic portion of the trouble, but also for any possible pancreatic injury that might have occurred at the same time. The objection to the removal of the spleen, that at times it was followed by persistent anemia, was well grounded, but the operation was followed by hypertrophy of the lymph nodes, thyroid, and long bone marrow, which compensated for the loss of the spleen. In animals after splenectomy there was an increased resistance to infection, and there had been reported one case of typhoid in a man after splenectomy, in which the disease ran a mild course. In Dr. Eliot's second case, about a year after the splenectomy, the patient had developed cholecystitis, becoming drowsy and comatose for sixty hours, with an imperceptible pulse, but she had recovered. She had again had pus in

the pleural cavity, which had been removed, with subsequent recovery.

Some Cases of Rupture of the Kidney, with Remarks on Conservative Treatment.—Dr. T. R. Nielson of Philadelphia reported four cases treated by packing and drainage. The first two had a primary laparotomy done, and then, after closure of that incision, lumbar exposure with packing and drainage. The other two cases had the lumbar incision only. Three of the cases recovered, and one died of an incidental complication. All cases of rupture of the kidney were not suited for this method of treatment, but didactic classification was difficult. Where there were only local symptoms, and the diagnosis was made on slight hematuria, expectant treatment was in order; otherwise operative treatment was necessary. The lumbar incision could be used only in the cases where there were no abdominal symptoms. If the organ had been pulpified, or the pedicle torn, nephrectomy must be done. If there were multiple injuries, but still enough sound kidney tissue, to make a possible functionating organ, conservative treatment should be tried. Dr. Nielson placed loops of gauze under the poles of the kidney to support and drain it. In some cases mattress suture of the injuries might be desirable. In some cases, after conservative treatment, a urinary fistula might necessitate nephrectomy.

Primary Sarcoma of the Prostate.—Dr. C. A. Powers of Denver reported a case of enlargement of the prostate in a man sixty years of age, who had had rapidly increasing difficulty in urination for two months. He had no residual urine. The rectal examination showed a large rounded prostate ballooning into the rectum. The mass was uniform in consistency and very large. The urine examination was negative. The perineal operation was accompanied with alarming hemorrhage, the growth being very friable. The upper part of the growth was adherent and could not be removed. The patient died on the fifth day of pneumonia. The pathological diagnosis was small round-celled sarcoma. The writer had collected nineteen additional cases from literature, making twenty, in all of which 12 were in patients under 15 years, four 15 to 30, three 30 to 60, and one over 60. All died either from the operation or from recurrence.

Prostatectomy.—Dr. Archibald MacLaren of St. Paul read this paper, saying that both suprapubic and perineal methods were well established, that he had previously done a combined operation, but that recently he had been doing the perineal operation by a single median incision, the advantage being that it gave better drainage than the suprapubic, and did not give the wide exposure of tissues which Dr. Young of Baltimore advocates. The time necessary for the wide dissection was not compensated for by the slight advantage in the field seen, as most of the work was done by feel. And, again, the saving of the ejaculatory ducts in the old men scarcely compensated for the danger of opening the rectum. He did prefer Young's operation for cancer of the prostate.

Dr. C. L. Gibson of New York said that he could add another case of sarcoma of the prostate to those reported by Dr. Powers; that he had operated on a case that was already septic, and that had died of sepsis three weeks after the operation. In connection with Dr. MacLaren's paper on prostatectomy, he said that he had formerly done a very extensive dissection similar to Young's, but that now he made a median incision in the perineum and quickly shelled out the prostate, seldom taking as long as ten minutes; that he had not had a death in several years; that the average age of his patients had been seventy-two years, and that they were up and out of bed inside of a week.

Dr. J. C. Munro of Boston said that he had had a case of sarcoma of the prostate which had been operated on, but died of recurrence.

Further Consideration of the Surgical Treatment of Cancer of the Head and Neck.—Dr. G. W. Crile of Cleveland read this paper. He said that he put the patient in the head-up position to save hemorrhage and shock, packed and intubated the pharynx to eliminate post-operative pneumonia, and to get the anesthetizer away from the field of operation. He considered that hemorrhage was not only an immediate danger, but that it decreased the resistance of the patient to the cancer. Therefore, he lost the least blood possible, and gave early transfusion. He left the wound open for *x*-ray treatment, which is promptly carried to the point of erythema to get the superficial effect of the *x*-rays, and he felt that these cases had done better than those not treated with the *x*-rays. In regard to the tissues sacrificed, while he did not permanently close either the common or internal carotid arteries (as he feared embolism and had never seen recurrence of the cancer in the sheath of the artery), yet he had not hesitated to excise both jugular veins. Of the muscles, he had removed one or both sternomastoids, omohyoids, sternothyroids, and sternohyoids, and the platysmas, all of which were compensated for by the action of the deeper muscles of the neck. The scar was not complained of if the patient was cured of his disease. Of the nerves, resection of one vagus, one phrenic, or one hypoglossal he had done, but section of any pair was fatal. He had done 150 operations on 139 patients, in which the primary foci had been in various portions of the head and neck. Prior to 1900, when he began this radical work, there had been only 15 per cent. of the cases that had lived more than three years after the operation. Since 1900, 31 cases, 39 per cent., had passed the three-year limit. The operative mortality had been steadily declining. He had lost none of the last 40 cases. He thought the operative results were as hopeful as for cancer of the breast.

Dr. S. J. Mixter of Boston, in discussing the paper, said that he, too, considered the *x*-ray applications to the open wound a very valuable aid.

Dr. J. C. Bloodgood of Baltimore said that he agreed with Dr. Crile in excision of the veins and temporary ligation of the arteries.

Dr. A. Vander Veer of Albany said that he did not object to tying the common carotid artery, and thought that at times it was necessary.

Acquired Diverticulitis of the Colon and Its Surgical Treatment.—Dr. W. J. Mayo of Rochester, Minn., presented this paper in collaboration with Drs. L. B. Wilson and H. Z. Griffin. Dr. Mayo presented five cases, all with the gross appearance of cancer of the colon, occurring in patients forty-five years of age or over, three of them males and two females. In some cases the trouble seemed to start with a sudden attack, like acute peritonitis, and a mass was found in the region of the splenic flexure or sigmoid. In other cases the principal symptoms were those of intestinal obstruction. There were still other cases which had not come to operation in which the symptoms had been mild, but of either type. The treatment in the abscess cases was incision and drainage of the abscess; of the obstruction cases, by resection of the colon. The pathological picture was one of multiple minute diverticuli of the colon, in which the mucous membrane had pouched through the muscular coat, usually at some distance from the teniæ. In one case there was a true diverticulum with a muscular coat outside of the mucous coat of the diverticulum. The other four cases had all been false diverticuli in having only the mucous coat. Many of the diverticuli contained fecal concretions, and these were surrounded by inflammatory tissue forming a dense mass that had passed the pathologist on gross inspection for cancer. In the cases where the diverticuli had allowed their contents to leak out there had been abscess formation. There had been little tendency towards perforation and more to inflammatory infiltration. The single case of true diverticulum had been properly called a diverticulitis, but the other cases had been peridiverticulitis.

The Diverticulum Ilei as a Cause of Complete Intestinal Obstruction.—Dr. F. H. Gerrish of Portland,

Maine, presented this paper, giving the history of a case of intestinal obstruction of four days' duration, in which a diverticulum arising 15 centimeters from the ileocecal valve in the ileum had passed through a rent in the mesentery, become adherent, and caused the obstruction. He did not think the diagnosis possible before opening the abdomen. He considered the diverticulum ilei as one of the gravest dangers, and urged that whenever found, accidentally or otherwise, it be removed.

A Consideration of the Etiology of Certain Cases of Left-Sided Intraabdominal Suppuration.—Dr. G. E. Brewer of New York presented this paper, reporting six cases of abscess in the lower left quadrant of the abdomen closely resembling appendicitis abscesses, even to the finding of fecal concretions in the pus or adhesions, but where the appendix was normal. In four of the cases no exact cause for the abscess had been found, but in two diverticuli of the colon had been found, and as the six cases were all so similar it seemed probable that the other four were also due to diverticuli from the colon. He had found records of eight cases of diverticuli of the colon, one in the ascending portion, two in the transverse portion, three in the descending portion, and two in the sigmoid. In one of the cases 79 pouches had been counted. These pouches were due to pressure from the feces in constipation.

Dr. S. J. Mixter of Boston saw one case of acute inflammation of the sigmoid which was opened before rupture. He had later seen two chronic cases which he considered more common that had been diagnosed cancer and had been cured by cancer quacks.

Dr. E. Eliot, Jr., of New York called attention to the cases of left-sided intraabdominal suppuration that were due to appendicitis, in which the appendix extended across the middle line, and in one of his cases was adherent to the sigmoid.

Dr. Reginald H. Fitz of Boston called attention to the fact that there were in the Warren Museum in Boston several specimens of multiple diverticuli of the colon. He thought that in the cases where patients passed fecal concretions that resembled rabbit dung this condition might be present. Dr. Fitz thought that this was a new disease and that more cases would appear. In connection with Dr. Gerrish's case of diverticulum ilei, Dr. Fitz said that the persistence of the vitelline duct causing a diverticulum was not rare; that most of the cases were harmless, though this diverticulum might be the seat of a typhoid patch or a tuberculous ulcer; that the adhesion of the tip of the diverticulum was the remains of the omphalomesenteric duct, which remained visible in all puppies until three or four days old.

Dr. W. L. Estes of South Bethlehem said that he had understood that the diverticuli of the colon occurred most frequently in adipose people with myocarditis, in whom the blood pressure was low, and that the diverticuli were at points where the blood-vessels, piercing the denser layers of the colon, left weak spots not filled by the vessels when the pressure was so low; that most of the cases occurred at the splenic flexure.

Dr. G. T. Vaughan of Washington, D. C., said that he remembered several cases where he had cut off coproliths with no bad effect, so that if they were in diverticuli from the colon the lumen of these had become obliterated.

Dr. H. Cushing of Baltimore said that he had seen some experiments on animals where as much as 80 per cent. of the intestine had been resected with a marked dilatation of the bowel. In these cases diverticuli often occurred, but there had been no diverticuli in the mesenteric border where the blood vessels entered.

Dr. C. B. de Nancrede said that he had had two cases of extraperitoneal abscess in obese men on the left side, that there had been no bowel communication, but that both cases had had their origin from the sigmoid.

Dr. Mayo, in closing, said that he believed that many of the cases where resection of the colon had been done with the diagnosis of cancer but where the patient had had no recurrence, were cases of diverticulitis and he would have the old specimens examined anew. He said that there had been no known myocarditis in his cases and that the diverticuli might occur anywhere on the lumen of the colon not only at the mesentery.

Dr. L. B. Wilson said that in 1904 Bier had reported eighteen cases of diverticulitis, in one case diverticulitis and cancer, but that such a combination had not been found at the Mayo clinic.

Dr. Gerrish said that his case was peculiar in that the diverticulum passed down on one side of the mesentery through an aperature in it and then out on the other side to become adherent to the abdominal wall. He did not think that the adhesion in his case could have been an omphalomesenteric duct.

Dr. Brewer said that if cancer occurred in association with diverticulitis it might well be caused by the irritation of the chronic inflammation.

Some Recent Modifications of the Gasserian Ganglion Operation for Neuralgia, with a Report of Fifty Cases of Operation Upon the Ganglion.—Dr. Harvey Cushing of Baltimore presented two cases, one of spasmodic tic, the other of tic douloureux. In the first case he had resected the facial nerve and then done an immediate anastomosis with the spinal accessory. The patient had recovered emotional control of the face within six months, though she had a slight droop of the shoulder and a movement of the face with the movements of the shoulder. These two symptoms were not as bad as the thickness of speech following anastomosis of the facial with the hypoglossal nerve. In the case of the tic douloureux the patient was an early case, having had the pain only six months. In the operation he had done the patient lost very little blood and got out of the hospital in six days. He had a mortality of about 2 per cent. He does not destroy the ganglion, but pulls out the sensory fibers at the meninges. It is followed by no loss of motion or atrophy of the muscles.

Dr. S. J. Mixter of Boston considered the operation always a serious one. In the twenty cases that he had done he had used a modified Abbe operation because the results had been very satisfactory, there having been no recurrence after three or four years. He injected osmic acid into the nerves after dividing the second and third divisions and then plugged the foramina and fossa with amalgam. He had had one death.

Dr. M. A. Starr of New York congratulated Dr. Cushing on the excellent results in the case of spasmodic tic. He had never seen as good results from the anastomosis of the seventh to the twelfth nerve. The neurologists believed that the lesion in the case of tic douloureux lay in the ganglion and that therefore it was futile to divide the peripheral branches of the nerves. That Dr. Cushing's evulsion of the nerve fibers from the ganglion was satisfactory.

Dr. S. H. Weeks of Portland, Me., said that he lifted the ganglion out of its fossa and cut it off, leaving the ophthalmic division and a part of the ganglion intact.

Dr. Cushing, in closing, said that he, too, believed that the ganglion was the seat of war, and that the brain-ganglion link should be severed. That if any of the branches were left, recurrence in that branch would follow.

Early Operations Upon the Nerves in Ischemic Paralysis.—Dr. Leonard Freeman read this paper. Of the pathology he said that if the blood supply to the muscles was cut off they would die in three hours and assume a post-mortem rigidity, and then the fingers contract so that they would dig into the palm of the hand. Later sensory and trophic disturbances would set in, the nerves themselves showing the lesions. Massage and electricity helped the hands to recover, but the massage had to be vigorous and persistent. That the muscle rigidity injured the nerves and the diseased nerves interfered with the use of the

muscles. That the indication was to operate on the nerve and relieve its trunk from pressure. That the median nerve was compressed most frequently in the pronator radii teres, the radial in the supinator brevis, and the ulnar in the flexor carpi ulnaris. The nerves should be exposed above the point of compression and followed down, and then when exposed buried, if necessary, in the subcutaneous fat. In one case where trophic changes had begun in the hand, making it useless, after operation the tingling of the fingers appeared in about three months and in three years the patient had good use of the hand. In two other cases of late operation, in one he had had a relief of the pain and in the other an improvement of sensation.

Dr. W. J. Mayo of Rochester, Minn., said that the cases were due to either bad splint application or to later swelling of tissues causing the compression. That only a few cases had been reported in the leg. That previously the treatment had been orthopedic shortening of the bone to relieve the muscle pressure, but that this nerve operation was a great advance.

Dr. B. F. Curtis of New York said that he had seen one case due to hemorrhage under the splint. That the bone removal was very helpful but did not relieve the pain or the trophic change.

Dr. H. L. Burrell of Boston said that he had seen a number of cases of ischemic paralysis in children where the results were not satisfactory, and he asked how early operation would be desirable.

Dr. Freeman, in closing, said that if a few weeks did not improve the nerve symptoms, no matter what happened to the muscles, operation would be desirable.

Officers were elected as follows: *President*, W. H. Carmalt of New Haven; *First Vice-President*, W. G. Macdonald of Albany; *Second Vice-President*, J. F. Binney of Kansas City; *Member of the Executive Council*, D. P. Allen of Cleveland.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Ninth Regular Meeting, Held April 5, 1907.

The President, Dr. Robert Abbe, in the Chair.

Medical Inspection in the Public Schools.— Dr. Hermann M. Biggs, in this paper, said it seemed rather remarkable, in view of the great importance of the subject, that no systematic medical supervision of the children in the public schools in the large cities of this country or Europe was attempted until very recent years, and that even at the present time such supervision was limited to a few cities, and for the most part to a search for cases of infectious disease. To the speaker's knowledge, there had been no effort made in a large way to have a general physical examination of the children in the public schools of any large city elsewhere than in New York. The first attempt at medical supervision in a limited way of school children appeared to have been in 1893, in Boston, during the prevalence of a severe epidemic of scarlet fever. Subsequent to this, a number of physicians were appointed whose duties were confined to the visiting of various schools upon the request of the principals or teachers. This was the first attempt at medical inspection of schools made in the United States. In 1894 and 1895, in New York City, in the study of the prevalence and extension of diphtheria and its spread in the public schools, and in the effort to formulate a basis on which bacteriological diagnosis could be made, it was found that in many instances there were distinct school outbreaks, which were largely confined to certain classes in certain public schools. In 1896 the Board of Health determined to make more extensive investigations to ascertain to what extent the schools served in the spread of contagious diseases. There had existed a long time previously a belief that the public schools played a very important part in the dissemination of contagious diseases, for each year the morbidity curves with relation to measles, diphtheria, whooping cough, etc., commenced rising soon after the opening of the schools in the autumn, and continued to rise, as a rule, until March or April, when they attained their maximum, and then, with the beginning of warm weather, they fell until after the closing of the schools, when a comparatively rapid decline followed. In the preliminary investigations undertaken by the Department of Health, a diagnostician was assigned to visit schools which children reported as ill with contagious disease had attended. A list of the absentees from the class attended by the sick child was obtained, and these children were visited at their homes. Further investigations showed that in most of the public schools, lead and slate pencils, pen holders, etc., were used in common by the children in a certain classroom. These were collected at night and distributed again in the morning, indiscriminately, and bacteriological investigation indicated the presence of virulent diphtheria bacilli on these writing utensils when they had been placed in the mouths of children sick or convalescent from diphtheria during periods of from five to eighteen days. These, with numerous other findings, were incorporated in a special report and forwarded to the Board of Estimate and Apportionment by the Board of Health, with the request for an appropriation to provide for a systematic inspection of the public schools for the exclusion of cases of infectious disease. This appropriation was granted, and in March, 1897, the system was inaugurated in the Boroughs of Manhattan and the Bronx, constituting the old city of New York. One hundred and fifty inspectors were appointed, at the rate of $30 per month, whose duties consisted in visiting certain schools each morning and examining all children set aside by the teachers as suspected of having some infectious disease. The inspectors also examined every child who had been excluded from school, or who was absent from school for illness, before its re-admission to the school. Essentially, this system obtained until 1902, when it was modified by reducing the number of inspectors to 50 and requiring their services for a longer time daily, at the same time increasing the compensation to $100 per month. Under the new plan, to each inspector was assigned a group of schools, the census of which was approximately 5,000 children. The inspectors were required to visit each of the schools under their supervision each morning before 10 o'clock. Dr. Biggs then described in detail the duties of these inspectors, and stated that with the extension of the work it soon became evident that the presence of trained nurses in the public schools would be of great value, especially as in some of the schools a very large percentage of the children were affected either with trachoma, acute conjunctivitis, pediculosis, or some contagious disease of the skin, and the treatment which they received at home or from dispensaries was often unsatisfactory and inefficient, and their exclusion from school decimated some of the classes and aroused a violent protest from the school authorities. Therefore, on December 1, 1902, eight nurses were appointed, at a salary of $75 per month, and their work proved so satisfactory that this number was soon increased, and additions had been made from time to time until now there were over 60 trained nurses working in the public schools throughout the city.

Dr. John W. Brannan said he had known something of the medical inspection of the schools, but had no idea of its magnitude and importance. He had been familiar with Dr. Biggs' campaign against tuberculosis during the past fifteen years, and he was inclined to believe that the work described this evening would prove even more valuable in its far-reaching results. What Dr. Biggs had said of trachoma carried the speaker back to the time when the spread of this disease was first called to the attention of the profession. Many physicians thought that its prevalence was perhaps exaggerated, and for a time he himself shared this opinion, but when he visited the clinic of the New York Eye and Ear Infirmary and saw the children crowding

about Dr. Derby in their desire to be operated on, he changed his views, and subsequently, when the clinic was opened at Gouverneur Hospital, he saw the same rush of patients to get within reach of the surgeons. He had been rather surprised to hear this evening that the disease was still so prevalent, in spite of the energetic work of the Health Department during the past four years, and he suggested the possibility that fresh cases were slipping into the city through Ellis Island. He had been told by surgeons stationed at the island that occasionally affected immigrants, instead of being excluded, as the law required, were admitted to the Government hospital, and after treatment were permitted to land. Mild cases of the disease might also be undetected by the surgeons, whose examination was necessarily hasty when thousands of immigrants arrived in one day.

Dr. Charles L. Dana said he thought the importance of the work of the Board of Health in connection with the medical inspection in the public schools could not be overestimated. He was particularly interested in that phase of the subject that related to the effect of physical defects upon the mentality of the children. More exaggerated examples of this type came under observation at the clinics and hospitals, and it would be extremely interesting to study the ordinary school cases more specifically, in order to learn exactly what was meant by the term defective mentality: whether it implied defective memory or some moral defect, or perhaps some peculiar forms of defect in language capacity, which in some children seemed to be very marked. There was, for example, an apparent congenital defect in the capacity to learn to read, or to understand syntax or remember words, so that their vocabulary was extremely small. Some of these cases could be much improved by specialized forms of teaching. The more common defects observed in the backward children in nerve clinics were those relating to the eyes, obstructions to breathing due to adenoids or enlarged tonsils, and defects to nutrition, resulting in a poorly nourished general system as well as brain. The latter type was not uncommon among the children of the better class, and was sometimes associated with a form of youthful neurasthenia.

Dr. William M. Polk said the information contained in Dr. Biggs' paper was interesting not only from the standpoint of the neurologist, but from every possible standpoint, and especially that of good citizenship. The entire subject was intermixed with one that was at present receiving the attention of the American Medical Association, namely, the enactment of legislation for the prevention of ophthalmia neonatorum. The plan would come up at the meeting in Atlantic City.

Dr. George L. Peabody said the work undertaken by the Board of Health was of such immense humanitarian importance that it should be aided in every possible way. No matter what the cost of the work might be, it would in time save much more to us in making useful citizens of children many of whom might otherwise have grown up to be not only useless, but criminals. Dr. Peabody said that in his official connection with a large institution for the blind he had become impressed with the fact that the number of children affected with blindness, especially in this vicinity, was steadily diminishing. This could probably be traced to the more rigid rules that now prevailed regarding cleanliness and to our knowledge regarding the prevention of eye diseases in the new-born. The speaker said he did not believe that the prevalence of trachoma in New York City to-day was due to fresh sources of infection in immigrants. The steamship companies were very careful to exclude these patients, as a fine of $100 was attached to each one they brought over, and, furthermore, they were compelled to take them back again.

Dr. L. Bolton Bangs asked if this work among the school children produced any educational reaction among the parents? Did the latter learn anything from it? The questions involved were not only hygienic and sanitary, but sociological, which would have its influence upon the immediate generation and succeeding ones, and in the course of time this system of school inspection would effect a marked diminution in the number of defective children.

Dr. Biggs said that while the medical inspection of the public schools had been in force long enough to draw any conclusions regarding its influence upon the parents of the children, it undoubtedly did exert some such influence. For example, in certain parts of the city entire families were affected with pediculosis; the children in those families were sent home on account of it; they came to regard this as more or less of a stigma upon them, and they, in their turn, converted their parents to regard it in the same light.

Dr. Joseph D. Bryant said that while he had been more or less familiar with the general trend of this branch of work of the Health Department, he had never before so fully appreciated the beneficent influences arising from it. It had impressed him more than ever before with the importance of having a sound body in order to have a sound mind. He thought no one would question the wisdom of the very earliest possible detection of these physical defects in children. Those of the spine were important, which later became absolutely irremediable, so far as complete recovery was concerned. In that connection he more especially had in mind incipient Pott's disease. In regard to the proper care of the eyes, particularly in the prevention of ophthalmia neonatorum, Dr. Bryant said he recently saw a statement to the effect that 25 per cent. of blindness was dependent upon preventable disease. He commended the work earnestly, and hoped that it would be continued, saying that the resulting increase in careful, self-suffering people would lessen the census of public institutions of charity and of punishment and add correspondingly to good citizenship.

Dr. Charles Stedman Bull said the medical inspection in the public schools, as outlined by Dr. Biggs, was without doubt the most colossal work that had ever been undertaken by any municipality, and no matter what the cost might be, the results would more than repay the money spent. In referring to trachoma and its prevalence at the present time in spite of the thousands of cases that had been treated during the past three or four years in this city, Dr. Bull said there was a large percentage of these cases that were inoperable; they were the cases in which there were no distinct granulations that could be taken hold of by any method of operation, and while they could be quickly cauterized, prolonged treatment was usually necessary, while, on the contrary, those cases that presented distinct trachoma nodules could be operated on at once and almost immediately cured, and they ceased to be contagious then and there. Dr. Bull said that another far-reaching effect of a proper system of medical inspection of the public school children in its relation to the eye was in the detection of errors of refraction or muscular anomalies which were susceptible of correction by glasses. In that connection, he did not have in mind the indirect influence of the corrected eyesight upon the child's mentality, which in itself was an important factor, but its even more far-reaching influence as a prophylactic measure in the later prevention of such destructive conditions as retinitis, cataract, and choroiditis. The speaker said that during the past fifteen years there had been a steady decrease in the number of cases of cataract dependent on nutritional defects of the lens, and he attributed that fact to the more general use of proper glasses for the correction of anomalies of refraction. It was doubtless true that cases of blindness in children were somewhat rapidly diminishing, which was probably traceable to the fact that the diseases which caused it were earlier recognized and treated.

Dr. Biggs, in reply to the question of whether other municipal bodies had taken up this work, said that something had been done along these lines in Boston, especially in reference to the contagious diseases and the eyes. It was also taken up in Philadelphia, but subsequently abandoned. In Berlin and other Continental cities the eyes of children

had received considerable attention, but, so far as he knew, there was no general physical examination. In England, the supervision of the school boards was largely limited to the infectious diseases and the eyes. The work in New York was more general and systematic than anywhere else.

The President, Dr. ABBE, said that as physicians we should not lose sight of the tremendous degenerative force that the defective element exerted on the community in general, and the corresponding benefit that would accrue from the correction of those deformities. One of the most striking features of Dr. Biggs' report was the rapid improvement made by some of these backward children after their defects had been corrected.

Dr. Biggs closed the discussion and, in referring to a riot that had taken place in one of the schools on the lower East side, said the cause of the excitement was that many of the children in that section of the city, on account of their race, preferred to go to a certain hospital to have their tonsils removed. The hospital was located at such a distance that a staff of physicians was sent from the hospital to one of the schools on a certain day with consent of the Board of Education, and in the course of a few hours 85 pupils of that school were operated on and sent home. This so alarmed the parents of the other children in the school that the report spread that the Board of Health doctors were cutting the children's throats, and a small riot ensued. As a matter of fact, the Department of Health staff had nothing to do with the operations.

A Comment on the X-Ray Applied to Prostatic Enlargement.—Reported by Dr. L. BOLTON BANGS. (See page 902.)

A Typhoid Fever Carrier.—Dr. BIGGS said that on March 12, 1907, the Health Department received a communication to the effect that outbreaks of typhoid fever had occurred in four families in this vicinity during the past four and a half years, and that in each instance the outbreak had occurred shortly after the employment of a certain woman as cook. An investigation was instituted which disclosed that in addition to these four families, typhoid fever had occurred in several other families where she had been employed in the same capacity. It was further learned that this woman was an excellent cook, and on that account had no difficulty in finding employment; she changed her position at frequent intervals, and would only work when she was compelled by necessity to do so. At one place where she had been employed she left the kitchen in such a filthy condition that it required the services of a scavenger to cleanse it. In several of her former places of employment, three to seven cases of typhoid fever had occurred, and in her last place there had been two cases, one of which proved fatal. The cook was a perfect Amazon, weighing over 200 pounds, and when an investigator tried to interview her he was ejected with very slight ceremony. A health inspector and officer were then sent to the house, but they failed to see her, and the same thing occurred to a female health inspector who had been advised to use tactful methods. It was then considered justifiable to employ force, and five police officers from the Sanitary Squad finally succeeded in taking the woman to the Reception Hospital, of which she is now an inmate. An examination of her urine gave negative results, but the feces were found to be loaded with typhoid bacilli. At one time nearly 90 per cent. of the organisms were typhoid bacilli. The woman gave no definite history of typhoid fever, at least not for the past five years. [See also MEDICAL RECORD, May 18, 1907, page 818.]

Local Applications in Inoperable Breast Cancer.—Any lotion or ointment containing morphine is suitable, but I know few more soothing applications to an incurable breast cancer than the old-fashioned conium poultice. This may be made from the fresh leaves, or one-half ounce of the succus conii may be added to an ordinary breast poultice.—MARMADUKE SHIELD.

Medical Items.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 24, 1907:

THE AMERICAN MEDICAL ASSOCIATION, ITS AIMS AND INTERESTS.*

By JOSEPH D. BRYANT, M.D.,
NEW YORK.

The fifty-eighth consecutive session of the American Medical Association is now at hand. Those members whom you kindly honored one year ago with your confidence in official station are now before you in token of their loyalty to your undertakings and of their obedience to your behests. These annual conferences are of prodigious moment to the entire medical profession and to the country at large; they serve to broaden the scope of general understanding; they extend the sphere and increase the vigor of professional fellowship and of healthy civic brotherhood, and they correspondingly elevate the station of our calling in the appreciation of thoughtful rightminded people everywhere in the land. Who of us was not made a better physician because of the visit to Boston a year ago? Who of us, then inspired by patriotic emotions, aroused by the memorable examples so abundantly at hand, did not again renew unalterable allegiance to the perpetuity of his country? In whom of us was not incited a higher fraternal sentiment by the warm grasps of fellowship which, while inviting delay a bit, everywhere urged us on to a completed hospitality?

Again, for the third time in the dawn of the twentieth century, we find ourselves in the warm embraces of the hospitable people of Atlantic City. Its wealth of sunshine and cheer, its pure and invigorating eastern breezes, and the joyous acclaim of its citizens assure us that we are in "honest waters which ne'er left man i' the mire," and, therefore, we feel entirely secure and correspondingly happy. We who before never yielded to subtle solicitation or to pressing demand now acknowledge that we have the Atlantic City "habit," and we refuse all treatment except that founded on the therapeutic virtue of the hair of the canine that inflicted the delightful traumatism! In the presence of such a felicitous environment as this, who is there among us who would be so thoughtless, or who could be so unfeeling, as to countenance a trifling with the sense of justice by individual favor, or of commendable desire by vain objection?

In looking about for a topic on which to base my allotted remarks on this occasion, I am, perhaps, unduly impressed with the idea that impersonal openhearted introspection might not be amiss at this period of the Association.

In this bearing I refer more especially, 1, to the organizing of the medical profession of the country and its potential perplexities; 2, to the elevating of the standard of medical education and its possible afflictions, and, 3, to the urgent demand for trustworthy medicinal means and of sincerer efforts on the part of every physician in securing a betterment of therapeutic methods.

Equity, consequent power, and the durability of human designs are the legitimate assets of wisely conceived organization. Power and durability, not thus sustained, are of uncertain tenure and organization resting thereon can be likened to a house of blocks tethered with ropes of sand. And it should be recognized at all times that the virile activities of the principles of human justice are wonderfully potent in all organized bodies of mankind.

The Object of the Association.—It is of great moment that this Association has (as set forth in its constitution) but one significant object in view, viz., The Promotion of the Science and Art of Medicine. And it is purposed in attaining this end "to unite into one compact organization the medical profession of the United States," in order to foster "the growth and diffusion of medical knowledge"; to promote "friendly intercourse among American physicians"; to safeguard "the material interests of the medical profession"; to elevate "the standard of medical education"; to secure "the enactment and enforcement of just medical laws"; to enlighten and direct "public opinion" regarding the "broad problems of hygiene," and to present "to the world the practical accomplishment of scientific medicine."

It follows, therefore, that the promotion of the science and art of medicine as provided by the constitution of the Association is, in effect, the promotion of the methods and the development of the means and the opportunities for relieving human suffering and thereby the adding of years and comfort to human existence. And true it is that to no class of persons is fraternal spirit and vigilant cooperation so essential as to those who are engaged in combating the insidious and tireless encroachments of the agents of human affliction and in relieving the abundant miseries which they beget. A transcendent service like this should be sheltered by the zeal of healthful personal and professional devotion and in no way depleted by the wiles of business ambitions. Those who regard the practice of medicine as a business enterprise should class themselves as brokers in a market of human affliction. To those who would infect the sound spirit of professional devotion and fellowship with the virus of sordid gain little heed need be given at the counsels of thoughtful men in the ranks of a beneficent profession.

The uniting of the medical profession of the United States into "one compact organization," making to the wise purposes already stated, is pro-

*President's Address at the Fifty-eighth Annual Session of the American Medical Association at Atlantic City, N. J., June 4-7, 1907.—From advance proofs through the courtesy of the *Journal of the American Medical Association.*

gressing in a decided manner, guided by the earnest activity and abundant experience of Dr. J. N. McCormack of Kentucky. Already the constituent members of the organization number nearly 65,000, of which the fully constituted members are about 27,000, showing a substantial increase of the former class during the present year of about 10 plus per cent. and of the latter about 12.5 per cent. And when it is recalled that the regular medical profession of the United States numbers about 112,000 it is not difficult to understand that in the near future the medical profession of these States might easily be united into one compact organization. But how compact it may be and how enduring it may become will depend on the degree of wisdom exercised by its builders and on the measure of justice dispensed by those in control of its affairs.

"Justice without wisdom is impossible," said Froude. "Wisdom is only truth," said Goethe. Therefore, justice and truth are inseparable, say we all. The search for truth and understanding is the inherent right of all men, and they who inhibit the effort are for some reason (or pretext) opposed to justice and to knowledge. Obviously the consensus of men of widely separated habitation, of differently constituted environment and opinion, is a wiser and a safer guide in the conduct of important and comprehensive human affairs than is the consensus of men of contiguous localities. The judgment of the former class represents the concentrated wisdom of the whole, of the latter only that of a part of the country. The principle of utterance or of action relating to matters of common interest and general effect in organized bodies, should in all cases be known and approved and be coordinated through the deliberate wisdom of broad constituted authority, rather than by the anxious thought or the hasty vocabulary of a few persons, no matter how experienced they may be or how wise they may be regarded as being. History not infrequently has demonstrated by untoward results the need of this rule of action in governmental and in other human affairs.

The lamented Lincoln emphasized the importance of this principle in no uncertain manner by the famous utterance, "The government of the people, by the people, for the people, shall not perish from the earth."

And in this relation it is well for us to keep in mind that a failure on the part of the responsible many, to plan and coordinate wisely the official acts of the few, often renders effeminate and inoperative the subsequent inhibitory efforts of those in established control.

Among the inspiring benefits provided by the constitution of this Association is embraced the fostering of the growth and the diffusing of medical knowledge and its beneficence, throughout the various channels of human intercourse. The promoting of the growth and the diffusing of medical knowledge should appeal with equal vigor to the people who experience relief and to those who contribute the products of medical enlightenment.

Every physician can contribute a definite share to the healthy growth and wise diffusion of medical knowledge and to its bounties. Those who strive in the workshops of medicine, the laboratories and the hospitals, more especially the former, have already bestowed a bountiful portion toward the attainment of this end. Scientific laboratory deductions, however, could not be regarded as final; they yet required the leavening proof from out the complex laboratory of the human body, as demonstrated by practical applications in the treatment of disease, to establish their worth. To the general and to the hospital practitioners of medicine belonged the duty of dispensing the fruits of laboratory research, and thus far so well has concurrent effort accomplished its purpose, that life's expectancy during the first forty years of existence has been advanced quite 30 per cent. But following this period only a little advance in this regard has yet been made, and principally because of the differences in the nature of the diseases which afflict those of the earlier and of the later periods of life.

The present and prospective civil worth of the toll levied by disease on the wisdom and experience of mankind, during the later period of life can not well be estimated. But the physical sufferings of this period are largely the characteristic outcome of its peculiar diseases, many of which might be prevented and perhaps cured by means of progressive investigation and therapy related to a full term of years, and thus life's span becomes yet longer extended.

As just observed, every physician, if he will, can contribute a definite share to this preeminent undertaking. The opportunities of the country practitioner in this regard are of special significance, because of the knowledge gained through the differing effects of environment on the diseases of country and urban patients. Painstaking cooperative effort directed to the solution of the problems of disease can be made wherever two or more physicians are in mutual contact with each other and shall undertake the task.

Medical Education.—It can not be gainsaid that comparatively few of the people constituting the medical profession of this country are tireless in their efforts to advance the scientific and practical status of medical knowledge. But what can be said regarding the great multitude of others of the people, referable to mutual response commensurate with the earthly blessings which they receive? As an earnest of the sentiments of those persons who give bountifully to beneficent ends, I quote from a comprehensive address delivered by President Keen at the annual session of this Association, held here in June, 1900, and based on the United Education Report of 1898. President Keen presented to the audience the following startling facts regarding the comparative endowments bestowed on theological and medical schools for teaching (not foundation) purposes in this country. It was shown that each of the 8,000 theological students had the income of $2,250 provided for his instruction, and that each of the 2,400 medical students had the income of $83 provided for the same purpose. Also that of the 178 endowed chairs in teaching, only five related to medicine. Then we were solaced by the thought, "A hard beginning maketh a good ending."

In this address President Keen gave as his opinion that the difference in the amounts of these endowments was chiefly in consequence of the "vicious methods of the conduct of medical teaching as represented in preparatory medical schools." And it is fair to say that many others were of the same opinion. In view of this hypothesis, and of the fact that since the time of the report on which it was based up to the final one[1] of five years later, and notwithstanding that distinct improvement in the administration and the teaching in medical col-

leges had taken place, and broader laboratory avenues of well-known scientific outcome were in operation, still it does not appear that a sufficient rising in the tide of advancement was reached to influence satisfactorily the inclination of munificent givers. For, according to the report of 1903-4, each of the 7,400 theological students of 1904 had the income of $3,031 provided for his instruction, and each of the 27,000 medical students of that year had the income of $54 provided for the same purpose, thus showing a gain over the previous report in favor of the theological student of $781 per capita, and a loss to the medical student of $29 per capita, for teaching purposes.

Endowments.—Substantially the benefit of $22,500,000 was available for the purposes of theological education, as against the benefit of $1,450,000 for medical educational use at the time of the report of 1903. At this time, of the 153 theological schools 77 report endowments and 76 report no endowments. And of the 152 medical schools 19 report endowments and 133 report no endowments. Also five of the theological schools had endowments varying in amount from $853,000 to $1,525,388 each. Now, more than ever, are we impressed with the force of another expression, "Help yourself and Heaven will help you."

In view of this later increase in the difference of the incomes bestowed for direct educational purposes, and under improved medical conditions, it seems quite likely that opposing factors more potent than first assigned, are extant. When, however, it shall happen that bountiful givers regard us in health as in acute affliction, perhaps greater heed will be given to the wisdom of making larger medical educational gifts. Irreverent comment has hinted of another compelling influence, especially related to generous adult minds, embodying the notion that the hope and faith of celestial expectancy, are more attractive than are the faith and outcome of terrestrial realization. Whatever may be the reason for the continued paucity of medical endowment, I am not prepared to say, but I hope that substantial improvement will be secured through the convincing influence of beneficent subjective and objective lessons, patiently, discreetly, and thoughtfully impressed by us on the public mind. Yet, confronting this hope, there appears an ominous specter pointing to the fact that only by laborious effort, chiefly supported by the medical profession, were the memory and brilliant services of the late Dr. Walter Reed meagerly characterized. Those who experienced the greatest blessings because of them gave the least to the care of those whom he loved most.

The simple, commonplace remark, "the promoting of friendly intercourse among American physicians," I regard as the most important announcement set forth in the opening declaration of the constitution of the Association, looking to the "Promotion of the Science and Art of Medicine." For, without the stimulating and guiding support of professional good-fellowship in all the term implies, discord and discredit are likely to delay or cripple the realization of this one great object in view.

The Journal.—I know of no agent so well fitted to contribute to the fostering of the growth and the diffusing of medical knowledge and the promoting of friendly intercourse among American physicians as rightly falls to the lot of *The Journal of the American Medical Association.* A journal with a weekly circulation of over 50,000 and accounted as the utterance of many more than this number of the organized medical profession of the country, may well be regarded in things of professional concern as the voice of the multitude proclaiming its will. Therefore, it is important that the tone and wisdom of its speech be in accord with the judgment of the great majority of our profession. I am inclined to believe that when the pages of our journal are the forum of temperate and instructive discussion of the policies of common interest to our membership greater impetus will be given to just causes and a broader scope to fraternal comfort among American physicians. One, however, can not be reminded of *The Journal* without being impressed by the creative ability, the abiding energy, and overtaxed assent of the editor, the Secretary of this Association.

I am deeply impressed with the belief that at this time the greatest danger to continued harmonious unity in the Association lies ill-hidden in the constituted expression, "to safeguard the material interests of the medical profession." It requires no special discriminating sense to foresee the devious interpretations which eager desire might willingly give to the phraseology of this declaration. Fortunately, however, no rendering of the language of this expression can be properly entertained which conflicts with that of the antecedent one, "the promotion of friendly intercourse among American physicians." However this may be, the following suggestive lines of Froude should not be overlooked: "Where all are selfish the sage is no better than the fool, and only rather more dangerous."

The War Against Disease.—The genuine products of completed organization of the medical profession are of infinite importance to the well-being of the country. The potent factors of common prosperity will be encouraged and protected; the hearts and homes of the well-to-do and the hopes and hovels of the needy will each reflect in joyous ways the benefits of cooperative action in fixing the nature, overcoming the causes, and lessening the burdens of disease. The war now under way against cancer and tuberculosis, two of the insatiable inflictions of humanity, can, along with that opposing ophthalmia, be waged with comprehensive rational designs and improved prospective results.

The broader the field of opportunity in this regard, and the greater the activity of the contest, the more bounteous will be the return and the greater a final victory. When, for instance, it is recalled that for unknown reasons the death rate from cancer is slowly advancing in spite of intelligent, earnest opposition; that acquired tuberculosis yet adds 13 per cent. to the total death rate; that unrestrained ophthalmia causes over 25 per cent. of the blindness from disease; that over 30 per cent. of the school children of New York, and perhaps of other large cities, suffer from defective vision, and that in 75 per cent. is their mentality impaired by causes yielding to curative measures of a simple and permanent nature, then, indeed, is the necessity for united action relating to control of human infliction emphatically demonstrated.

The alleviation and cure of such afflictions serve to lighten the burdens of public care, to lessen the tenantry of charitable and penal institutions, and to lay the foundation of good citizenship.

A National Board of Health.—The fact that communicable disease has no boundary restraints in the presence of unguarded human pursuits is quite as familiar to the lay as to the medical mind.

Also that human indifference and human ignorance and established sectional state policy often contribute an unfortunate share to human distress is well known to the medical profession. It would seem wise, therefore, that interstate sanitary regulations should be established, thus affording even-handed opportunity of protecting interstate enterprise from the effects of current disease. Duties of this nature and others of national sanitary importance can be properly met when an awakened sense of the need on the part of those controlling the affairs of the country shall invite the cooperation of our profession looking to the acquiring and preserving the best results, which wise statesmanship and wise sanitation can jointly secure.

A national board of health having in charge such things as properly fall under its consideration and action would be a national blessing of ever-increasing importance. But in this relation candor compels me to state that I find little encouragement for those of our profession who at the outset would demand a seat in the executive council at the head of the nation as an acknowledgment of professional capacity, or as a retainer for prospective service. Instead, we and others laboring in mercy's cause should be willing to serve in allotted capacity as Jacob served for Rachel, with unostentatious patience, tinctured perhaps with cruel disappointment, but leaving the results of our labors as an earnest of our worth and of the reward which best befits us.

Not a little has been said in the near past regarding the possibility of securing national incorporation of the American Medical Association, with power to hold property and transact business anywhere in the United States. The gaining of such incorporation is no longer speculative, for within the last year several charters of similar scope to that framed by Judge Ray for us have been secured for other organizations. I am inclined, however, to hesitate in recommending a renewal of endeavor in this respect until assurance can be had of earnest, genuine effort on the part of all, looking to the securing of incorporation and also cooperation in the adjustment of the business matters essential to a completed consummation of the act. A policy which would contemplate the locating of the business affairs of the Association at Washington in the event of incorporation, I regard as hostile to the best interests of the profession and contributive to the impairment of fraternal peace.

Medical Legislation.—The enactment and enforcement of just medical laws is a matter of superlative importance. Fair and equitable relations, founded on uniform standards, should be established between the respective States regarding the requirements of medical education. Under this arrangement, fully qualified physicians going from one State to another would not be obliged to submit to annoying State board scrutiny concerning fitness to practise medicine. Since no unusual professional attainments are necessary to meet the exigencies of practice in any State of the Union, but little difficulty should be experienced in establishing a grade of educational requirement, permitting of practice through reciprocal comity.

The unwelcome thought arises at this time that, in the absence of equitable State reciprocity, one or more States not blessed with first-class educational opportunities might endeavor to protect their own interests against the professional encroachments of the graduates of first-class medical schools by requirements to practice of such character as not to merit serious thought on the part of the faculties of highly reputable medical institutions. It is difficult, however, to conceive that this idea can be more than a passing fancy, for how a course of this kind could receive the sanction of good judgment is not easily understood. Relative to competent practitioners of long standing who may desire to change their State environment, a greater difficulty attends a proper adjustment of their situation. It seems to me, however, that common justice requires that a form of examination should be given in these instances, which in its scope is measured by practical methods consistent with the experience of the applicant, rather than by one of modern requirement. For I am quite certain that if a member of the teaching faculty of a modern medical school were unexpectedly to find himself outside the halls of his own institution, a creditable return through the enlightened channels prescribed by his catalogues for students, would be shadowed with great doubt and probably attended with humiliating disaster.

Medical Education.—Beneath this opinion lies a thought pregnant with important professional responsibility relating to all those who have to do with regulating the requirements to begin the study of medicine. Should it occur to them that ideals may not everywhere be needed and that the object might be to meet the requirements of the whole country—a country yet comparatively new in professional opportunities and rewards for ambitious young men in a great part of its area? Should it occur to them that the coming into the field of action of vast business enterprises has begotten corresponding opportunities attended with less preparatory drudgery and expense and by greater prospective rewards than generally attend the practice of medicine? Ought they to keep in mind that the increase in educational requirements above a certain point has not resulted, at least in New York State, in a corresponding increase in medicine of those of the highest qualifications, but instead their comparative numerical status (21 plus per cent.) in this and in other common respects has remained practically unchanged for the last ten years? Is it not possible, therefore, that many worthy and able young men who are less favored than their fellows have sidestepped because of the comparative hardships imposed by educational requirements and the uncertain and delayed rewards that attend earnest endeavor in the medical profession?

Whether or not the standard of medical education should soon be raised in this country to equal that of the old world is a matter concerning which honest differences of opinion are earnestly pronounced. While no one can consistently contend that knowledge is not power, yet the adjustment of more than a requisite amount of knowledge in the practice of medicine to the sparse occupancy of many broad areas of this country is a matter which for some time to come may concern the stern power of economics more than the needs of ideal culture. Possibly, therefore, those who are blessed with commendable professional dignity and with pleasing remunerative environment might willingly pause for a time while giving thought to the demands for professional care in broad necessitous surroundings.

The analytic work being done by the Council on Medical Education is mercilessly disclosing the comparative status of the medical schools in this country, to the discredit of many heretofore differently regarded. The active manner in which the

labor is carried on under the chairmanship of Dr. Arthur D. Bevan is creditable to the committee and to the cause in hand. Inasmuch as the standard of suitable preparatory medical attainment depends more on the capacity of a faculty to impart knowledge and beget character than it does on the phraseology of the curriculum, the outcome of the committee's efforts is being watched with solicitous interest by all concerned in honest standards of moral and medical qualifications.

Apropos of the importance that the faculties of medical schools should lead the way to higher station in professional ethical conduct, both by precept and example, I am prompted to say that there appears to be no doubt that uncanny business instincts are encroaching in the reciprocal vulgar ways characteristic of lay methods not a little on the sacred domain of professional propriety. I am of the opinion that trespasses of this kind are chiefly the outcome of acquisitive intentions based on delusive selfseeking desires. The remedy for the cure of this unprofessional propensity rests largely in the hands of the faculties of medical schools. They should inculcate a high sense of professional honor in those who come under their tutelage. Ample instruction of medical students in the tenets of moral philosophy, as applied to the practice of medicine, and substantial disapprobation of offending practitioners by their colleagues will, in my judgment, hasten the reduction of this evil to a minimum.

In this glorious country of ours, "the will of the people is the law of the land." And in this bearing it is needful that we should act with good sense concerning our personnel in all matters which are of special interest to the commonalty, so as not to encounter the adverse activity of popular desire. In this connection it is important to know that in the United States there are about 84,000,000 people, the great majority of whom are capable of satisfactorily judging of the practical things of life relating to themselves as they come into thought. Also in the United States there are about 112,000 physicians who are eligible to membership in the American Medical Association, but of which as yet little more than one-half are affiliated in any capacity with the organization. It logically follows, therefore, that a judicious estimate should be made of how the great majority of the 84,000,000 of people plus nearly half of our own calling would regard out intentions before venturing at all rather than prematurely to court defeat and corresponding loss of station. The question is *not* altogether what we think of ourselves and our causes, but the question *is* how we ourselves and our causes may be regarded by the people concerned and by their friends, to say nothing of the balance of our own profession. And, too, it should be kept in mind that it is not likely that general mutual accord will prevail in all matters of common interest which arise in organized bodies of men. In a humane profession appeals should be made to judgment, not to passion or prejudice. It is within the easy recollection of most of us that sturdy efforts were made by the united medical profession of a State in what was regarded to be a justifiable cause. Yet, as it appears, decided defeat was the outcome, because the majority of the interested people were not in harmony with the contention. This suggestive lesson should not pass unheeded, if experience and good judgment are to become available assets in the conduct of the affairs of medical organization.

The Need of Honest Drugs.—It is written that Oliver Cromwell, while fording a river with his army to attack the enemy, exclaimed, "Put your trust in God, but mind to keep your powder dry!" No less determined than Cromwell was, do many physicians now feel on account of the fact that their figurative powder (drugs) is quite apt to be worse than wet, being alarmingly defective in quality and fickle in strength. As an illustration of these facts, no evidence more convincing can be presented than that of the Health Department of New York City. This efficient department has for some time labored with discreet energy and with astounding results in this heretofore comparatively untilled field of interrogative scrutiny. That the crude drugs and standard preparations approved by the United States Pharmacopœia and prepared and exploited by reputable pharmacists should, in all instances, be found trustworthy admits of no denial.

It appears, however, from the reports of the Board of Health of New York City, on the analytic findings incident to the examination of crude drugs, tinctures, fluid extracts, etc., as compared with corresponding standards adopted in the United States Pharmacopœia, that reputable pharmacists have, because of commercial indifference, or studied intention, not infrequently contributed to therapeutic misfortune through the quality and strength of their drugs. I will call your attention to only a few illustrations which are an emphatic earnest of the need of general scrutiny of the pharmaceutical part of our therapeutic armamentarium.

It is a matter of general knowledge that aconite is a drug of potent nature and in comparatively common use. Of this drug five of the thirteen samples analyzed were of the tincture and fluid extract of the root. Of the three specimens of the tincture one had 9 per cent. more, and of the remaining two 6 and 20 per cent., respectively, less of aconitin in than the standard requires. The two samples of extract of the root had 13½ and 25½, respectively, more aconite in than is required. The remaining six samples were of the powdered root which in no instance was sufficiently abnormal to call for admonition. The samples of belladonna showed, respectively, from 35 to 45 per cent. less of mydriatic alkaloids in the powdered extract of the leaves, 11½ per cent. less in the fluid extract of the root, 17 per cent. more in the tincture of the leaves, and 47½ per cent. in the fluid extract of the leaves than is required by the United States Pharmacopœia. Powdered nux vomica was found to be comparatively worthless, but in the tincture and fluid extract was revealed an excess of strychnine above the required standard of 19 and 17 per cent., respectively. In the tincture of opium was found, of morhpine 7 to 13 per cent. more than the accepted standard of composition.

In 1-100 grain tablet triturate of nitroglycerin was discovered only 1-1600 of a grain of the drug. It is said that this preparation of nitroglycerin was known by the manufacturers to be unreliable and, therefore, should not have been exploited at all or in a guarded manner. It is not difficult to foresee how the failing to secure proper response from the use of these or other tablets of uncertain strength that the substitution therefor of a fresh solution of the drug might result unfortunately, especially if the dose of the fresh preparation were of the same amount as was that of the tablet last given. I have in mind an instance of this kind in which the use of a fresh solution of strychnine caused a fatal result.

It further appears that of the first sixty-one samples of drugs examined by the Health Department, all of which "articles are of exceptional importance, most of them potent poisons, and all are represented by definite chemical standards in the Pharmacopœia," only about 28 per cent. of the whole number was considered good and 16 per cent. were so bad as to justify legal action. It is proper to say that the majority of the manufacturers recognizing the awkward position in which they were placed, with a spirit of yielding opposition complied with the reformatory demands of the Health Department. This list of producers is small in number compared with those who are engaged in similar business in the United States, and, no doubt, present as favorable picture of this class of the drug evil as can be drawn.

Nor is the foregoing distress the only torment in pharmacy with which the medical profession has to contend. The idealized, savory products of pharmacy with which the market is cloyed are often quite as fickle in their nature and virtues as was a certain ancient queen of the Nile. Discreditable business thrift supplemented by cooperative professional contentment and convenient indifference, patronized by confiding and credulous people, yields princely returns for the diminutive cash and equivocal integrity invested in it.

Not all of those, however, engaged in the pharmacal trade are unworthy of the trust and confidence given to men in other avenues of business. Very many, indeed, thus engaged are as sincere and trustworthy in their business affairs as are the best of those in other undertakings. Therefore, the old and revered principle of common justice, while emphasizing the fact that every person should be regarded as being honest until the contrary is proven, should be kept in mind and action. Consequently, in our conduct of matters imbued with professional or business virtues, the resolution should be to estimate uprightness of character by the tenets of common justice, and not by preconceived notions hostile to the principles of established equity. Purposes thus graciously fortified command respect, and gain in strength because of opposition. The reverse, however, will beget distrustful thought and may finally cause defeat. In this recital I can not overcome the belief that we ourselves contribute a major share to the inception and success of many medicinal ventures by our indifference or ignorance relating to savory prescribing and also by our thoughtless employment of proprietary medicines. Here, too, is a chance for medical teachers to instill proper notions regarding consistent ethical and therapeutic refinements.

When John Dryden wrote, "virtue is her own reward," he expressed a sentiment in keeping with the self-sacrificing spirit characteristic of the members of the Council on Pharmacy and Chemistry of the American Medical Association. I am creditably informed that these gentlemen are serving the profession and the people in this labor without the expectation of vulgar reward or the anticipation of special favor. I desire to commend their motives, approve of their work, and bespeak on the part of the profession an earnest support of all wise conclusions. Those who labor in a just cause without stipend are deserving of great praise; those, however, who serve for pay can only expect approbation.

But little less important than the preceding, in some respects, would be the careful scientific consideration of the therapeutic value of the abundant springs of our country. There is much, indeed, of special significance regarding their popular use which might well be garnered and put on a sound basis. A scientific cooperation with those who are in charge of certain baths possessed of traditional specific value might readily guide to improved conditions of significant importance to all those who seek relief. A country as rich as ours in these spontaneous endowments can well afford, in proper ways, to court the attention and support of the afflicted and to the decided advantage of all concerned.

The Medical Profession in Civic Life.—The sincere belief, on my part, that the outcome of professional governing policies of common interest in our affairs are practically alike in county or State prompted me in a recent parting address to the united medical profession of the State of New York to say: "The organization of the medical profession here and everywhere throughout the country contemplates the realization of more than the scientific advantages arising from personal contact and local cooperative thought. It should be regarded as an earnest that the medical profession intends to take an active and controlling part, if possible, in those affairs of civic life which relate to the well-being of the body politic. There should be no question regarding the status of the medical profession in all matters relating to the securing of pure food, pure drugs, and wise public sanitation." Also it was said: "It would be sadly amiss, indeed, were I not to admonish you at this time, the opening of a united career, of the grave perils begotten by a spirit of paternalism which not infrequently is a pernicious byproduct of organized power. The seductive and aggressive influence of this spirit often usurps and may inhibit that nobler, more enduring, and beneficent spirit characteristic of common manhood and professional brotherhood. And it should not be forgotten that the greater and more extended is the membership of a fraternal body the greater and more extended are self-seeking desires apt to be. Consequently the longer the chain of affiliation is the weaker it may become, for, as you already understand, "no chain is stronger than its weakest link." I pause to inquire, is there any good reason to doubt that the medical organization of the nation might not respond to similar influences? Let us, however, cherish the belief that wise discretion fittingly stimulated by just conceptions of fraternal spirit will guide us securely along the pathway of increasing professional attainment and good fellowship to the end of useful life.

And, finally, when by the aid of Divine Providence, the medical profession of the United States shall have been made into "one compact organization" and impelled in dutiful desires only by the highest motives of professional purpose and of public welfare, no enlightened opposition will oppose its desires, nor will irrational outcry, nor vagrant motives, find patient listeners or available foothold in the councils of the organization or in those concerned in the requirements begetting of public confidence and respect.

Earnings of German Physicians.—A report by the Medical Chamber of Berlin and Brandenburg shows that the average income of Berlin's doctors is $2,250. In the case of 1,322 of them, however, it is less than $1,250.

THE EUSTACHIAN TUBE, ITS ANATOMY AND ITS MOVEMENTS: WITH A DESCRIPTION OF THE CARTILAGES, MUSCLES, FASCIÆ, AND THE FOSSA OF ROSENMULLER.

By W. SOHIER BRYANT, A.M., M.D.,
NEW YORK.

During the last twenty years the writer has paid much attention, clinically and anatomically, to the tympanopharyngeal tube, and long since noted certain physiological and anatomical points which are not usually accepted but which, by clinical observation and post-mortem dissection, he has established to his own satisfaction.

Movements.—The normal tube opens during act of swallowing or gaping. It opens partially during phonation, in proportion to the movement backward of the *velum palati*, which is greatest with the letters K, T, EE, etc., and least with M and N. Inspection through the nasal fossæ when the lower turbinates have been removed (Fig. 1), or through

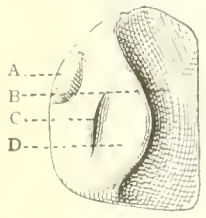

Fig. 1.—Pharyngeal orifice of the right tympanopharyngeal tube at rest, seen from the anterior nares in the living. The lower turbinate has been removed. A—Middle turbinate. B—Fossa of Rosenmuller. C—Mouth of tube, closed. D—Torus tubæ.

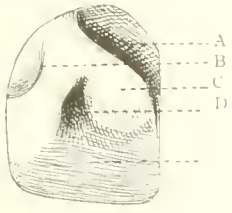

Fig. 2.—The same as Fig. 1 during an act of swallowing, the upper surface of the soft palate has risen into view and occupies the foreground. The ala cartilage has swung inwards and upwards, enlarging the orifice of the tube. A—Fossa of Rosenmuller. B—Middle turbinate. C—Torus tubæ. D—Mouth of tube, opened. E—Soft palate.

a salpingoscope (Fig. 3), discloses the pharyngeal mouth of the tube and the *torus tubæ*. The act of swallowing, or an act which raises the soft palate and applies it to the posterior pharyngeal wall, is accompanied by movements of the *ala tubæ* in proportion to the palatal movement (Fig. 2). The ala is seen to rise, moving inward and backward, and at the same time the mouth of the tube changes its shape from a nearly vertical slit to a triangular opening—formed by the backward movement of the posterior wall of the closed tube (Fig. 4). The an-

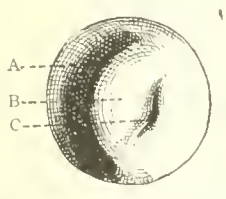

Fig. 3.—The same tube as in Fig. 1, at rest, view through a Eustachian salpingoscope. The fossa of Rosenmüller is seen on the left because the lenses reverse the image. A—Fossa of Rosenmuller. B—Torus tubæ. C—Mouth of tube, closed.

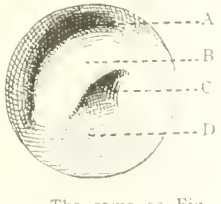

Fig. 4.—The same as Fig. 3, during an act of swallowing. The upper surface of the soft palate occupies the foreground. The fossa of Rosenmuller is nearly closed by the backward and upward movement of the ala cartilage which has distended the tube. A—Fossa of Rosenmuller. B—Torus tubæ. C—Mouth of tube, opened. D—Soft palate.

terior wall remains stationary. The inferior wall of the open tube is formed by the stretched inferior commissure of the closed tube. The motion of the *ala tubæ* or cartilage takes place in the pharyngeal sinus or fossa of Rosenmüller. When the tube is wide open at its mouth the depths may be seen nearly to the *isthmus tubæ*.

*The following figures from the living and anatomical preparations were drawn by Dr. A. Braun of New York.

Anatomy.—The cartilaginous portion of the *tuba auditiva* is very irregular in the arrangement of its component parts. The posterior wall of this part is composed of a plate of cartilage which has a nearly right-triangular posterior surface and forms the greater part of the anterior wall of the fossa of Rosenmüller. The apex of the triangle of cartilage lies at the junction of the cartilaginous with the osseous tube. The upper border of the cartilage is attached to the skull and fits into a depression on the sphenoid bone. The right angle of the triangle is situated at the pharyngeal end of the upper border of the cartilage, and is attached near the base of the inner pterygoid process. The inner border of the triangle forms the short limb or vertical side. It is also the free border of the cartilage and forms the *torus tubæ*. Its lower extremity ends in the angular process of the cartilage. The third and lower side of the triangle is freely movable. This triangular or alar cartilage passes above and forms the hamular process, a small part of the anterior wall of the tube. The cartilage as a whole is made up of one large piece and several accessory ones. The cartilage and its attachments are elastic and yield readily to pressure, which allows fairly free movements.

The greater part of the anterior wall of the tube is a strong membrane. The lower wall of the open tube is a loose elastic sheet of fibrous tissue which contracts and folds together when the tube is closed. The lumen of the inner third is obliterated by the contact of the anterior and posterior surfaces when the tube is closed. The upper and lower boundaries of the external half of the cartilaginous tube are formed by the concavity of the alar cartilages. The tube always remains open because the anterior wall does not wholly collapse against the concave posterior wall. The outer part of the tube, which normally is open, has a rigid and comparatively non-elastic wall, while the pharyngeal end is collapsible. The mucous membrane of the closed tube lies in longitudinal folds, especially toward the pharynx and floor of the tube. Here the thickness of the submucous layer is much increased. When the tube is dilated, these rugæ mostly disappear. The long diameter of the closed pharyngeal ostium measures, on the average, 7 mm. The open ostium, an equilateral triangular, averages 6 mm. in height and 6 mm. in width.

The anterior wall of the tube rests upon the tensor palati muscle, and that in turn on the internal pterygoid muscle and the intervening fasciæ. The pharyngeal ostium rests against the posterior surface of the pterygoid process. This backing prevents the collapse of the anterior wall. The cartilage of the posterior wall swings and bends easily at its line of attachment, and allows considerable increase in the lumen of the tube.

The tuba auditiva has two important fasciæ alternating with its two chief muscles. The fasciæ lie in the same plane as the axis of the tube and are nearly parallel to each other. The fibers of the fasciæ are almost at right angles to the tubal axis. The more important of these fasciæ—the salpingopharyngeal—lies between the levator and the tensor tympani muscles. It is attached to the membranous Eustachian tube at the angle between the anterior and inferior walls of the open tube, or the lower angle of the closed tube. It extends to the hamular process of the sphenoid. The other fascia lies posterior to the levator palati, and is attached to the lower free edge of the alar cartilage, which

prevents the levator palati muscle from slipping off the angular process of the cartilage when the muscle contracts.

Several muscles are situated on, or in the neighborhood of the tube and affect it by their movements. Chief of these are the levator palati or dilator tubæ, and the tensor palati. The fibers of both these muscles run practically parallel to the long axis of the tube. The levator lies below the lumen of the tube and anterior to the angular process of the alar cartilage (Fig. 8). It is attached peripherally to the base of the skull at the edge of the carotid canal. Sometimes the fibers are attached to the lower border of the alar cartilage. (Fig. 12). The sheath of the muscle is strongly attached to the perichondrium of the alar cartilage. Its muscular fibers form a strong round belly. Its inner extremity is attached to the muscular mass of the velum palati. This attachment moves with the soft palate. When the soft palate is relaxed and hangs forward, the palatal attachment of the levator is drawn downward and forward (Fig. 5). If

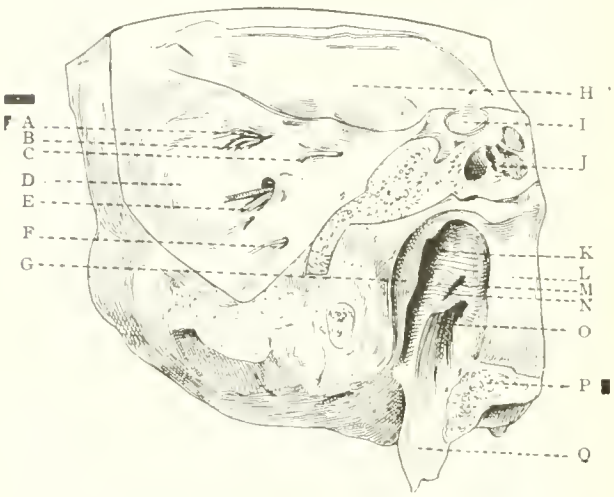

Fig. 5.—Shows the left post nasal space and soft palate which hangs placid. The belly of the levator palati muscle has been uncovered and hangs downward from the mouth of the pharyngeal be A—Internal auditory meatus. the palate is drawn upward and backward, the inner attachment of the levator is also drawn up and back (Fig. 6). The levator palati muscle pushes the

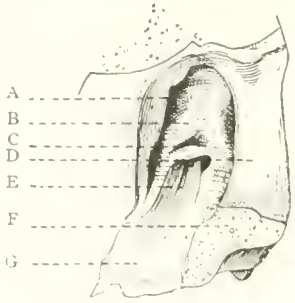

Fig. 6.—The same specimen as Fig 5. The soft palate has been drawn up and back carrying with it the levator palati muscle whose fibers now run downward and backward from the tubal mouth. The tension of these fibers has swung the ala cartilage backwards and upwards and opened the tube A—Fossa of Rosenmuller. B Torus tubæ. C—Mouth of tube, opened D—Nasal septum. E—Levator palati F—Hard palate G—Soft palate

alar cartilage backward, upward, and inward, opening the pharyngeal orifice of the tube (Fig. 9). The muscle at rest forms an obtuse opening backward at the point where it touches the angular process of the cartilage. If the palatal attachment of this muscle is drawn up and back, the angle is made less obtuse. When the muscle contracts it tends to straighten this angle and presses the angular process backward, upward, and inward. The cartilage swings inward because of its oblique attachment to the base of the skull.

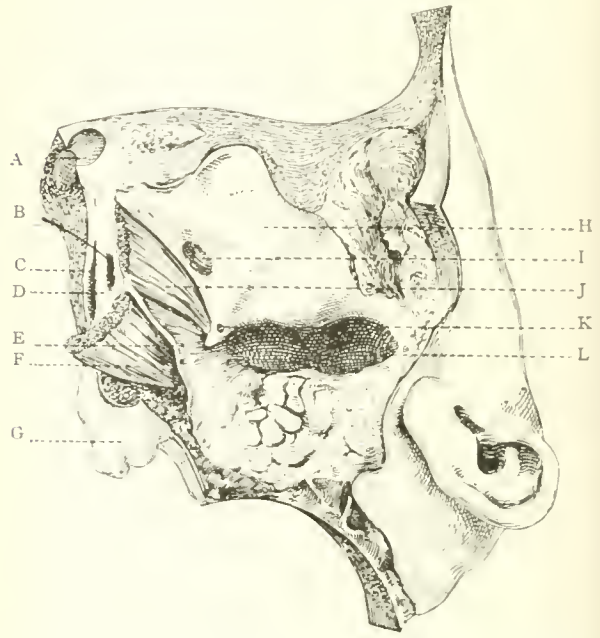

Fig. 7.—Base of the skull, lower jaw removed and part of the sphenoid bone exposed The pharyngeal mouth of the left Eustachian tube is seen in position The tensor and levator palati muscles are cut at the level of the tubal mouth and dissected bare. Between them lies the salpingopharyngeal fascia. The fibers of the tensor palati and levator palati muscles are seen to run parallel to the axis of the tube. The broad outer surface of the tensor is seen. The belly of the levator rests against the lower part of the tube and anterior surface of the lower angle of the cartilage A—Sphenoida, sinus. B—Probe in tube. C—Fossa of Rosenmuller D—Torus tubæ E—Fascia between levator and tensor palati. F—Levator palati G—Soft palate. H—Greater wing of spheroid I—Foramen oval J—Tensor palati K—Foramen spinosum L—Glenoid fossa

The tensor palati is a thin muscular and aponeurotic sheet covering the anterior surface of the tube. It varies more widely in its peripheral attachment than the levator. It arises from the sphenoid bone close to the outer side of the attachment of the cartilage of the tube (Fig. 11), and often extends by aponeurotic and muscular fibers to the upper surface of the hamular process of the cartilage. In 20 per cent. of the specimens examined the attachment spread downward, covering part of the anterior membranous wall on which the muscle rests, but it was never attached as far as the inner third of the tube. The muscle is often attached to the fascia lying on its outer surface. The external belly of the tensor palati is fixed by its tendon to the hamular process of the sphenoid. The outer extremity is fixed at the base of the skull and to the external fascia of the tensor. The direction of the muscular fibers ranges from being absolutely parallel to the tube to an angle of 10°, consequently they cannot have a forward pull on the anterior wall of the tube or a downward pull on the hamular process (Figs. 7 and 10). In fact, the contraction of the muscle can affect the lumen of the tube but little, if at all. The muscle is firmly supported anteriorly by the fascia which rests on the internal pterygoid muscle and the pterygoid process.

The less important muscles connected with the tube are inconstant. They are a slip from the palatoglossus—the salpingoglossus—which is rerely present, a slip from the superior constrictor of the pharynx—the salpingopharyngeus—and a slip from

the palatopharyngeus. The last runs along the inner border of the salpingopharyngeal ligament, and is attached with it to the angle between the anterior wall and the floor of the tube. It distends the tubal mouth by a pull forward and downward at the anterior angle. The fibers from the salpingopharyngeus can only depress the ala and draw it downward and forward, thus closing the tube. It is attached to the angular process of the alar cartilage. The upper fibers of the constrictor of the pharynx loop under the tubal mouth, and occasionally run to the triangular cartilages and form the salpingopharyngeus. Other fibers, twisting externally to these, go to the back wall of the pharynx behind the fossa of Rosenmüller. The point of bifurcation of the muscular fibers forms the lower commissure of the fossa of Rosenmüller.

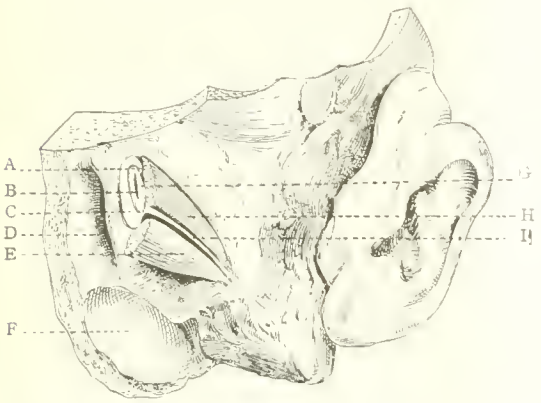

FIG. 8.—A similar specimen showing the tube in cross section. Two mm. of the pharyngeal extremity has been removed. The fibers of both the tensor and levator muscles are seen running parallel to the tube and are separated by the salpingopharngeyal fascia. The levator palati is seen resting on the anterior surface of the angular process of the cartilage. A—Hamular process of cartilage. B—Cross-section of tube. C—Section of cartilage. D—Fossa of Rosenmüller. E—Levator palati. F—Condyle. G—Section of membranous portion of tube. H—Tensor palati. I—Fascia between tensor and levator palati.

The fossa of Rosenmüller, or the pharyngeal sinus, is extremely variable, and does not exist in the infant. It is lined by the mucous membrane of the pharynx and is rich in adenoid tissue. It furnishes room for the movements of the alar cartilage, which lies on its anterior wall. On cross section the fossa is somewhat lenticular in shape. Its upper angle is formed by the angle of the attachment of the alar cartilage to the base of the skull. Its lower commissure is formed by the upper border of the superior constrictor of the pharynx, or by the angle between the two slips of this muscle.

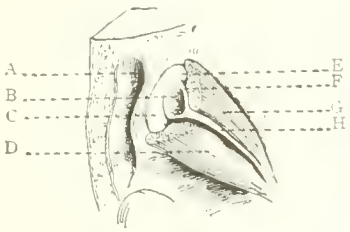

FIG. 9.—The same. The levator palati has been drawn tense in the backward direction which it occupies when the soft palate is raised as shown in Fig. 6. It now pushes the angular process of the cartilage upwards and backwards, encroaches upon the lumen of the fossa of Rosenmüller, and opens the tube. The anterior wall of the tube remains fixed. The increased circumference of the open tube is furnished by the elasticity of the tubal wall between the cartilage and the attachment of the salpingopharyngeal fascia. A—Fossa of Rosenmuller. B—Section of tube, opened. C—Cartilaginous portion of tube. D—Levator palati. E—Hamular process of cartilage. F—Membranous portion of tube. G—Tensor palati. H—Fascia between tensor and levator palati.

The apex of the fossa reaches nearly to the lower orifice of the carotid canal. The posterior wall is supported by the vertebral muscles. The depth of the sinus pharyngeus measured along its anterior wall averaged 18 mm. in twenty-five cases. The distance from the upper to the lower commissure aver-

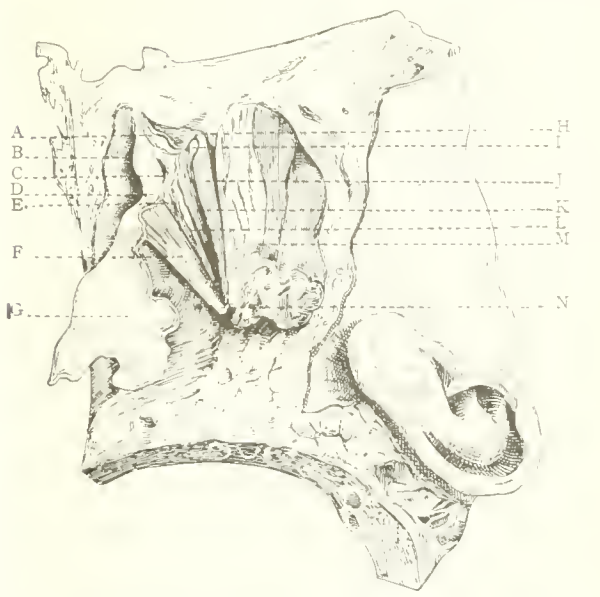

FIG. 10.—Similar specimen with more dissection of the structures at the floor of the tube. The two mouths are seen running parallel to the tube and between them the anterior wall of the tube; the attachment of the fascia and part of the lower border of the cartilage against which the levator palati rests. The thin, lower edge of the tensor is shown. A—Palatal portion of tensor palati. B—Fossa of Rosenmuller. C—Mouth of tube. D—Torus tubæ. E—Cartilaginous portion of tube. F—Levator palati. G—Soft palate. H—Tendon of tensor palati. I—Hamular process. J—Tensor palati. K—Membranous portion of tube. L—Attachment of fascia to tube. M—Internal pterygoid. N—Spinous process of sphenoid.

FIG. 11.—Similar specimen of the right side. The tensor palati is dissected and turned sharply outwards exposing its inner or posterior surface and showing the anterior wall of the tube free from muscle fibers, which in this case were not fastened to any part of the tube, but passed beyond it to their attachment at the base of the skull. A—Tensor palati. B—Cranial attachment of tensor palati. C—Membranous portion of tube. D—Levator palati. E—Soft palate. F—Sphenoidal cell. G—Fossa of Rosenmüller. H—Mouth of tube. I—Edge of cartilage. aged 26 mm. When the auditory tube was closed the width of the sinus averaged 11 mm.

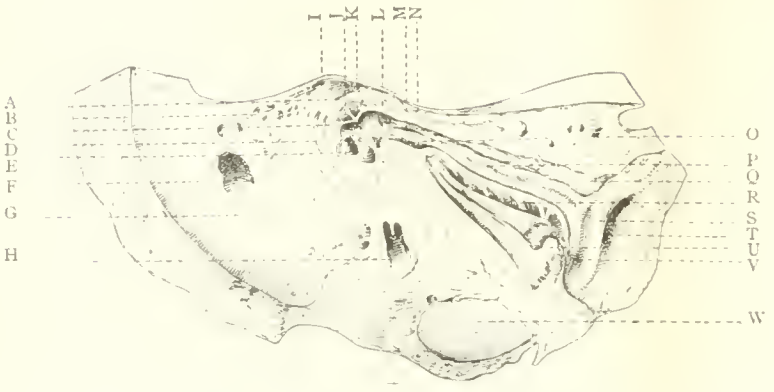

FIG. 12.—A nearly vertical section of the right middle ear tract. The inner posterior half of the Eustachian tube is shown with a concave wall. The levator palati muscle is seen below the tube. It has been lifted from its bed along the floor, the tube against the cartilage and show attachments to the cartilage. A—Canal for facial nerve. B—Mastoid cells. C—Pyramid. D—Facial nerve. E—Round window. F—Sigmoid sinus. G—Mastoid process. H—Internal carotid artery. I—External semicircular canal. J—Stapedius muscle. K—Oval window with stapes. L—Promontory. M—Crista falciformis. N—Canal for tensor tympani. O—Bony portion of tube. P—Cartilaginous portion of tube. Q—Cut section of cartilage. R—Fasciculus joining muscle to cartilage. S—Torus tubæ. T—Fossa of Rosenmüller. U—Levator palati. V—Angular process of cartilage W—Condyle.

Conclusion.—The physiological function of ventilating the tympanic cavity is accomplished mainly by the dilator tubæ or levator palati. The mechanism which allows the opening of the tuba auditiva is the backward pressure of this muscle on the angular process of the alar cartilage, which swings backward, upward, and inward on its superior attachment, dragging with it the floor of the tube and forming a triangular ostium.

Through the kindness of Prof. George S. Huntington, the author was allowed the privilege of completing these investigations in the Anatomical Laboratory of the College of Physicians and Surgeons of Columbia University.

LEPROSY IN THE PHILIPPINE ISLANDS AND THE PRESENT METHODS OF COMBATING THE DISEASE.*

BY VICTOR G. HEISER, M.D.,

P. A. SURGEON, U. S. P. H. AND M. H. SERVICE; DIRECTOR OF HEALTH, AND CHIEF QUARANTINE OFFICER FOR THE PHILIPPINE ISLANDS.

THERE has already been so much said and written about leprosy in the Philippine Islands that it is appropriate that I should ask your indulgence as I enter the ranks of the contributors to the literature on this subject. If it were not that much of the work which promises a solution for the leper problem in these islands was begun during the past year, and that the details have not yet become generally known, I would not have the temerity to write on this subject for a Philippine audience.

Considering the disease historically, in its relation to these islands, it may be said that the data are very meager, and that a careful search of libraries, both public and private, and of the official records fails to throw much light on the subject. Among the royal documents on file in Sevilla, for the period from 1500 to 1638, in Section 5, drawer 2, bundle 23, is a record that the King of Spain acknowledged the receipt of a communication from the Captain-General of the Philippine Islands, on June 8, 1632, in which His Majesty had been informed that one hundred and thirty-four "converted Christians" who had been sent over by the Emperor of Japan had arrived in Manila Bay. The King directed that the "converted Christians" should be received with a parade, and that in addition to the five hundred reales already set aside by the Captain-General for their reception, two hundred reales be expended for their maintenance. In a book by Felix Huerta, entitled "The Geographical, Historical, Statistical, and the Religio-Historical State of the Philippine Islands," Edition of 1865, page 67, it is stated that these people were lepers, and were taken to the San Lazaro Hospital. This statement finds confirmation in the "Ultima Pieza del Expediente Institudo sobre la Organizacion del Hospital de San Lazaro" (The Last Part of the Report of the Investigation Made Upon the Organization of the San Lazaro Hospital), dated 1823, which records that one hundred and thirty lepers who arrived from Japan in the year 1632 were admitted to the San Lazaro Hospital in that year. There is also on file at the office of the Bureau of Health a letter from the Honorable Goro Narita, formerly Japanese Consul at Manila, to the effect that he had referred the foregoing statements to his home government for investigation, and had received information that the most minute researches had been made to ascertain the truth of the allegations, but the matter had not been definitely settled by the investigation, although several records had been found in ancient writings respecting the deportation of Roman Catholic friars from Japan to Luzon, as well as of the expulsion of Japanese believers in Christianity who were afflicted with leprosy, but that these records did not agree as to dates and other important particulars with the statements under inquiry. He added that the opinion of the governing authorities was that no lepers had ever been deported from Japan for sanitary reasons, but that there might have been some among the Japanese Christians who were banished when the feudal system prevailed in the empire.

From the recorded data it is impossible to determine whether the disease existed in the Philippines prior to the coming of the Japanese Christian converts or not, but the fact remains that it is now here in all its loathsome characteristics and menacing dangers, and the great problem is, how to get rid of it.

Before the American occupation, it was not so much a question of eradicating the disease as it was one of caring for the unfortunate victims of the malady who were poor or had no friends to take care of them. The care of lepers was a matter of charity rather than legal proscription, and was controlled by the church authorities. This method of dealing with leprous patients left many at large to spread the disease without restraint. The excellent work of the charitable orders that engaged in this laudable cause should, however, not be undervalued. The self-sacrifice and devotion of the noble men and women who gave their talents and their energies to the alleviation of the condition of the poor victims of this loathsome disease will ever stand as a monument to the greatness and godliness of human character; but such a policy, while paving the way for something better, could not in itself be reckoned as a factor in the elimination of the

*Address delivered before the Philippine Islands Medical Association.

scourge. This feature of the work was not seriously undertaken until after American rule had been established. Almost at the very inception of the Civil Government, negotiations were set in progress by the Secretary of the Interior, which led to the setting apart of Culion Island for the purpose of establishing a leper colony and for the complete isolation and segregation, not of the poor and outcasts, but of all alike. This policy may seem cruel and heartless, especially to those who are directly affected by its operation, but it was hoped that the close proximity of the island of Busuanga, where the friends of the lepers might locate or at least find temporary abode, and from which they could make frequent visits to Culion, would do much to mitigate this objection. Isolation is for the best interests of all concerned, for the benefit of the patients and for the protection of the public. But, unfortunately, this is a case where the ends of science and sentiment diverge, and the policy is far from being popular in the Philippine Islands, especially when it affects the homes of the rich and influential. The Government is proceeding slowly and cautiously, with the full assurance that the wisdom of its course will soon be manifest to all.

A study of the history of the war waged upon leprosy during the past few centuries shows that isolation offers the only method which has been consistently successful in eradicating or at least greatly reducing the number of victims. Even now, at the very beginning, a study of the statistics of the Philippine Islands will show that leprosy has already decreased to the extent to which the policy has been put in practice. In the Philippines, for the year ended August 31, 1904, there were 3,623 cases; for the year ended August 31, 1905, 3,580; for the year ended June 30, 1906, 3,494; for the quarter ended September 30, 1906, 3,473, and for the quarter ended December 31, 1906, 3,225.

A study of the history of leprosy in Hawaii shows that until isolation was carried out the number constantly increased. In 1866 there were 105 lepers; in 1894 there were 1,341; in 1900, 1,023; in 1901, 942; in 1902, 915; in 1903, 874; in 1905, 858, and in 1906, 828. For the twenty years preceding 1900, isolation was not very rigidly enforced, and it was not until after American occupation that the practice began to be systematically carried out; the above figures show that the disease has declined rapidly since that time.

The present capacity of the Culion Leper Colony is about 800. The actual number on the island January 1, 1907, was 546. In addition to the above, 219 are segregated in the San Lazaro Hospital, Manila. The remaining are distributed throughout the various provinces as shown in the table.

Undoubtedly, the simplest and easiest method of stamping out the disease and protecting the public would be to segregate all lepers at the colony, but when it is remembered that it would require an outlay of about 50 centavos (25 cents U. S. currency) per capita per diem to maintain the colonized lepers, or about 800,000 pesos ($400,000 U. S. currency) annually, and that the entire receipts of the Government are only about P20,000,000 per annum, it will be apparent that the financial difficulties are practically insurmountable; therefore, it has been necessary to plan a campaign which would be compatible with the finances of the Government as well as meet the requirements of practical sanitation. Fortunately, the geography of the islands is such that a plan could be put into operation at once, which offers great hope of success from the very

beginning. This plan consists in removing all lepers from those islands which are well isolated and at the same time have only a few victims, and subsequently, of removing all lepers from such islands as soon as the disease is detected. In this way a large amount of territory can be freed from lepers in a very short time, and by thus removing the principal sources of infection, there are good grounds for believing that the early disappearance of the disease will result.

The conclusion of the Germany Leprosy Conference of 1897, and also, more recently, that of Kolle and Black, was that the initial lesion is a small ulcer in the nasal mucous membrane. If this is true, it is quite possible that many of the cases in which the source of infection is so difficult to understand may be explained upon the hypothesis that they came in contact with lepers who were not known to have the disease. In order that the policy outlined above may have best hope of success, special attention is being given to this matter.

The islands of Mindoro, Masbate, Romblon (including Tablas and other islands of the same provincial government), Siquijor, Oriental and Occidental Negros, Panay, Palawan, and Cuyo are now practically free from lepers through the operation of this plan. At the very inception of this work, it became the fixed practice not to confine anyone at Culion from whom leprosy bacilli cannot be recovered and demonstrated by microscopical examination. In pursuance of this plan, it is worthy of record that a fair percentage of those who were reported to be suffering from leprosy, in the islands mentioned, were found to be negative on microscopical examination, and that by proper medical treatment many were cured of their ailments and re-

stored to society. If this same proportion is found to maintain in the remaining islands, the number of lepers will be much smaller than heretofore estimated and the solution of the leper problem will be far less serious than it has been supposed to be.

The question of a self-supporting leper colony and of lepers contributing to their support has received most careful attention, with the result that very little in this direction can be hoped for under the present conditions. In the majority of persons, the disease soon produces disabling deformities, with destruction of tissue, loss of fingers and toes, serious impairment of the nervous system, loss of muscular power, and general debility, and renders the patients incapable of performing the amount of manual labor which would be required in the operations necessary to support themselves in agricultural pursuits. They are precluded from engaging in manufacturing on account of the widespread prejudice against buying articles that have been handled by lepers, even though they may have been rendered safe by sterilization; then again, so many of the patients are confined to their beds, and the wounds and ulcers of others require so much attention, that a large proportion of the services of those who are able to work must be devoted to these duties, so that really very few are in position to give their time to profitable pursuits. Considerable work is also necessitated in the purely domestic duties, such as cooking, the making of clothes, cleaning and taking care of the houses, and in maintaining the streets, roads, and other public utilities in a state of repair.

The industry of cattle raising seems to promise better results than anything else that has been considered so far. The cattle could be shipped to Iloilo, Cebú, Manila, or other markets for slaughter, thus avoiding the prejudice that would naturally obtain against prepared products or manufactured articles. As cattle are not subject to the disease, and as they would not have to be handled by the lepers, there would probably be very little danger to the public in shipping them from the colony to noninfected districts.

The colony at Culion has been in actual operation since May 28, 1906, on which date 365 lepers from the San Lazaro Hospital at Cebú, which had been abandoned on the day before, were landed on the island. Four Sisters of Charity, belonging to the Order of St. Paul de Chartres, and a Jesuit priest, who were already at the colony, assisted in receiving the lepers, who were agreeably surprised and very much delighted with their new home, and expressed themselves as thoroughly satisfied with the provisions which had been made for them. After the novelty of their surroundings ceased to attract and divert them, many became oppressed with a feeling of homesickness, and yearned for the old familiar scenes to which they had been accustomed all their lives, but at no time did they find fault with the conditions at the colony.

The present colony consists of about 125 nipa houses, each of which is large enough to accommodate from five to seven lepers. These houses have been built with due reference to street lines, so that symmetry and uniformity add to the natural beauty of the "leper city." The new town is located on a plateau, the highest portion of which is about 150 feet above the sea level. This plateau slopes in all directions towards the sea, thus giving ideal drainage conditions. A pipe line about a mile long conducts water from a running stream to the colony, and in addition there is a reservoir into which water is forced from a spring by a gasoline water pump. This reservoir has been constructed at a height of more than 250 feet above the level of the sea, and from it water is conducted through a modern system of pipes to all parts of the town, and supplies the kitchens, halls, bathrooms, modern water-closets, and laundries. A complete sewer system with septic tanks, through which the sewage passes before it is finally conducted into the sea, has been installed.

The old town of Culion, which was purchased by the Government, has still a sufficient number of buildings standing to furnish a presidencia, or town hall, and residences for the presidente and consejales. The old stone church, built in Spanish times, is still in a state of good repair, and is used as a place of worship by the lepers. A band of forty pieces has been organized and frequent concerts are given.

The lepers are given the greatest possible liberty, and are controlled largely by regulations for which they themselves are responsible. They punish those who commit misdemeanors, in accordance with their own ideas of justice. The law-making power of the colony is vested in a presidente (president) and twelve consejales (councillors) who are elected by the people, while the police power is administered by twelve police who hold office by selection from among their own people. The police force, under the direction of the presidente, is charged also with the maintenance of proper sanitary conditions in the town, and with the arrest of offenders against the local regulations. A government could not possibly be more democratic than that which prevails at the Culion Leper Colony.

Quarters have been provided for the nonleprous employees at a distance of about a quarter of a mile from the colony.

In addition to attempting to combat the disease by isolation, a great deal of attention is given to every method of treatment that offers any hope of curing the disease. So far, the only treatment that has given any hope of success is the application of the *x*-ray. Encouraged by the results obtained with the Roentgen ray in the treatment of certain forms of skin diseases, and of lupus and cancer, the Secretary of the Interior and the Commissioner of Public Health, in 1903, decided upon the purchase of an *x*-ray machine, and the treatment of leprosy by this method was begun for the first time in the Philippine Islands, in January, 1904, by Dr. H. B. Wilkinson, the resident physician at the San Lazaro Leper Hospital. Dr. Wilkinson's method was to select those cases which presented the greatest amount of leprotic deposit, and expose the most afflicted portions of the body to the rays for ten minutes, at a distance of from seven to ten inches, the apparatus used being a ten-inch spark machine with a bifocal tube exhausted for a ten-inch spark; the distance and time of exposure being subject to such variations as were indicated by the individual peculiarities of the area under treatment, so as to approach as nearly as possible the burning point without actually inflicting injury. In only two cases was the process carried sufficiently far to burn the skin, and it is interesting to note that these two cases were the first reported as cured. In all, three cases were reported as recovered; of these, the first patient died a few weeks afterward of atrophic cirrhosis of the liver. Upon the completion of the autopsy in this case, Dr. Herzog of the Bureau of Science reported that the histological and bacteriological examination furnished no evidence that the

patient at the time of his death was suffering from leprosy, either cutaneous or internal. The treatment of the two remaining cured cases was interrupted for a long time on account of the breaking down of the machine and the necessity of sending to the United States for additional apparatus, which could not be supplied in Manila. Before the treatment could be resumed, the two cases relapsed, one about six months after the original treatment was stopped, and the other about nine months afterward.

The *x*-ray treatment is now in progress again, on a larger scale, and a report will be published when the data and results are sufficiently verified to justify definite conclusions, but it may be of interest to report here that one of the cases that was reported cured before, and which later relapsed, and in which leprosy bacilli were continuously found for a number of months, again, after treatment was resumed, at the end of three months, shows an entire absence of leprosy bacilli in the skin scrapings taken from regions in which they were previously found.

Since the American occupation, there have been only one American and one European known to have developed the disease. The cause of death is almost invariably some intercurrent disease; tuberculosis and beriberi being the most frequent causes during the present year.

The policy of the Bureau of Health aims at the segregation of every leper in the Philippine Islands, but until this becomes practicable the situation must be handled so as to secure the greatest amount of free territory possible in the shortest time. In the colony and elsewhere, lepers are entitled to every chance for their lives that science can give or suggest, and it is the aim and purpose of the present administration to secure to them every advantage that can possibly accrue from a systematic plan of action which has for its purpose the protection of the public, the alleviation of the suffering of the afflicted, with such chances for their lives as science can offer, and the ultimate eradication of the disease from the Philippine Islands.

In conclusion, it is submitted that whatever may be the views of well informed persons with regard to the communicability of leprosy, and however widely eminent medical men may differ upon his question, yet the incontrovertible fact remains that every leper who is capable of giving off leprosy bacilli to the media which surrounds him is at least one center of infection, and the utter hopelessness of successfully eradicating the disease so long as the exact mode of transmission is not conclusively proven, will be apparent to all. Prophylactic medicine should not be permitted to be turned by a few sentimentalists from its march to a goal which offers the magnificent victory of the eradication of this plague from the face of the earth, and the saving of hundreds of innocent human victims who are now sacrificed annually to this most loathsome disease.

MANILA, P. I

Contribution to the Study of Facial Hemispasm of Peripheral Nervous Origin.—Giuseppe Roasenda presents five cases of facial hemispasm of peripheral nervous origin. There is clonic spasm of the side of the face, of a subacute nature, without pain in the mastoid region. Electrical excitability is lessened, there being partial degeneration reaction. There is absence of response to external muscular stimuli, due to paresis of the muscles. The muscles are not painful, which distinguishes the condition from painful tic. These symptoms indicate a peripheral origin for the disease. The treatment should be moderate faradism of the side of the face.—*Rivista Neuropatologica.*

A NEW BLOOD TEST.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE AT THE NEW YORK POST GRADUATE MEDICAL SCHOOL

EXAMINATIONS for the presence of blood have recently increased in significance ever since Boas[1] reported the occurrence of occult blood as an almost constant symptom in carcinoma of the stomach. Usually the aloin or guaiacum test is employed for the demonstration of the blood.

Recently a new test with benzidin has been described by O. and R. Adler.[2] According to Schlesinger and Holst[3] it is made as follows: (1) A knife point full of benzidin (Merck's) is added to two c.c. of glacial acetic acid and allowed to stand. (2) A small piece of feces (about the size of a pea) is mixed with two c.c. of water and boiled in a test tube closed with cotton. (3) Ten to twelve drops of benzidin solution are added to two and a half to three c.c. of a three per cent. peroxide of hydrogen solution. (4) Three to four drops of the boiled fecal solution are added to reagent three. In the presence of blood a green or blue color results.

For the testing of stomach contents Schlesinger and Holst advise boiling the filtrate and proceeding in a similar manner as in testing the feces.

The guaiacum-aloin, or benzidin test, require the preparation of fresh solutions, which makes the test more difficult. I therefore have tried to simplify the test by making a reagent paper. I prepared an aloin paper and a benzidin paper. Aloin paper was made by saturating ordinary filter paper with a solution of aloin in seventy per cent. alcohol; the benzidin paper by moistening filter paper with a saturated solution of benzidin and glacial acetic acid, and drying it. In preparing the paper, as well as in making the test, it is of importance to avoid contact with the fingers, as a drop of perspiration causes a similar reaction. In handling the paper it is best to use an ivory tipped forceps, or protect the hand by means of a towel. Aloin paper is much inferior in sensitiveness to benzidin paper; I would, therefore, recommend the latter.

Mode of Procedure.—A piece of benzidin paper is immersed in the solution to be examined and a few drops of hydrogen peroxide are added. The piece of paper is placed on a piece of white porcelain and is examined for the development of a blue color. In the presence of blood a green or blue color arises in a few seconds to a minute.

Regarding the sensitiveness of the reaction it is greater, if we allow more time for its occurrence. In dilutions of 1 part blood to 500 parts of water a distinct reaction occurs in between thirty to sixty seconds. In dilutions of 1 to 2,000 a trace of blue occurs one to two minutes later. To wait longer for the reaction does not seem advisable, as after thirteen minutes the benzidin paper with hydrogen peroxide alone without blood will yield a blue color. For practical purposes it will be best to wait but one minute for the occurrence of the reaction. If after one minute there is no trace of blue, then the test must be considered negative.

In examining for blood in stomach contents too great a sensitiveness is not important, but rather a certainty that the test will indicate only blood. The longer we wait for the reaction the more substances besides blood may cause it. Benzidin paper can be used for testing for blood in stomach contents, urine, and feces. As all kinds of food may be

*Read before the German Medical Society of New York on April 15, 1907.

met with in the stomach contents, I have examined various articles of diet with the benzidin paper:

Benzidin paper + coffee + milk + sugar = 0.
" " + coffee = 0.
" " + pea soup = 0.
" " + boiled peas = 0.
" " + prune juice = 0.
" " + prunes = 0.
" " + tea + sugar = 0.
" " + red wine = 0.
" " + milk after one minute = 0, after one and one-half minutes = trace; aloin negative.
" " + milk ether extract after one minute = 0; aloin negative.
" " + potato substance = + trace.
" " + water in which potatoes have been boiled = 0.
" " + farina boiled with milk (thick) = + (at once).
" " + farina boiled with water = + (at once).
" " + white bread steeped in water = 0.
" " + hard boiled white of egg = 0.
" " + hard boiled yolk of egg = 0.
" " + boiled chicken = 0.

Farina and boiled potato applied to benzidin paper in substance produce a reaction. Decoctions of potato as well as thin gruels do not react. Milk after one minute gives a trace of reaction. If, when testing, we take the liquid part of the stomach contents and do not use the firm substance, the occurrence of the above substances (farina, milk, potato) would hardly influence the reaction.

To study the action of HCl on the benzidin paper the following experiment was made:

Benzidin paper + 1 to 1,000 HCl solution after one minute = 0, after two minutes = trace (?), after three minutes + green color.

Benzidin paper + 1-10 normal sodium hydroxide solution after thirty minutes = 0.

Benzidin paper + water after nine minutes = + trace.

Benzidin paper + stomach contents free from blood after three and a half minutes = +.

We can see, therefore, that HCl may cause the reaction, usually only after two to three minutes. If, therefore, we want to use the benzidin paper in testing for blood, we must not wait for a reaction longer than one minute.

I have made comparisons between the result obtained by benzidin paper and that by the usual aloin ether extract. It was as follows:

I.

TABLE OF STOMACH CONTENTS EXAMINED WITH BENZIDIN PAPER ALONE, AS WELL AS THOSE EXAMINED WITH BENZIDIN PAPER AND ALOIN ETHER EXTRACT.

No. of Stomach C'nt'nts Exam'd	Benzidin Paper Test	Aloin Ether Extract Test
54	Negative.	Not made.
8	Positive.	Not made.
13	Negative.	Negative
13	Positive.	Positive.
2	Positive (strong).	Negative.
4	Positive (trace).	Negative.
2	Positive.	Negative.
2	Test with ether extract, negative	Negative.

II.

COMPARISON OF THE BLOOD TESTS WITH BENZIDIN PAPER AND ALOIN ETHER EXTRACT IN VARIOUS DISEASES OF THE STOMACH.

a. Functional Diseases of the Stomach and Catarrh of the Stomach.

No.	Benzidin Paper	Aloin
09	Negative.	Negative.
4	Positive.	Positive.
1	Positive.	Negative.

b. Organic Diseases of the Stomach.

Disease	No.	Benzidin Paper	Aloin
Ulcer of Stomach	2	Negative.	Negative.
	11	Positive.	Positive.
	1	Positive.	Negative.
Cancer of Stomach	1	Negative.	Negative.
	5	Positive.	Positive.
Stenosis benigna	1	Negative.	Negative.
	1	Positive.	Positive.

Although there was no absolute coincidence between the benzidin and aloin test (see Table I), yet in most cases the result was the same.

Table II shows that the stomach contents may very well be utilized for blood examinations for the purpose of diagnosis instead of the more generally employed methods of examination of the feces. The frequent occurrence of occult blood was found, as stated by Boas, in cases of ulcer and cancer of the stomach.

The benzidin paper test can be recommended as a preliminary test. If there is a strong reaction at once or no reaction at all, we may regard the result as reliable. If, after one minute only a trace of reaction is present, then the aloin ether extract method may be used. If we use the ether extract for the benzidin test it makes it more sensitive and certain.

In examining urine and feces for blood I have also made use of the benzidin paper. For urine it is not as sensitive as an aloin ether extract. Feces of people living on common foods usually gives the reaction. The stool of a patient on a milk-and-egg diet does not give the reaction, except blood be really present. The stool may be examined in the following manner:

A small piece of feces (the size of a pea) is rubbed up with about two c.c. of water, the benzidin paper is immersed; a drop of hydrogen peroxide is added, and it is examined for blue color. Several stools of patients that have been on a diet free from meat were tested with benzidin paper and for comparison with aloin ether extract and with one exception the same result was always obtained.

I do not hesitate, therefore, to recommend the benzidin paper as a convenient method of testing for blood of the stomach contents, the urine, and the stool.

Too Much Civilization.—The South African Native Affairs Commission reports that while the adoption of European clothing by the natives has promoted public decency it has injured the health of the wearers.

SOME EFFECTS OF SPIRIT AND DRUG TAKING ON THE UPPER AIR PASSAGES.*

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.
SUPERINTENDENT WALNUT LODGE HOSPITAL.

THE object of this paper is to point out some facts which have not been considered prominent in a study of the causes of the inflammatory conditions of the throat and nose. While specialists in this field are familiar with these factors in the causation, they have not given them the importance which they deserve, simply because they are not familiar with the modern research work concerning the effects of alcohol and drug taking. The theory that alcohol is purely a stimulant and in so-called moderation has little or no influence on the membranes or organs of the body, is considered a fact beyond question, hence no inquiries have been made to determine its correctness. The conclusions from modern research that alcohol is a narcotic and corrosive in its action, particularly on the membranes, will be new to the general profession, yet the evidence on which it is based is voluminous and exhaustive. The multiplicity of new topics and tremendous advances in all departments of medicines are not only confusing to the general practitioner, but frequently turn his attention away from matters along every-day observation, and only when they are particularly pointed out are they recognized. The effects of spirits and drugs on the upper air passages are very marked and common, and yet they do not attract attention. It is always a question whether these effects are due specifically to any one cause or combination of causes, or are the results of general conditions, one intensifying the other; thus low vitality, sudden changes of temperature, reflex irritations, and congestions in distant parts, may all combine to produce disturbances: (1) The direct irritant action on the bronchial, pharyngeal, and nasal membranes, with thickening, anemia, and congestion; (2) the reflex irritant action from gastritis and other disturbances and irritations to other parts; (3) organic changes and paralysis of nerve tracts, cirrhotic states of the liver, kidneys, and mucous membranes generally. In my experience of nearly thirty years in the constant study and care of spirit and drug neurotics, it is an exception to the rule to find persons who have used spirits and drugs that do not suffer from catarrah and subacute inflammations of the throat and nose.

It is always an interesting question whether these inflammatory changes preceded the spirit and drug taking as exciting and predisposing causes, or followed as a natural result. Many persons have a history of nasal and throat congestions due to direct irritation, followed by exhaustion and debility, for which spirits and narcotics have been found most agreeable remedies. Common examples are of persons breathing air containing irritants and exposed to great changes of temperature, who have found cocaine, morphine, and other narcotics to give great relief. This is quickly followed by an addiction and a distinct drug neurosis in the future. Other persons have bronchitis and inflammatory states of the throat which are treated by spirits covered up with syrups, and the narcotic effect is so pleasant that the drugs are continued. All specialists and general physicians understand that there are degrees of susceptibility to take on inflammatory states of the membranes of the throat and nose from very slight and apparently insignificant causes. There is present a feeble resisting power in the mucous membrane to any changes and irritations; this is frequently inherited and depends very largely on the defective nerve centers controlling these parts, as well as want of training, bad surroundings, bad diet, etc. The direct irritant effect from alcohol on the membranes is well illustrated by comparison with its effects on the surface of the hand or body. Placing a drop of alcohol on the surface, a sensation of chill and irritation which follows will be increased by more alcohol, until inflammation and destruction of the skin follows. This is an example of its action on the mucous membrane of any part it comes in contact with. This is due specifically to its rapid water-absorbing properties, abstracting the moisture from the tissues with such rapidity as to give a sense of chill, followed by irritation, and finally ending in inflammation. These effects are noted in alcohol taken as a beverage in any form and the sense of irritation and burning in its passage over the mucous membrane is due to its water-abstracting property. Water is used before and after spirits are taken to overcome the sensation; the more pronounced the irritation, the greater the amount of alcohol. It will be readily understood that the frequent and continuous use of spirits, producing a constant irritant action of a greater or less degree, is a direct cause of inflammatory states of the membrane. Clinical observation confirms this, not only by examinations of the throats of drinkers, but the changed tone of voice indicating thickening and changes of the vocal cords. In chronic cases, both the bronchial and nasal tones are pronounced, the carrying properties of the voice are markedly lowered, and its volume is diminished and replaced by harsh, jerking, indistinct sounds, and even beer drinkers who sing bass lose their power of control and the tone becomes broken and harsh.

Leading singers quickly discover that alcohol and tobacco seriously impair and finally destroy their vocal powers. We shall show that these effects are due to both local and constitutional changes in the blood-vessels and nerve filaments and absorbents. It will be new to many persons that the congestion of the face so common in spirit takers is an exact duplication of what occurs in the membranes of the brain and mucous surface of the throat and nose. One with an intensely red or pallid face, showing hyperemia or anemia, has deranged capillary circulation of all the membranes, particularly those rich in blood-vessels. The vasomotor paralysis of the facial nerves diminishing the contractile power of the arteries on the face is the same in the throat and nose. A recent German writer has declared that "this palsy is followed by varicose states of both veins and arteries in the membranes of the throat and nose, accompanied with fibrinous deposits and exudations." The supposed stimulant action of alcohol is found to be an irritant and a paralyzant, and also a narcotic. It is a chemical irritant absorbing the water from cell and tissue. The flushed face of the spirit drinker is simply palsy and narcotism of the vasomotor centers regulating the circulation and the contraction and dilatation of the walls of the blood-vessels. The heart is greatly increased in activity by the use of spirits; more blood is sent to the surface, but with it comes the diminished contractile power of the nerves to force the blood back again, hence the forcing of the blood to the surface distends the blood-vessels and de-

*Read before the Buffalo Academy of Medicine, February 12, 1907, Buffalo, N. Y.

ranges the circulation more and more with each repetition until permanent degeneration follows. The whole capillary system of the membranes of the brain, upper air passages, and face is disturbed, deranged, and diseased. Drugs which produce anemia or blanching and diminution of the flow of blood in the vascular structures are followed by the same results. The nutrition suffers from this profound derangement and the metabolic processes are interfered with. The toxins and waste products are retained and form new centers of irritation.

Elimination is checked and suppressed. The mucous membrane of the throat and nose is very vascular and abundantly supplied with arteries, veins, and nerves, and hence suffers more directly from this cause. This is evident by the increased secretion of water and mucus. After a time the flushing of the face by the use of spirits becomes permanent and the walls of the arteries are hypertrophied, and the nerves atrophied. The mucous membranes suffer in the same way. In constant spirit drinkers the burning sensation of the throat becomes less and less, and strong spirits produce only slight sensations. Hypertrophy of the membranes and mucous exudations with subacute inflammatory states follow, then come bronchial coughs and distressing irritations of the nose and throat, resisting all ordinary treatment. In many instances these conditions are regarded as premonitory symptoms of tuberculosis and are treated with spirits, morphine, cocaine, and other narcotics. Dr. McKenzie of London remarked long ago that "it was comparatively easy to cure bronchial and nasal inflammatory states in persons who abandoned all use of alcohol or narcotics, but unless this was done the disease would continue almost indefinitely." The changes in the voice are very significant symptoms of both the inflammatory conditions of the nose and throat and their influence on the vocal cords. Good judges assert that it is possible from a study of the voice to determine the health or disease of the membranes, and also that there are certain peculiar sounds which distinguish the spirit drinker from the opium or cocaine taker. In a general way the spirit drinker has a rasping, explosive echo, while the drug taker has a tremulous, soft, muffled tone of voice. It is very evident in a singer, in whom tobacco and spirits sharpen and ruffle the timbre and volume of the tone. A tenor singer invariably exhibits the use of spirits or tobacco by his inability to sustain high or continuous notes, and by his constant tendency to sharp the notes. Some very interesting studies have been made with a phonograph to show the change of the voice and improvement following total abstinence in persons who have chronic inflammatory conditions of the throat and nose. The patient talks into the phonograph at different times, pronouncing sentences, or singing bars: the notes, volume, and timbre of the voice are thus accurately recorded. Defects of the senses, particularly of taste, smell, and hearing, following these inflammatory states of the membranes, offer a most fascinating field of study, because the changes and variations can be noted with a degree of exactness: also perversions of sight and mental changes due to these inflammations are of intense interest.

Many of these conditions are physiological variations, not only local but constitutional. There are now certain conditions and effects which may be considered positive from the amount of evidence on which they are based, thus the constitutional action of alcohol, not only as a vasomotor paralyzer, but as a disturber of nutrition, is continuous. The result of capillary congestion and anemia is diminished osmosis between the veins and arterial capillaries, associated with defective oxygen-carrying properties of the blood, and accumulation of carbon and fibrinous deposits. The blood corpuscles are shrunken and deranged and do not take up oxygen from the lungs freely, as is readily seen in examination of the blood of persons who are using spirits. In the blood currents the red corpuscles are diminished in exact proportion as the system becomes saturated with spirits. The phagocytes are shriveled and diminished, the hyperemias and anemias can be traced, not only in the blood counts but in the blood-cells. Another fact equally well established is that vascular congestion and defective circulation due to alcohol are always followed by accumulation of toxins, which form deposits and foci for the development of inflammatory states, and with this there is diminished power of resistance and ability to neutralize and throw off the germs lodged on the surface. Another fact is that alcohol coming in contact and carried by the blood vessels to the capillaries has a special corroding action on the cells and dentrites, not only because of its water-absorbing properties, but also by its union with the granular matter of the cell. Another fact which has not been noted is this, that when the system is saturated with spirits to a degree it is exhaled from the lungs as vapors and spirits, the mucous membranes of both throat and nose suffer directly from its irritant action. This point of saturation is not confined to local congestions of any one part of the body, but extends to all the organs, particularly the liver and kidneys. Its action is both corrosive and erosive of the dentrites, cells, and tissues, and is to all intents and purposes a veritable neuritis. Recently we have recognized that the so-called rheumatisms and pains, both local and general, in the extremities, in persons who use spirits, are due to inflammations of the nerve extremities, and are literally neuritis; also that many of the conditions termed la grippe, malaria, biliousness, and other derangements associated with chills, fevers, and exhaustions are purely toxemic. The poisons from alcohol and other irritants have concentrated on the nerves of the extremity as well as in the degeneration of the nerves of the mucous membrane, checking elimination and practically encouraging states of disease and inflammation.

The influences so prominent at this time of the year are very pronounced and intractable in the spirit and drug taker. Sir William Barlow declared that "alcohol was the largest factor in the production of la grippe and chronic catarrhs of the throat and nose, by deranging the capillary circulation and destroying the nutrition and vitality of the nerve cells." The periodic drinker, who uses spirits to excess, then abstains, recovers in some degree from the damage and immediate effects of spirits, but the continuous user of wine, or beer, or other spirits, in so-called moderate doses, has always pronounced throat and nose affections. It may be of a minor character, and not attract much attention at first, and is treated by home or proprietary remedies, but later, when the inflammatory conditions become chronic, degenerations and growths follow, and also ulcers and distinct local inflammatory conditions. When the spirit is removed the improvement is so marked as to prove beyond question the intimate relation as cause and effect between the alcohol and these disorders.

Probably one of the most dangerous and seductive drugs is cocaine, which has come into very common

use, both medically and surgically, for its analgesic action. Its value depends on its sudden paralysis of the nerve-fibers and capillary blood-vessels, producing pronounced blanching and anemia. The sensory fibers are suspended first and the walls of the blood-vessels are paralyzed, the blood is driven out, and then the motor nerves are checked and slowed up. When this action passes off there is an intense vascularization and secretion of water and mucus and a degree of irritation that calls for a repetition of the drug. It is asserted that this action is due to the chemical combination of the drug with the plasma and cell contents, suspending their action at once, and this is reflected to the brain and spinal cord. Later as an irritant, and still later when the amount is large and the use continues, the effects are noted by peculiar hallucinations; this paralyzing action becomes cirrhotic, the walls of the blood-vessels retract and become varicose, nutrition is lessened, and degeneration of a corrosive nature follows. The blanching of the face is palsy of both the constrictors and dilator nerves. All sensation is cut off and this condition of the membranes of the nose is followed by a deceptive sense of comfort. The drug is literally a narcotic, suspending nerve activity and nutritional force. After a time this derangement extends to the higher cerebral functions and becomes a neurosis of the most dangerous and seductive character. Constant erosion follows, which is concealed and covered up. Cocaine prescriptions for diseased conditions of the throat and nose have proved very useful and valuable remedies, but they must be given with care and discretion. The paralysis resulting from the constant use of this drug in the nasal passages extends down to the throat and larynx. And the changed tone of the voice registers this inflammatory condition. The hearing is also affected, and profound anemia of the nasal passages is often a symptom of the use of this drug. It should be remembered that many persons take this drug secretly, but after a time the mental and other symptoms betray them.

Tobacco is another irritant and narcotic to the upper air passages. Like cocaine, its effects are direct and in chronic conditions, where the system is thoroughly infected, it is an active cause of disease of these membranes. One of the worst forms in which it can be used is the cigarette, and this is due specifically to the combustion taking place in close proximity to the mouth, where all the gases and products come in immediate contact with the mucous membrane. In the case of the pipe and cigar, many of these poison products are condensed and deposited in the stem of the pipe and body of the cigar, and only a small part is carried into the mouth. In the cigarette, when the smoke is inhaled and driven through the nose, its action is direct and cumulative. The nicotine and other products are corrosive and irritating, not only to the terminal nerves, but the capillaries, and these poisons are absorbed and carried to all parts of the body. The injury not only disturbs the surface circulation and the osmotic and metabolic changes, but it destroys nutrition and produces states of local starvation. The cigarette smoker has both anemia and hyperemia of the mucous membrane of the throat and nose. He complains of catarrh and defective smell and change of voice, and his nerves become hypersensitive. By inhalation small quantities of smoke and other products are more thoroughly absorbed than if the quantity was larger and the smoking more rapid. There are various degrees of resistance to the poison of tobacco, but the effect of its continuous absorption is marked, not only on capillary disturbances, but on the nerves and brain sooner or later.

Morphine and other forms of opium have no specific direct effect on the upper air passages, except that of a narcotic, and these effects are followed by anemia and general pallor of the face and eyes. The senses are diminished and low forms of subacute inflammatory states of the membranes follow. They are thickened, and fibrinous deposits come on. The control of the voice is weakened and general conditions of exhaustion appear. Other drugs have a similar effect, only more pronounced, on the constitution.

In my particular work very marked changes are noted in the disappearance and practical relief from long-standing catarrhs and chronic inflammation of the throat and nose by abstinence from spirits. I have noted a number of cases of bronchial troubles supposed to be tuberculosis occurring in moderate drinkers. Removal of spirits, nerve rest, and constitutional remedies are often followed by recovery. A number of persons in these times of stress and strain who are secret spirit and drug takers, and who suffer from throat and nasal troubles, are the subject of much anxiety to both physicians and friends. When their real trouble is discovered and the drugs removed, the obscurity of the case clears up. One is greatly impressed with this fact by the number of persons supposed to be temperate who have decided disorders of the voice and who frequent the specialist for conditions that are very ill defined. Efforts to give relief by catarrhal remedies are unsuccessful, and a great variety of causes are considered as active, together with degrees of debility and general feebleness. Such persons go to sanatoriums and recover; in reality they have become abstainers, and the degenerative action of alcohol has been removed. There can be no doubt that rhinitis and bronchitis may precede tuberculosis, and the result of efforts to check these inflammatory states and prevent their so-called passage downward is of great uncertainty, unless the general constitutional condition of the person is known and treated. The general fact is coming more and more prominent, viz., that the effects of alcohol and drugs, taken either openly or secretly, in small or large doses, falls most heavily on the capillary circulation; this derangement predisposes to the growth and development of bacteria, and with this a diminution of the resisting forces of the body; these all form a chain of causes that should never be overlooked or misunderstood. I conclude with the statement made some years ago by the late Dr. Gross of Philadelphia. "The upper air passages reflect the damage of alcohol and tobacco, and should always be considered in a study of inflammations of these parts."

Surgery of the Biliary Passages.—Lejars considers choledochoenterostomy a makeshift among the various methods for exploration and drainage of the chief biliary passages. In one of his own cases, in which he had intended to perform cholecystenterostomy, he found the gall-bladder so small and retracted that he was not able to make the desirable anastomosis with the intestine. He consequently did a choledochoenterostomy. Although the patient seemed to improve, he died three days later. Lejars believes that this operation should be employed only as a last resort when nothing else can be done. In a case of old obstruction of the ductus communis choledochus, Lejars had recourse to duodenotomy. The result was excellent, the circulation of the ductus communis choledochus being reestablished. Since his last report of three cases, this operator has added to the list three more cases treated according to Kehr's method. In these six cases recovery took place.—*Gazette des Hôpitaux Civils et Militaires*

RECENT ADVANCES IN OUR KNOWLEDGE OF SYPHILIS.

THE theory of syphilis established by Ricord and his school long remained unchallenged, but in the last few years many discoveries have been made which have greatly modified our conception of this disease. Mehler, writing in *Die Umschau* of March 16, 1907, briefly summarizes some of the more important work which has been done in this line. Experience had proved that syphilis is a contagious disease, communicable by direct contact, but the germ of syphilis remained unknown until Schaudinn and Hoffmann identified it, a few years ago, as a very thin filiform protozoon, *Spirochæta pallida*. This organism has been found in so many cases that there is now little doubt that it is the cause of the disease. Greff, a Berlin oculist, after producing syphilis in the eye of a rabbit by inserting a fragment of a syphilitic inguinal gland, found the spirochete in the rabbit's eye before any visible morbid change had occurred. But with the gradual accumulation of white blood corpuscles the germs diminished in number and ultimately vanished. This is a striking confirmation of Metchnikoff's theory of the agency of phagocytosis in the prevention of disease.

Now, although the spirochete can usually be found, without difficulty, in the primary and secondary stages of syphilis, its occurrence in the tertiary stage was not proved until very recently. Doutrelepont of Bonn has, however, found the protozoa, though in small numbers, in four cases of tertiary syphilis. Finally, in inherited syphilis, the spirochete has been found, both in the child after birth and in the fetus, in almost every organ, though chiefly in the liver, stomach, and intestine.

According to Ehrmann of Vienna, the germs spread from the focus of infection along and even through the nerves. This is an important discovery, which appears to confirm the current attribution of certain serious nervous diseases to antecedent syphilis, and as it is reasonably certain that the spirochete, like typhoid and many other bacilli, may remain in the organism for years in a latent state, we find here strong support for the view that tabes, at least in some of its forms, is a product of the syphilitic virus.

Next in importance to the discovery of the germ is that of the communicability of syphilis to monkeys. Neisser, in particular, has experimented on a large scale in Java and produced symptoms very similar to those of human syphilis in all species of monkeys and apes, the closest approximation to the human disease occurring in the highest species. Last year (1906) Neisser and others finally succeeded in inoculating monkeys with tertiary syphilis. Recent tertiary growths, in which suppuration had not occurred, whether appearing late or soon after the primary infection, produced typical primary syphilis in monkeys to which they were transplanted. The inoculation was not always successful, doubtless owing to the relatively sparse occurrence of the spirochete in tertiary syphilis.

In the light of these experiments every person showing even tertiary symptoms must be regarded as a possible source of infection. The primary and secondary products, however, are particularly dangerous, because they contain greater numbers of germs, occur on the genitals and mucous membranes of the mouth, and often present a harmless appearance. Inherited syphilis can also be transmitted by inoculation and the nasal mucus of syphilitic children is particularly virulent. Hoffmann has also apparently proved, in contradiction to current opinion, that the blood of recently infected patients is a source of contagion. From all this follows the extremely important conclusion that syphilis is contagious in every stage and type, and that every organ of a syphilitic person may harbor the germs of the disease.

It was formerly believed that a person who has once had syphilis is henceforth immune to the disease and that this immunity is shared by children of syphilitics, even if they have not inherited the disease—a reversal of the law that the sins of the fathers shall be visited upon the children, but this last assumption has long been disproved by the frequent occurrence of syphilis, acquired by contagion, in children of syphilitics. The supposed impossibility of a second infection has also proved illusory in numerous cases, although repeated infection is still regarded as exceptional. Recently, however, so many cases have been reported by competent observers that we can no longer speak of permanent immunity produced by a first infection. Finger and Landsteiner assert that a second infection is possible even before the first attack is cured. This second infection is not necessarily followed by the primary symptoms which it would have caused in a previously healthy subject, but rather by an aggravation of the symptoms already present as a result of the first infection. If the patient, therefore, is already in the secondary or the tertiary stage, the fresh infection simply increases the secondary or tertiary symptoms. This view, however, is disputed by some authorities.

Although these discoveries have thrown much light on the origin and nature of syphilis, they have suggested little in regard to treatment, except to indorse most emphatically the classical method. Mercury still remains the sovereign remedy for syphilis. Every attempted serum treatment has failed. Mercury alone is able to influence the disease in every stage, probably by paralyzing the spirochete. But it must be remembered that the administration of mercury simultaneously with the introduction of the germ does not prevent the outbreak of primary syphilis, although recent experiments would seem to show that the hope is not

without foundation that an effective serum will yet be discovered and that the cure of syphilis, as of other diseases, will ultimately result from the discovery of its germ.

THE TREATMENT OF CAISSON DISEASE.

The disease known by this name is not often seen by the general practitioner, yet it is of considerable interest, as the march of improvement has provided more opportunities for its occurrence. Caisson disease is met with in those who work in compressed air at pressures greater than the normal fifteen pounds to the square inch, and is believed to be due to the presence of gas emboli in the circulation. The liability and frequency of this condition make it necessary to institute the proper prophylactic measures in every undertaking where caissons are employed as part of the construction work, and these precautions are directed primarily to the physical character and condition of the men employed. The thoroughness of this examination may be appreciated from a recent article on the subject by Pelton (*American Journal of the Medical Sciences*, May, 1907), in which it is stated that the candidate's previous history with regard to ophthalmic, nasal, aural, rheumatic, cardiac, pulmonary, hepatic, renal, and venereal conditions and cranial injuries, is carefully inquired into. Observation has shown that the Anglo-Saxon and the negro are less subject to the evil effects of air pressure than are Italians, Poles, and men of other races. It seems to be very important to accustom the intended worker to the increased air pressure gradually. This is done by putting him in a pressure of from twenty-five to thirty pounds for a time and then submitting him to a second examination. Even if accepted for this work, the men must observe especial precautions, in which they are carefully instructed. The change from the caisson to the outer air must always be gradual, and proper living in the intervals of work must be insisted on. Four types of caisson disease can be distinguished, which are termed bends, staggers, paralytic, and comatose states, but no distinct lines can be drawn to differentiate these groups, the symptoms of which are often closely interwoven.

In the treatment of this so often fatal disease the first step is recompression of the patient—that is, he must be again subjected to the influence of compressed air—and this is accomplished in a specially constructed chamber called the hospital lock. In the milder cases this is usually sufficient to produce relief from the pains, although the process may be aided by the application of various counter-irritant measures. Analgesics, including antipyrin, codeine, and morphine, may be necessary, although aside from recompression little can be done in the way of specific treatment In the severer types, symptomatic treatment is indicated, particularly as regards stimulation of the heart and respiration. The after-treatment is also very important, and in addition to the general tonic measures the paralysis requires the routine measures applicable to the chronic stage of peripheral neuritis. It will be seen therefore that the treatment of this condition, which so long as the present methods of constructing certain engineering works are in vogue will be constantly met with, is now fairly well understood. The dangers connected with caisson work will not be correspondingly diminished unless the workers can be made to appreciate properly the necessary precautions, and this is apparently something which the human mind, as exhibited in many of the workmen, can only be made to realize with difficulty. We have had numerous reports of fatal accidents in compressed air workers which were distinctly due to carelessness on the part of the workers or those directly responsible for their welfare, but as we are now sufficiently well acquainted with the conditions, excuses for their occurrence cannot well be tolerated.

THE CAUSE OF SUBCUTANEOUS HEMORRHAGES.

Among the pathological conditions of which our knowledge is still very unsatisfactory are the hemorrhagic lesions associated with certain forms of septicopyemia, purpura, and a number of dermatoses, erythema nodosum among them. It has been assumed that these phenomena are the local or distant effects of some irritant, but whether of bacterial or other origin has never been satisfactorily ascertained. Naturally enough, the attempt has been made to reproduce these lesions in animals by the injection of bacteria or their toxins, but thus far no definite result has been obtained. The most recent study is made by Heyrosky (*Wiener klinische Wochenschrift*, No. 9, 1907), who used in his experiments sterile filtrates of bacterial cultures, and by inoculation in white mice produced hemorrhages under the skin and mucous membranes. For the purpose he employed glucose-bouillon cultures of *Diplococcus pneumoniæ* and *Streptococcus mucosus*, two varieties which are believed to be closely related in a biological sense. Within twelve hours after the subcutaneous or intraperitoneal inoculation of the filtrate the mice showed a localized hemorrhagic exanthem over the parts thinly covered with hair, while the more thickly covered parts were entirely free from this lesion. They were also affected with a more or less bloody diarrhea. The majority of the animals, which had received but one injection of from 0.2 to 1 c.c., recovered; when a second injection was given the mice either died or, in a number of cases, survived and resisted further injections.

Autopsies showed extensive minute hemorrhages in almost all the organs of the body, although those in the skin, the lungs, and the rectum were the most marked. Cultures made with the blood from these animals remained sterile, and staining of the tissues with methylene blue or the Gram-Weigert failed to show the presence of any bacteria. The report of the histological examination of the specimens is reserved for a later communication, but the preliminary statement as to the possible specific toxic character of this hitherto obscure disease is to be regarded with considerable interest. If proved to be true, it will not be long before an attempt will be made to place the treatment of the condition upon a more satisfactory and rational basis, the possibilities of which are indicated by the explanation of the etiology of the disease.

The Treatment of Frost Bite by Artificial Hyperemia.

While the number of plans of treatment recommended for the relief of the immediate and secondary results of the local action of excessive cold is very large, it must be confessed that they still leave much to be desired. It has been the object of some of these measures at least to reduce the venous stasis that forms so prominent a feature of the clinical picture of pernio, but according to Ritter (*Münchener medizinische Wochenschrift*, May 7, 1907) this vascular condition is to be looked upon as being a conservative process. In local freezing both arterial and venous hyperemia have the same object, that is, to protect the frost-bitten tissue with more blood and to assist regeneration of the injured cells. The stage of stasis is always preceded by a period of anemia, and the hyperemia is a curative effort. Ritter has employed artificial means to augment this natural hyperemia in about one hundred and fifty cases of freezing of various degrees of intensity, and recommends the method as being superior to all others. Two methods are used, passive congestion by means of Bier's bandage and the use of the hot-air chamber. While the author thinks highly of the former procedure, he states that he considers the hot-air treatment the best of all, especially for chronic cases. Usually daily sessions increasing in duration from fifteen minutes to one hour are given, and cures of even extensive lesions about the hands are to be expected in from three days to two weeks. The effect is said to be especially beneficial in promoting the healing of chilblains and ulcers, and great relief is afforded from the itching that is usually complained of by patients of this class. One drawback that would seem to attend this plan of treatment is the demands on the time of the physician that it entails, but the lesions of frost bite, while not ordinarily dangerous to life, are often incapacitating and well worthy sacrifices on the part of the patient and medical attendant for their relief. One especially valuable feature of the treatment is said to be the fact that it relieves the affected parts from the heightened susceptibility to cold that ordinarily persists for years after the original freezing.

Sea Air in the Treatment of Neurasthenia.

The value of climatic factors in the treatment of the disease indicated has been frequently disputed, mainly on account of the uncertainty of the results obtained, and idiosyncrasy has apparently been nowhere more marked than in this respect. In a recent article on this subject in the *Neurologisches Zentralblatt*, No. 14, 1906, Ide acknowledges that sea air has a two-fold action on the nervous system, as it may act either as a sedative or a stimulant. The sedative effect resides in the quality of the sea air itself, which provides in the first place for an equable and uniform evaporation of heat and moisture from the body, and in the second place stimulates the oxygen absorption. The latter, by increasing oxidation, naturally aids the excretion of various intermediary metabolic products which have an influence in bringing about certain neurasthenic symptoms. A stimulating effect, on the other hand, is produced by the physical properties of the sea air. Among these is the wind, and, further, the fact that, owing to the readier conductivity of the sea air, the warmth generated by the body is more quickly dissipated. These factors exert, however, a tonic effect on the system, and if the individual is too weak, or if the stimulus is too strong, the sedative is subordinated to the stimulating action, and the result is unfavorable. The essential point in the treatment, therefore, is properly to equalize the sedative and stimulating factors. The former may be brought out by rest cures, the latter by a gradual but methodically increased sojourn in the open, in the wind, and along the shore. It would appear, therefore, that with a sea-shore climate we can at will produce a sedative or a stimulating effect on the nervous system and at the same time favorably influence tissue metabolism.

Dissecting Puerperal Metritis.

Although puerperal infections are fortunately declining in frequency, severe types of the condition are still encountered. One of the more unusual forms is that known as dissecting metritis, and Offergeld (*Deutsche medizinische Wochenschrift*, May 9, 1907), as the result of an analysis of sixty-three reported cases, describes it as being a destructive uterine infection in which, in consequence of the necrosis of the deeper layers of the uterine wall, the dead tissue is cast off in a continuous membrane reproducing the form of the interior of the organ. It is the result of a coccal infection in which the organisms penetrate deeply into the substance of the muscle, and by virtue of great virulence cause extensive death of tissue. The symptomatology of the condition includes a progressive enlargement of the uterus beginning shortly after delivery, and accompanied by a moderate degree of fever. The pulse is very rapid, but is characterized by a better quality than is that of sepsis. The lochia are fetid, uterine tenderness and evidences of peritoneal irritation increase, and finally, in the course of the fourth week, the gangrenous tissue is cast off. The prognosis is bad, one patient in four succumbing, and, even if death does not follow, the uterus is usually so seriously damaged as to be incapable of functionating, and, owing to the stenosis of its lumen that is likely to result, hematometra and hematosalpinx are common sequels.

News of the Week.

Dr. Wm. Kelly Simpson will give a clinical lecture on "Intubation of the Larynx" in the amphitheatre of the Vanderbilt Clinic on Monday afternoon, June 10, at 4 o'clock, in connection with the exercises celebrating the one hundredth anniversary of the College of Physicians and Surgeons. Members of the medical profession are cordially invited to attend.

New York State Board of Medical Examiners.—The Board of Regents has appointed the following as members of the new State Board of Medical Examiners provided for by the consolidation of the three former boards: Drs. W. W. Potter and Lee H. Smith of Buffalo and W. S. Searle of Brooklyn for terms of three years; Drs. W. S. Ely of Rochester, Eugene Beach of Gloversville, and Floyd M. Crandall of New York City, for two years; Drs. Frank W. Adriance of Elmira, Floyd S. Farnsworth of Plattsburg, and Ralph H. Williams of Rochester, for one year. The Board of Regents elected Dr. Maurice K. Lewi of New York City, the present secretary of the joint medical boards, as secretary of the new medical board. Four members of the board are regulars, three are homeopaths, one is an eclectic, and one is an osteopath.

Public Health and Marine Hospital Service Examinations.—A board of officers will be convened to meet at the Bureau of Public Health and Marine Hospital Service, Washington, D. C., on July 15, 1907, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service. Candidates must be between 22 and 30 years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination, as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of thirty, forty, and fifty dollars a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, 10 per cent. in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service. Further information may be obtained by addressing the Surgeon-General, Public Health and Marine Hospital Service, Washington, D. C.

Civil Service Examinations.—The State Civil Service Commission will hold examinations on June 29, 1907, for the position of physician, sixth grade, regular school, State and County Hospitals and Institutions, with a salary of $900 and maintenance. The last day for filing applications is June 22. Full information and application forms may be obtained by addressing Mr. Charles S. Fowler, the Chief Examiner of the Commission at Albany.

To Restrict the Spread of Rabies.—At last week's meeting of the Board of Health it was decided to urge the Board of Aldermen to pass an ordinance giving the police authority to shoot all dogs without muzzles or collars found at large in the city, and to prosecute all persons suffering such dogs to roam at large.

Hospital Transfer Bill Passed.—Both the Senate and Assembly have passed over Mayor McClellan's veto the bill making the transfer of seriously ill patients from one hospital to another a misdemeanor punishable by a fine of $100.

A New Measure for Identification.—M. Bertillon, the Chief of the Intelligence Department of the Paris detective service, has introduced a new feature into his system of measurements of criminals by the aid of which the identification of suspects may be facilitated. It consists of a specially constructed piece of photographic apparatus, by means of which accurate measurements to scale of the prisoner's features may be obtained and recorded. In this great importance is attached to the measurement of the distance from the outer canthus of the eye to the external auditory meatus.

Medical College at Manila.—A medical school that is designed to be the first college of a future University of the Philippine Islands is shortly to be opened in Manila. The Philippine government has appropriated the sum of $62,000 for the first year's expenses, and a building formerly used by army engineers is being remodeled and equipped for this purpose.

Incoming Steamers Quarantined.—The liners *Kroonland* and *Statendam*, from Antwerp and Rotterdam respectively, were retained at Quarantine on account of the presence of smallpox and typhoid fever among the steerage passengers. All of these were transferred to Hoffman Island and the steerage quarters were fumigated before the vessels were allowed to dock.

Quarantine Against Havana.—The United States Marine Hospital Service has imposed a quarantine against Havana to be effective throughout the Gulf States.

Meningitis in Glasgow.—None of the medical or nursing staff of the Glasgow City Hospital have contracted cerebrospinal meningitis during the recent epidemic, although for weeks they had very large numbers of such patients under their care. Dr. Chalmers, the health officer of the city, as the result of an investigation of the question, has come to the conclusion that infection usually takes place through the nasopharynx and that the practice of promiscuous kissing, especially of infants and children, should be discouraged.

Berlin's Declining Birth Rate.—The Municipal Statistical Bureau draws attention to the decline in the birth rate in Berlin, which has been almost constant since 1876, when there were 240 births for every 1,000 married women. In 1906 the rate was only 10 per cent. Illegitimate births steadily increase, being now nearly 17 per cent. of the whole, compared with 15 per cent. in 1901 and 12 per cent. in 1875.

An Examination of Canned Meats.—The State Health Department has made an examination of 154 samples of roast, corned, dried, and potted beef, potted and deviled ham, canned chicken, turkey, and sausages. Twenty-five of the samples were found to be preparations with low grade meat contents, and seven with very poor meat contents, but one can of potted ham was found to be a preparation from diseased meat. Preservatives were found in many of the samples and adulterants also existed.

To Restrict the Use of Tobacco by Minors.—The Wisconsin Assembly has passed a bill prohibiting the use of tobacco by boys under the age of sixteen years.

A Title as a Fee.—According to the press despatches, Dr. Guiterrez, the Spanish physician who, with the English physician, Dr. Glendenning, was in attendance upon Queen Victoria during her recent accouchement, has refused to accept any pecuniary remuneration for his services, but will receive the title of Marquis bestowed upon him by the King.

Post-Graduate Hospital Tuberculosis Annex.—Owing to a lack of funds, the Post-Graduate Hospital annex for the treatment of tuberculosis will have to be restricted in scope or discontinued unless financial aid is secured for this object.

Dr. Andrew P. Biddle, of Detroit, for the past six years secretary of the Michigan State Medical Society, on the occasion of his recent resignation from that office was presented by the society with a suitably inscribed platter of silver.

Dr. George Sumner Huntington, Professor of Anatomy, College of Physicians and Surgeons, Columbia University, New York, received the honorary degree of Doctor of Laws at the eighty-second annual commencement of the Jefferson

Medical College of Philadelphia, held on June 3, 1907. Professor Huntington delivered an address on "Modern Advances in the Teaching of Anatomy and Other Medical Sciences."

Dr. Robert Smart, Lieutenant and Assistant Surgeon, has obtained an honorable discharge from the Army and will engage in private practice. He was admitted to the medical corps of the Army in 1901.

Dr. J. Blake White of this city was recently elected by the Board of Trustees a member of the consulting staff of the Littleton, N. H., Hospital.

Demonstration of Teaching Methods.—In connection with the celebration of the one hundredth anniversary of the College of Physicians and Surgeons, New York, a series of demonstrations illustrating some of the newer methods of teaching will be held on Tuesday, June 11, as follows: 9-10 o'clock. *Physiology*: at the laboratory of the department, by Professor Burton-Opitz and Dr. Haven Emerson: The action of the valves of the heart; the circulation of the blood in the capillaries; clinical methods of recording certain facts of circulation and respiration. 10-11 o'clock. *Surgery*: at the physiological laboratory, by Professor J. A. Blake and Dr. J. W. D. Maury: Recent studies at the surgical laboratory; the technique of undergraduate teaching in surgery. 11-12 o'clock. *Biological Chemistry*: at the laboratory of the department, by Professor W. J. Gies and assistants: The action of enzymes; some of the chemical phases of the newer physiology of digestion. 12-1 o'clock. *Pharmacology*: at the recitation room of the department, by Dr. A. N. Richards: The action of certain common drugs upon the heart.

Tuberculosis Camp.—A free sanatorium for indigent tuberculous patients is to be established at White Pine Camp, Mont Alto, Pa., at a cost of $300,000 or more, out of an appropriation of $600,000 made by the Legislature. The site is an admirable one by reason of its elevation, atmospheric conditions, and physical conformation.

American Gastroenterological Association.—At the tenth annual meeting of this Association, held in Atlantic City, N. J., June 3 and 4, 1907, the following officers were elected for the ensuing year: *President*, Dr. J. P. Sawyer of Cleveland; *Vice-Presidents*, Dr. J. A. Lichty of Pittsburg and Dr. G. D. Kahlo of Indianapolis; *Secretary and Treasurer*, Dr. Charles D. Aaron of Detroit.

New Jersey State Medical Association.—The coming meeting of this organization will be held at Long Branch on June 25, 26, and 27, 1907, instead of at Cape May as originally announced.

Middle Tennessee Medical Association.—Officers as follows were elected at the meeting of this society held in Murfreesboro on May 17: *President*, Dr. R. Douglass of Nashville; *Vice-President*, Dr. E. Jones of Murfreesboro; *Secretary and Treasurer*, Dr. William Litterer of Nashville.

Wayne County (Michigan) Medical Society.—Officers for the ensuing year were elected as follows by this society at its meeting held in Detroit on May 20: *President*, Dr. A. N. Collins; *Vice-President*, Dr. Kenneth Cunsolus; *Secretary*, Dr. W. D. Ford.

Vermont State Homeopathic Medical Society.—At the meeting of this society held in Montpelier on May 22 officers as follows were elected: *President*, Dr. W. E. Locke of Bradford; *Vice-President*, Dr. W. H. Everett of Castleton; *Secretary*, Dr. G. I. Forbes of Burlington; *Treasurer*, Dr. F. E. Steele of Montpelier.

Michigan Homeopathic State Medical Society.—The thirty-eighth annual meeting of this organization was held in Detroit on May 23, and officers were elected as follows: *President*, Dr. S. H. Knight of Detroit; *Vice-Presidents*, Dr. J. H. Ball of Bay City and Dr. A. V. Avery of Parma; *General Secretary*, Dr. D. W. Myers of Grand Rapids; *Corresponding Secretary*, Dr. F. A. Kelley of Detroit; *Treasurer*, Dr. R. M. Richards of Detroit. The next meeting will be held in Ann Arbor.

Connecticut State Homeopathic Medical Society.—At the twenty-seventh annual meeting of this society held in Norwich on May 17 officers as follows were elected: *President*, Dr. S. S. Ives of Meriden; *Vice-President*, Dr. S. Worcester of Stamford; *Secretary*, Dr. H. A. Cameron of Waterbury; *Treasurer*, Dr. E. J. Walker of New Haven.

Nebraska State Homeopathic Society.—At the annual meeting of this Society, held May 21 and 22, at Lincoln, the following officers were elected: *President*, H. R. Miner, Falls City; *First Vice-President*, F. A. Marsh, Seward; *Second Vice-President*, F. F. Teal, Omaha; *Corresponding Secretary*, W. K. Foote, Omaha; *Recording Secretary*, F. S. Whitman, Omaha; *Treasurer*, O. S. Wood, Omaha.

Obituary Notes.—Dr. Edward R. O'Reilly of Elizabeth, N. J., died on May 27 of appendicitis, at the age of forty-eight years. He was born in Norwalk, Conn., and after receiving his degree from the New York University Medical School began practice in Elizabeth in 1882. For five years he was a member of the New Jersey Board of Health and was for eight years City Physician of Elizabeth. He was also at one time County Physician.

Dr. J. Fields Hasty of Murray, Ia., died on May 21, at the age of forty-four years. About a year ago he was compelled to give up active work on account of the development of a tumor of the brain, which was the cause of his death.

Dr. Joseph D. Mansfield of Wakefield, Mass., died on May 22, at the age of ninety years. He was born in Lynnfield, and received his medical education at Dartmouth College and from the Vermont Medical College at Woodstock, from which he was graduated in 1841. Since the date of his graduation he had practised in Wakefield, and he had been a member of the Massachusetts State Medical Society for more than half a century.

Dr. J. P. Lewis of Topeka, Kan., died on May 20, at the age of fifty-eight years, after an illness of several months. He was born in Sulphur Springs, O., and in 1873 was graduated from the Ohio Medical College at Cincinnati. After practising for a time in Lexington, and later at Pleasantville, O., he came to Topeka in 1883. He served in numerous public offices, and was the first county health officer of Shawnee county.

Dr. George D. Duggins of Denver, Col., died on May 17, at the age of sixty-seven years. He was born in Saline county, Mo., and served through the Civil War as regimental surgeon in McGruder's division. At the close of the war he completed his medical training at the St. Louis Medical College, from which he was graduated in 1866. He practised for a time at Fort Leavenworth and Miami, Mo., and in 1881 removed to Pueblo, Col., where he had remained until a few months before his death.

Dr. P. A. A. Collet of Fall River, Mass., died on May 21, at the age of sixty years. He was born

in St. Henry, Can., and received his medical degree from Lavalle University in 1871. He came to Fall River ten years later, and had served several terms as city physician and member of the Board of Health.

Dr. CHARLES SIMPSON of Minneapolis, Minn., died on May 17, at the age of sixty-four years. He was graduated from the College of Physicians and Surgeons in 1871, and began practice in Minneapolis shortly afterward. He served as Health Commissioner, was a member of the Board of Education, and from 1895-1898 was a member of the State Board of Medical Examiners.

Dr. EDGAR POPPLETON of Portland, Ore, died on May 16, at the age of seventy-four years. He was graduated from a medical college in Cincinnati in 1854, and shortly afterward made the journey across the Continent, settling at Lafayette, where he resided for many years, afterward removing to Portland. He was the first coroner of Multnomah county.

Dr. GEORGE BOICE DURRIE of this city died on June 1 of heart disease. He was born in New Haven, and served in the Twenty-seventh Connecticut Volunteers during the Civil War. After the close of the war he completed his medical education at Yale, from which he was graduated in 1865. For thirty-five years he practised in this city, and was formerly visiting physician to the Metropolitan and Hahnemann Hospitals.

Dr. AMASA M. BUCKNUM of Denver, Col., died on May 25 at an advanced age. He was graduated from Castleton Medical College in 1849 and practised for thirty-two years in the two towns of Spring Harbor and Parma, Mich. In 1881 he went to Denver, and had practised there since that time, occupying several hospital and dispensary positions.

Dr. JAMES B. EVERETT of Everett, Mass., died on May 20, at the age of seventy-nine years. He was graduated in medicine from Dartmouth College in 1860, and after practising for ten years in Falmouth, N. H., removed to Everett.

Correspondence.

THE TRYPANOSOME OF DOURINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Pathologists will be interested in the information that the *Trypanosoma equiperdum* has been found in a mare clinically affected with dourine, or *maladie du coit*, at the Quarantine Station established by this Department at Lethbridge, Alberta, in 1904. The first demonstration was made by Drs. E. A. Watson and M. V. Gallivan on February 11, 1907, in material taken from a vesicle on the mucous membrane of the vagina of the animal above referred to, which was found to be affected with dourine on the premises of her owner, Mr. R. Tiffin, near Lethbridge, on December 21, 1906, and subsequently removed to the Quarantine Station for purposes of experimental observation.

The disease was successfully transmitted in February to a yearling filly and the parasite subsequently observed in preparations from a fresh plaque. The finding was confirmed by Dr. C. H. Higgins, pathologist of the Department, on March 21, and was further observed in preparations taken by him on the 23d and 25th of the same month.

The identity of dourine, or *maladie du coit*, as seen on this Continent, and hitherto diagnosed by American and Canadian veterinarians from clinical manifestations alone, with the disease as known in Africa and Asia, as well as in southern Europe, is thus fully established. A detailed report of the discovery and of the work which led up to it, as well as of the steps subsequently taken, will be issued at the earliest possible date.

J. G. RUTHERFORD
Veterinary Director General

OTTAWA, ONTARIO.

"DIPSOPHILIA."

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In Boswell's Life of Johnson, we read: "After supper, Dr. Johnson told us that Isaac Hawkins Browne drank freely for thirty years, and that he wrote his poem, *De Animi Immortalitate*, in some of the last of these years. I listened to this with the eagerness of one who, conscious of being fond of wine, is glad to find that a man of so much genius and good-thinking as Browne, had the same propensity."

As I do not agree with the opinion of many eminent members of the medical profession that alcoholism is a disease, but consider it rather a propensity, hereditary or acquired, I shall, for want of a better term, designate it "dipsophilia," otherwise any similar addiction, or fondness, for some inordinate passion, such as bridge-whist, golf, or any sport or pastime, might, with equal justification, be inserted in the index of morbid conditions. Any defect in our nature which exhibits a tendency to withdraw us from the path of morality or rectitude must not necessarily be regarded as a diseased process, and to term alcoholism a disease is an abortive attempt on the part of the profession to elucidate a social problem in a manner altogether inconsistent with modern thought and progress.

I have always considered, regarding the regrettable habit of indulging in alcoholic beverages, that those who are thus afflicted are made infinitely worse by those who themselves boast of their rigid adherence to total abstinence or irreproachable sobriety. The man who takes liquor is no more to be despised than the inveterate snuff-taker, the confirmed tobacco-smoker, or the society sylph who, weary and worn, is ushered into the Land of Dreams by her familiar chloral hydrate or sulphonal. All are equally guilty of moral turpitude—just the same as the poor laboring man who "cannot do without his glass of ale." Fierce and blatant harangues against drinking, in which the unhappy toper is reviled, scorned, and painted by some anemic orator as a foul and loathsome creature—a vampire sucking the life's blood of his wife and children, and a being altogether outside the pale of salvation—are unworthy of a moment's consideration. These enthusiasts forget that Christ himself drank grape juice in moderation, and that many of the ancient patriarchs were themselves wine-bibbing profligates.

Let us take the percentage of suicides. We shall find that no small number are recruited from the ranks of drunkards. What does this teach us? It discloses the fact that some unstable individual, who has been unable to control his irresistible and insatiable appetite for alcoholic stimulation, has awakened from his debauch, and, smitten with a horrible remorse, has sought to expiate his downfall by "a sleep and a forgetting." Instead of finding sympathy extended towards him; instead of finding his tremulous hand grasped by the firm fingers of an honest brother, he too frequently awakes to find himself battered, beaten, and bruised in the *atrox spelunca* of a modern dungeon. Then he is brought before a sleek and sarcastic Recorder (probably no angel himself) and openly proclaimed a hopeless and abandoned outcast. He is then sentenced to a harsh term of imprisonment—instead of some sequestered retreat—amid the jests of a ribald multitude and the tears and anguish of his starving dependents. Thus the last state of that man is worse than the first.

In order to improve this lamentable condition of affairs we want no nauseating doggerels about "Father, dear father, come home to us now," nor do we want to punish the inebriate any more than the morphine-taker or the tea-tippler—we want to find out how the evil can be remedied without having to appeal to the justice of the Middle Ages. We punish some poor, discouraged, and distraught wretch for attempting to commit suicide, when a ten-dollar bill would snatch him from the stygian slough in which he is engulfed. It is not the drunkard or the suicide that is to blame: it is "man's inhumanity to man." It is the State which makes its citizens drunk; it is for the State not only to sober them, but also to lead them into no further temptation. Under any conditions it is the Legislature that is culpable and not the individual.

RAYMUND H. PHILLIMORE, M.D.

MONTREAL.

PILOCARPINE IN PRURITUS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Regarding the use of pilocarpine in pruritus, as advised in the MEDICAL RECORD of May 25, it has been the writer's custom for many years to use this drug with advantage in cases of urticaria (so-called, really lichen urticatus), with intolerable itching. As these cases have usually

a debilitated condition as their underlying cause, a mixture containing quinine, arsenic, strychnine, and pilocarpine, all in the form of the chloride with dilute hydrochloric acid, has been found uniformly successful.

JOHN W. MCCULLOUGH, M.D.

ALLISTON, ONTARIO.

OUR LONDON LETTER.

(From Our Special Correspondent)

OLIVER-SHARPEY LECTURES; DEGENERATION AND REGENERATION OF NERVES—SANATORIA FOR WORKERS' ASSOCIATION; PRINCE OF WALES PRESIDING—TEMPERANCE HOSPITAL—TOTTENHAM HOSPITAL—OBITUARY.

LONDON, May 17, 1907.

PROFESSOR HALLIBURTON delivered the Oliver-Sharpey lectures at the Royal College of Physicians on the 29th and 30th ult., taking for subject "New Facts in Relation to the Processes of Nervous Degeneration and Regeneration." In the first of the two lectures, he dealt almost exclusively with nerve degeneration from a chemical point of view. He pointed out that the decomposition products of lecithin, as shown by Dr. Mott and himself in previous investigations, can be detected in the circulating fluids in degenerative nervous diseases. Accordingly, taking cholin as one such product, they suggested that if found in the blood or cerebrospinal fluid it showed that nervous tissue was breaking down, and therefore would help to distinguish organic lesions from functional disorders. The methods first used for detecting cholin have been held by some observers to be unreliable and further investigations have been made. The plan now adopted by the lecturer is to add a strong solution of iodine in potassium iodide to cholin platinochloride, whereupon the crystals are replaced by dark-brown plates and prisms somewhat like crystals of hemin. This periodide of cholin rapidly changes into oily droplets of a brown color if the slide is left to stand to evaporate. The addition of more solution causes a repetition of the changes. The obtaining of a large crop of crystals, whether of the cholin salt or a mixture of potassium and cholin salts was stated to be diagnostic of extensive breakdown in nervous tissues. The contrast between such cases and the insignificant yield from normal blood was most striking. A further investigation has been started for the estimation of the potassium in the cerebrospinal fluid and blood in cases of acute degenerative diseases of the nervous system in comparison with the normal. At present no final figures were given, but as far as the preliminary work has gone the lecturer said it indicates a considerable increase of potassium in those cases where disintegration has occurred and where cholin is discoverable.

In his second lecture, Professor Halliburton turned to the question of regeneration of nerves. He related experiments designed to settle whether the autogenetic regeneration theory, which has lately been revived in this country and Germany could be maintained. His investigations, and those of others working with him, led to the conclusion that it cannot, and so far go to rehabilitate the Wallerian theory. In no one case did he obtain any evidence of autoregeneration. Rather, his facts taken in conjunction with those of Cajal, Langley, and Anderson are strongly in favor of the Wallerian doctrine that new nerve fibers are growths from the central ends of divided nerve trunks. The facts recorded by Bethe and Kennedy he held are easily explained on the lines emphasized by Langley and Anderson of accidental, unnoticed connection of the peripheral segments with the central nervous system by means of other nerves cut through in the experiment. If such connection is effectually prevented, real regeneration of structure and restoration of function never occurs. Moreover, the regenerated fibers always degenerate in a peripheral direction, and that only when the link binding them to the central nervous system is again severed. The most striking new fact brought forward by the lecturer is in reference to the development of the medullary sheath; this appendage of the axis cylinder appears earliest at situations near the point where the ends of a nerve have been joined together and reaches the distal portions later. In the peripheral segment of a divided nerve there is multiplication, elongation, and union into long chains of the neurilemmal cells, and the same change occurs in the central end, but is more vigorous. Here the nutritive function is effective, and provides for the nourishment of the actively lengthening axis cylinders, while at the peripheral end it is ineffective unless the axons reach it.

The Prince of Wales presided on Tuesday evening at a dinner in aid of the National Association for the establishment of sanatoria for workers suffering from tuberculosis. The gathering was a very influential one, including royalties, ambassadors, and other notabilities. The health of the King having been honored, the toast of the other members of the royal family was proposed by the American ambassador, who said this was a toast always welcome to more than British circles, there never having been a time when American chivalry did not bow low in respect to the Queen of England. Touching gracefully on the advent of the Danish princess and subsequent events, he passed on to say no characteristic has distinguished the Queen, as well as the whole royal family, more than their eager identification with every beneficent helping hand held out by those who have to those who have not, and particularly in the struggle by the well-to-do to sustain hospitals for the poor—that tender recognition of the common brotherhood of the human race which becomes so strong a hope for the permanence of social order and the development of human progress. Other equally felicitous expressions filled the Ambassador's speech, to which the Prince replied, proposing success to the Association which has established the first sanatorium, as I have previously informed you, and which is already in need of enlargement. The subscriptions announced at the dinner amounted to £13,261

On Tuesday the Princess Louise opened a new out-patient hall at the London Temperance Hospital. The chairman, in an address, pointed out that last year the patients attending averaged 220 a day, and, though no charge was made and they were very poor, they had contributed £300 to the funds. The Princess hoped the new hall would enable the hospital to do tenfold the work it had been doing. It is curious how managers still harp on the large numbers they provide for, and yet the profession has long been protesting against the abuse of the out-patients' departments. A very different interpretation might be placed on the figures with which the public is supplied.

The Prince of Wales opened new wards at the Tottenham Hospital last week, and announced that at the request of the Princess Louise, president, and the governors, he was willing for the institution to be named after him. Accordingly, in future it will be known as the "Prince of Wales' General Hospital."

The death of Dr. Robert Barnes, in his ninetieth year, will recall to the oldest members of the profession one whose name was among the most honored in their early days. His M.D. Lond. dates from 1848. He was made F.R.C.P. in 1850, and there are only three Fellows surviving who were senior to him in the Fellowship. As perhaps the foremost obstetrician of his time, he filled in due course the various offices in his college, was examiner from 1864 to 1876, Lumleian lecturer 1873, councillor 1876, censor 1877-8. He was also F.R.C.S., Eng., 1883, and in 1887 the Irish College of Physicians conferred on him the honorary Fellowship. The societies and academies at home and abroad which conferred their highest distinctions upon him are too numerous to mention. The Royal Maternity Charity, the London Hospital, St. George's Hospital, the Children's Hospital, the Seaman's Hospital, St. Thomas's Hospital, and others had the benefit of his work, and the attached schools that of his teaching. In all these positions he was admired for his great acquirements, his able teaching, and the high tone of his conduct, so that his name was synonymous with all that is most learned and most upright. His "Obstetric Medicine and Surgery" and his lectures on "Obstetrical Operations" will be known to your readers as the text-books of a generation. His "Clinical Exposition of Diseases of Women" and his works on "Placenta Prævia and Fatty Degeneration of the Placenta" may also be mentioned among his contributions to obstetrical literature. The *Transactions* of the Obstetrical and Gynecological Societies contain other valuable essays from his pen. He was one of the principal founders of both these societies, and retained his interest in them to the last. He was a hale and healthy man, full of energy in his old age. He had for some years retired to Eastbourne, but thought nothing of a run up to London when his affairs seemed to him to need attention. He had a cerebral attack some three or four weeks ago, but recovered enough to drive out daily, and he came to London in the first week of this month. On the 10th, however, he had another attack, and died on the 12th.

Mr. J. F. C. H. Macready, F.R.C.S., Consulting Surgeon to the great Northern Central Hospital, died on the 29th ult., aged fifty-seven. He was a son of the celebrated actor. He became a student at St. Bartholomew's Hospital, took his M.R.C.S. in 1874 and the Fellowship in 1876. Two years later he was appointed surgeon to the Great Northern, which he served through many years on the committee as well as the staff. He was also surgeon to the Truss Society, to the City of London Chief Hospital,

and other institutions. He wrote a "Treatise on Ruptures" in 1893 and contributed to the journals on this and allied surgical topics.

Dr. John Mill Frodsharn, J.P., formerly Physician to the North London Consumption Hospital and some other institutions, died on the 12th inst., at the age of seventy-two. He took the M.R.C.S. in 1856 and M.D., Edin., the next year. He was a King's College student, of which he became Associate.

Dr. Samuel Lodge of Bradford died on the 9th inst., aged eighty-three, after a long illness. He was many years surgeon to the police, and on one occasion was stabbed with a pen knife by a lunatic. Early in his practise he also lost the sight of one eye, and later he broke a thigh, from which he became permanently lame. He wrote on Woolsorter's disease, as to which he had considerable experience; also on hydrophobia, on china grass as an absorbent and antiseptic, etc.

Surg.-Maj. L. Armstrong of the old Thirteenth Light Dragoons (retired) died at Weston-super-mare on Saturday after a brief illness. The late officer, who was seventy-seven years of age, served as an army surgeon throughout the Crimean war and attended the wounded among the survivors of the six hundred at Balaclava.

The death is also reported from Mentone of William Higginbotham, M.D., in his ninety-fourth year.

PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

FOURTH ANNUAL MEETING.

(From Our Special Correspondent.)

At the closing session of the Philippine Islands Medical Association, held March 2, the first paper, entitled "Quantitative Investigations of the Phenomena of Agglutination" was read by Dr. Y. K. Ohno of the Biological Laboratory, Bureau of Science. The next paper was entitled "Observations on the Etiology of Dengue Fever," by Captain P. M. Ashburn, Assistant Surgeon U. S. Army, and First Lieutenant Charles F. Craig, Assistant Surgeon, U. S. Army. The principal feature of this paper may be summarized by the statement that the authors have conclusively shown that dengue can be transmitted by mosquitos, and that in all probability the offending mosquito is the *Culex fatigans;* that the average incubation period of the disease is three and a half days, and that eleven cases were produced experimentally in United States soldiers who volunteered for the experiment, and that the most painstaking scientific research has failed to show any microorganism as the causative factor of the disease. The authors were further of the opinion that the organism must be ultramicroscopic and to be classed in the same category as that of yellow fever. They concurred in the findings of Stitt that leucopenia is an important diagnostic aid.

The next paper, entitled "Some Remarks Concerning Kubisagari, or Vertige Paralysant," by Kinnosuke Miura, Professor of Internal Medicine in the Imperial Japanese University at Tokio, was read by Dr. R. P. Strong. He stated that this interesting disease had prevailed for a considerable period among the peasant class of Japan, more especially in the neighborhood of Homori and Iwatekin, northern provinces. The principal symptoms are dimness of vision, ptosis, diplopia, difficulty in speech, in deglutition, and in mastication, weakness in the muscles of the back of the neck and of the extremities. He stated that this disease was identical with that observed by Gerlier in Ferney, Switzerland. The disease was most common in the summer time. He stated that the length of the attack was short, not exceeding ten or fifteen minutes. The patients were apparently perfectly well between the intervals of the paroxysms. The causative factors of the disease are not definitely known, and are usually ascribed to bodily exertion, especially to labor in a stooping position, and repeated uniform movements. The attacks are usually diminished, or stopped altogether by a change of climate and by rest. Many superstitions have been ascribed as being the cause of the disease. Gerlier was the first to emphasize the close connection between those who work in horse and cow stables, and pointed particularly to the fact that it occurred in laborers and other persons employed in the care of cows or horses, or who lived in houses in which cows and horses are kept. The writer found that the disease occurred among the same class of people in Japan. Prophylactic measures consisted in removing from the neighborhood of cow and horse stables, and the avoidance of such places especially for the midday or night sleep. Very little can be attained by the use of medicaments, but potassium iodide and arsenic seem to give the best results.

"Infant Feeding in the Tropics" was the title of a paper read by Dr. W. E. Musgrave, of the Biological Laboratory, Bureau of Science. He quoted statistics from the Bureau of Health, which showed that of 26,180 children born since 1903, 18,795 had died before they reached the age of one year. This was a most appalling mortality. He attributed it principally to the lack of knowledge in proper infant feeding, and stated that the milk of the Filipino mothers was entirely inadequate in quantity and in quality, in consequence of which rice, and even sometimes meat, were fed to the young offspring. In addition to the efforts which were made by the Bureau of Health to spread information of this kind throughout the islands by means of circulars, and through instruction in the different schools, he believed that a large public movement was necessary before satisfactory results could be obtained.

Dr. Sia Tien Pao, Delegate from His Imperial Chinese Majesty's government, delivered an address before the Association which was not strictly of a medical nature, yet was full of interest. He took occasion to justify the American occupation of the Philippines, and stated that no disinterested observer could come to the Philippines and fail to be impressed with the grand work of beneficence which was being carried on by the United States. He believed that his country was now awakening, and that the Chinese would naturally turn to the United States as the fountain of higher learning, and to obtain therefrom valuable aid necessary in the greater part of the work along lines of medical reform.

The last paper before the Association was entitled "A Summary of Some Experimental Work in Plague Immunity," by Dr. R. P. Strong, Chief of the Biological Laboratory, Bureau of Science. He stated that among prophylactic and curative serums there were encountered those which possessed antitoxic properties, of which diphtheria serum might be named as a type; those which manifest a bactericidal power, an example of which is encountered in immunization against cholera; those which combined antitoxic and bactericidal power, such as one obtained from animals immunized to the dysentery bacillus; those which possess antiinfectious power, of which plague serum may be given as an example. With regard to opsonins, he stated that much of the work that had recently been reported upon was done by trained investigators, yet a considerable proportion had been performed by men new to the field, and he felt convinced that the claims by many of the results attained would not be warranted by more careful work in the future. He stated that there were many sources of error in determining opsonic indexes and the personal equation is of considerable importance. It seemed to him not unlikely that in some of the experiments performed in the study of opsonins it is sometimes the action of the complement alone, and sometimes, although more rarely, the action of the immune body which has been considered to represent the opsonic action. He also investigated the question as to whether human beings and animals vaccinated against plague organisms, possess a higher opsonic index against the organism than do normal human and animal sera. His method was to take an unimmunized animal, such as the guinea-pig and inoculate it intraperitoneally with 10 c.c. of a sterile suspension of aleuronat. After from 12 to 16 hours the animal was killed with chloroform. The abdominal exudate, if sterile, is collected and mixed with a 1 per cent. of ammonium oxalate solution in 0.85 per cent. sodium chloride solution and thoroughly centrifuged. The packed corpuscles were then washed several times in excess of saline solution, and each time recentrifuged. In performing the tests one volume of leucocytes, plus one volume of the serum to be tested, are thoroughly mixed and incubated for 30 minutes at 37 degrees centigrade. After this, smears are prepared and stained with methylene blue. Control experiments with two normal sera of the same species of animal, as well as the control of the nonphagocytic power of the washed leucocytes, were prepared. The method of counting the phagocytic cells, as suggested by Simon, rather than the number of bacteria in each phagocyte, as recommended by Wright, is simpler, and the error of variation between repeated counts is obviously not so great. In carrying out the above experiments it has not been difficult to show that the blood of an individual or animal immunized against pest usually shows increased opsonic action over that of normal human or animal blood. However, since the normal opsonic index varies considerably in different individuals, and in the same individual from time to time, variable results may sometimes be encountered in a few instances. The general law may be determined from the study of a series of cases. In conclusion, he stated that plague immune serum acts neither as an antitoxic nor typical bactericidal serum, but that its action may be said to be antiinfectious and opsonic in nature.

At the business meeting of the Association different reports were read and a number of resolutions were passed.

In connection with the meetings of the Association, a pathological exhibit, which was changed every day, was also ready for examination at the Bureau of Science; some 200 specimens were shown. Among other things shown were piroplasmata, about which Dr. Kannusuke Myajima read a paper, and excellent specimens of the disease gongosa, which has recently been found in the Philippines, and many other interesting specimens.

Several resolutions were passed to the effect that the Committee on Public Policy and Legislation should report to the commission the desirability of appointing a commission to investigate uncinariasis in the Philippines, and also that steps be taken to arouse public interest in connection with infant mortality.

The following officers were elected for the ensuing year: Dr. W. E. Musgrave, *President;* Dr. C. F. Craig, *First Vice-President;* Dr. G. Singian de Miranda, *Second Vice-President;* Dr. Paul C. Freer, *Councillor* for five years.

Progress of Medical Science.

New York Medical Journal, May 25, 1907.

A Case of Melanuria.—The patient of F. Bierhoff was a man nineteen years old in his first gonorrheal attack in its fifth week. In addition he had a prostatic abscess. After a steady improvement from three weeks' treatment in the author's hands, he passed, one morning, blackish, sooty urine and examination showed that the color was caused by granules and clumps of melanuria. The patient had been subjected to an intense nervous shock some thirty-six hours before the melanuria was noticed. Its occurrence did not lead the author to make any change in his treatment of the gonorrheal condition, and in forty-eight hours more the urine was clear. The microscope still showed granules of pigment, but even these disappeared in two days more. In all the patient remained under observation six weeks longer without any return of the melanuria. The author makes some remarks as to the occurrence of this condition, stating that the urine may be dark on voiding, or it may in the presence of the chromogen of melanuria become dark only after exposure to the air. Under the lens the pigment is visible as dark brown or perfectly black granules or masses, irregular in shape, and usually of small size.

Congenital Stenosis of the Pylorus.—A case is reported by J. J. Gilbride, who refers to recent literature on the subject and gives a general description of the condition. His own patient was a male infant seven weeks old who, after he had passed his fourteenth day of life, began to vomit intermittently after nursing. The condition gradually grew worse and finally everything was rejected and he fell off from ten pounds, the weight at birth, to five. The chest revealed nothing abnormal. Inspection of the abdomen showed epigastric distention and the outline of a dilated stomach. Peristaltic waves passing from left to right were distinctly visible. Abdominal wall was thin and the pylorus palpable. A diagnosis of complete pyloric stenosis was made and operation advised. The parents wished that medical treatment should be followed a few days before surgical intervention. Lavage of the stomach, small amounts of food by mouth, and nutrient enemata brought no relief and the child died. No autopsy was held. Medical treatment may be of benefit in cases of partial stenosis only. Mortality from medical treatment in complete stenosis is 100 per cent.; from surgical 4.65 per cent.

Serum Therapy and Serum Diagnosis in Syphilis.—S. Pollitzer reviews recent progress along the lines indicated in his title. Space forbids the description of all the laboratory and clinical experiments which have led to our present knowledge. It has been demonstrated (1) that the immune serum of syphilitics contains antibodies and (2) that the syphilitic extracts contain antigens. By way of control it has been shown that (1) the immune serum of apes gives the reaction only with the syphilitic material of man or apes, not with the nonsyphilitic materials of either; (2) that normal nonsyphilitic ape serum is ineffective with syphilitic material; (3) serum of apes treated with extracts from the organs of nonsyphilitics gives no reaction with known syphilitic material. Finally the immune serum works equally well whether prepared with human or simian syphilitic material, a striking corroboration of the identity of human and simian apes. This, then, is a specific serodiagnostic reaction for syphilitic material which enables us to determine in the laboratory *in vitro* the presence of specific antibodies against the syphilitic organism in human serum or in prepared immune serum, and, second, to show the presence of syphilitic substances in a given organ.

The Results of Excision of the Hip in Tuberculosis of the Joint.—C. Ogilvy discusses the relative values of early and late excision, the bearing on the question of the age of the patient, etc. He prefers the Langenbeck operation, which is thus described: A longitudinal incision four to five inches long is made in the middle of the great trochanter, extending upwards beyond the trochanter for two to three inches, in a line the direction of which runs towards the posterior spine of the ilium. The bone is immediately exposed, the gluteal muscles are separated, and the rotators now exposed are cut transversely. The finger is passed along the neck of the bone. The capsule comes into view as the superior external part of the acetabulum. The capsule is split longitudinally, and the head exposed. The muscles over the trochanter with their attachments are raised with the periosteum by the scalpel and elevator. The cotyloid ligament is incised, the head rotated out and the ligamentum teres cut. The head of the bone can now be pushed through the opening in the capsule, and the excision be completed. This can be done rapidly and with very little hemorrhage; sometimes without having to ligate a single vessel. After operation, extensive immobilization and protection should be continued for at least a year. The length of time for continuance of mechanical treatment will depend upon the grouping of conditions in each particular case. Passive and active motion of the limb and, later, weight-bearing should be begun as soon as possible, care being taken not to cause inflammatory irritation sufficient to again light up the disease. Mortality is always high. Statistics are given from different reporters. At least 10 per cent. of all deaths are caused by general miliary tuberculosis. Excision is by no means a prevention of systemic infection. It would even seem at times that it was a cause rather than a prevention if we consider the number of cases which develop miliary tuberculosis after the operation.

Journal of the American Medical Association, June 1, 1907.

The Final Triumph of Scientific Medicine.—N. Senn reviews the progress of medicine, especially of late years, and says that there is no country, with the possible exception of Japan, in which the medical profession has made more rapid strides than in the United States. As evidence of this he points out our many thoroughly equipped medical schools and laboratories, the activity of the profession as shown by the number of medical societies and the interest in their meetings, the reorganization of the American Medical Association and consequent greater unity of the profession, the higher status of American medical literature, and the higher standards in medical education and in the conditions for admission to practice. All these things, he says, have been brought about in a very short time by the voice and action of a hard-working united profession. The triumphs of preventive medicine are also reviewed from the discovery of vaccination, over a century ago, to the more recent acquisitions in the prophylaxis of tetanus, typhoid fever, cholera, yellow fever, malaria and bubonic plague. The medicine of the future is preventive medicine, and its final triumph will be the suppression of disease.

The March of Sanitation.—The progress of modern sanitation and the duties of government, both as regards their own special jurisdictions and their international relations, form the subject of an address by Surgeon-General Wyman of the Public Health and Marine-Hospital Service. He refers to the numerous recent advances that have been made, the lowering of the death rates and the elimination of typhus in English towns, the disappearance of smallpox and typhoid from Germany, the conquest of malaria in Italy and elsewhere, the sanitary measures in Mexico and Brazil, the suppression of yellow fever, the passage of the Food and Drugs Act, etc., and says that the nations are now beginning to see that international cooperation is required for complete success in the war against disease. This idea has found expression in the suggestion of a combined effort against yellow fever in the Western Continent, in the international conferences at Venice and Paris, and in the sanitary convention of the American republics in 1905. So far, the actual agreements have related almost exclusively to quarantine matters, but the idea of international sanitation as an advance on international quarantine, was brought forward in the Third International Conference of American States at Rio Janeiro in 1906, and resolutions were passed recommending that the delegates to the next international sanitary convention, to be held in Mexico in December, 1907, be authorized to study and ascertain the practical measures required for this purpose.

Wyman offers the suggestion that the subject might also be considered to advantage in coming peace conventions and that international hygienic work would divert the energies now uselessly expended in warlike matters. The sanitary awakening in this country is noticed as shown in the increased activities of municipalities and State boards, in the antituberculosis movement, etc. The well-to-do cannot afford to neglect the poor in this matter: the disease germ is a social climber and social position or wealth is no protection if disease-breeding slums are neglected.

Bimanual Vibratory Palpation.—H. A. Kelly finds that the difficulties of accurately outlining a kidney or uterine or ovarian tumor can be overcome by using what he calls vibratory palpation. In the case of a pelvic tumor, for example, the finger in the vagina rests lightly on the cervix if it is uterine, or on its lower pole if it is ovarian. Then the upper hand plays lightly over the abdominal wall, over the tumor, touching first its central portions and then advancing radially out toward its periphery, in all directions, communicating a series of very rapid light vertical succession movements. These little vibrating thrills are felt very distinctly by the finger in the vagina as long as the tumor is played on, and are lost as soon as the vibrations fall on the intestines or fat abdominal wall just beyond the edge of the growth. The vibrations are communicated by giving from three to five little tremulous movements every second to the palpating fingers. The actual to and fro movement need not extend over one centimeter. In this way an accurate outline of the tumor and its irregularities can be obtained.

Erythromelalgia.—I. W. Voorhees treats at some length of the theories of this disorder and describes what is known of its symptoms and treatment. He is inclined from his investigation of the subject to agree with Lewis and Benda that it is not a distinct disease entity, but is a symptom-complex that may have either a central or a peripheral origin, and with Eulenberg, would put it in the same class with Raynaud's disease, as simply different phases of the same condition, the one being dependent on undue dilatation of the terminal arterioles and the other to an undue contraction of the same. They have been observed in the same patient by different observers, and there is not the slightest doubt, Voorhees says, that they exist together as symptoms of some marked pathologic state and notably in that disease of the blood-vessels, known as arteriosclerosis. Treatment has generally been ineffective, and he considers that in intractable or specially distressing cases, even recourse to surgery would be advisable.

Radical Cure of Umbilical Hernia.—W. J. Mayo describes his overlapping from above down method of operation for the relief of umbilical hernia, by which he finds the largest protrusions can be satisfactorily reduced and the hernial opening closed without tension. The tendinous aponeurotic structures involved are among the strongest in the body, and when overlapping is accomplished the resistance is nearly perfect. The sutures merely maintain the structures in apposition, while the intraabdominal tension itself prevents displacements. The operation is simple. Two transverse elliptical incisions are made, cleanly exposing the neck of the sac and the aponeurotic structures for several inches above and below it. The neck of the hernial protrusion is cleared as high as the aponeurotic structures extend, the sac is then opened and any contained intestine returned into the abdomen. The contained omentum, if any, is ligated in sections on a level with the abdominal orifice and the stumps returned into the abdomen. The sac, with all adherent omentum, including the skin, is cut away without further manipulation. A stout curved needle threaded with strong celluloiden linen is passed from without in through the aponeurotic structures and peritoneum from two to three inches above the margin of the opening. A large tablespoon to guard the needle as it enters the peritoneal cavity is a valuable aid. The needle and thread are drawn down and out of the hernial opening. A firm mattress stitch is then caught in the upper edge of the lower flap about one-fourth of an inch from the margin, the needle is then carried back through the hernial opening into the peritoneal cavity and made to emerge one-third of an inch lateral to the point of original entrance. On each side of this is introduced a similar mattress suture of strong chromicised catgut. These three sutures are drawn tight, pulling the entire thickness of the aponeurotic and peritoneal structures behind the upper flap. The margin of the upper flap is now retracted to expose the suture line, and what gaps exist are closed with catgut sutures. The upper flap is now sutured to the surface of the aponeurosis below by continuous chromicised catgut suture and the skin and superficial fat closed. The patients are kept in bed for from twelve to twenty days. It is thirteen years since this operation was first performed and of the 88 patients operated on between 1894 and 1895, 75 were traced. One had a partial relapse described by her physician as a boa-shaped stretching at the site of the former operation, but giving no inconvenience. Another patient supposed to have suffered a relapse was operated on and a second opening found to exist above and lateral to the umbilical opening which was found closed. The operation is illustrated.

Hemoglobinuric Fever.—W. H. Deaderick holds that hemoglobinuric fever is always malarial in the human subject, and explains its pathogenesis substantially as follows: The primary blood destruction is due directly to the malarial parasite, chiefly through the act of sporulation, possibly also by the production of a toxin, though this has not been demonstrated. The hemoglobin thus liberated is carried to the liver, where certain receptors of the liver cells are capable of transforming free hemoglobin into bile pigment. When these receptors are exhausted the deficiency is met by overproduction, and when the cell becomes overfilled some of these side-chains are cast off into the general circulation, where the receptor becomes an amboceptor, and meets the complement present in normal serum and the complete hemolysin is formed. The nature of the complement is unknown, but certain facts throw suspicion on lecithin. It is highly probable that when the production of the hemolysin is not too rapid there is formed at the same time an antihemolysin that may exactly balance the hemolysin without destroying it. So long as this balance is maintained no hemolysis occurs, but should the balance be greatly disturbed by fresh malarial invasion, cold, fatigue, quinine or other and probably unknown factors, hemolysis and hemoglobinuria occur. Under this exact equilibrium the patient is in a condition very similar to that of paroxysmal hemoglobinuria; a close relation between these two affections has been claimed by Sambon. It is possible that a slight and temporary loss of equilibrium may result in a limited hemolysis, producing hemoglobinemia instead of hemoglobinuria. Some cases of anemia, cachexia, and post malarial secondary fever can be explained in this way. Deaderick believes that this theory "explains the occurrence of hemoglobinuric fever during and after malarial infection, with or without the use of quinine; it explains why the malarial attack may precede by months the appearance of blackwater; why cold, fatigue, etc., may bring on an atack; why the hemolysis does not always coincide in time with the sporulation of the parasites when the latter are present; it accounts in a measure for the complex relation with quinine and explains obscure anemia and post malarial secondary fever. Lastly, it coincides with the prevalent ideas of tropical physicians of an intimate relation between hemoglobinuric fever and biliousness."

The Lancet, May 18, 1907.

On the Control of Supernormal Arterial Pressure.—George Oliver notes that a persistent pressure rise may be regarded generally as the outcome of some alteration in the chemical composition of the plasma or of organic changes in the circulatory mechanism. His own observations were made by means of a special secondary instrument referred to in his paper. Treatment of this abnormality should begin with diet. The bulk of each meal should be reduced as much as possible, and various salts, soluble extractives, alcohol, etc., should be avoided, as they stimulate the cardiovascular apparatus. Fluids at meals should be cut down to a minimum. Mildly alkaline waters are preferable. Tea and coffee may be used in moderation, provided no disturbing results, as palpitation, giddiness, etc., follow. Alcohol is better cut out altogether. A chloride-free diet should be aimed at. Milk and vegetables are our chief dependence. Cheese in moderation is the least objectionable form of proteid. Boiled meats are preferable to roast meats. Fresh water fish are allowable. Tobacco should be cut off. Rest in bed plays an important part. The skin must be kept active. Venesection may be of service in some cases when vasodilator drugs fail to act. The author then passes in review the various drugs which have been recommended, dwelling particularly on ingested thyroid. He finds that the ingestion of this substance increases arterial caliber and lowers arterial pressure. He finds it especially serviceable in gouty and obese patients from

forty-five to fifty years, but it should not be given in a more routine manner. Results with any plan of treatment will depend greatly on the fact as to whether the patient can completely rest or is compelled to follow his regular avocation.

A Case of Chloroma.—A detailed history of the case is given by W. E. Reynolds, whose patient was a boy of fourteen years with symptoms which led to a provisional diagnosis of acute leukemia. The whole period covered from the initial symptoms till death was about ten weeks. The terminal symptoms were a rapidly progressive anemia, an irregular fever, and enlarged spleen. No progressive glandular enlargement could be made out and with the exception of the last day or two of life the patient did not complain of any pain. Autopsy findings are given in full and microscopical examination was made of sections of tissue from different parts of the body. The final diagnosis was chloroma. This disease, says the author, is often classed with melanotic sarcoma. Some authorities regard it as a form of leukemia. In this particular case the history, clinical course, and distribution of gross lesions suggested an infective process. The morbid histology showed a general dissemination of what looked like lymphoma, but the blood-vessels were well formed and the presence of newly formed capillaries indicated changes analogous to those found in subacute and chronic infections; but in spite of this the characters of the cells and their nuclei were indistinguishable from those found in sarcoma. The quantity of the pigment found in the tissues was greater than could be accounted for by hemolysis alone. It was therefore evident that it was derived in part from cellular and nuclear destruction. The pigment appeared to be of the nature of a fatty acid combined with iron, and it had very strong reducing power. The whole case is fully worked out from every point of view.

Diseases of the Upper Air Passages in Relation to Life Assurance.—W. H. Kelson dwells particularly on paralysis of the larynx, laryngeal tubercle and syphilis, nasal obstruction, the condition of the tongue, and nasal discharge suggesting disease of the accessory sinuses. He suggests that the life insurance examiner should include in his category of questions such inquiries as "do you ever suffer from hoarseness or difficult breathing," "can you breathe freely through the nose," "have you any mattery discharge from it," "is your tongue sore," etc., and on the replies obtained thereto advise his company as to the acceptance or postponement or rejection of a given risk. He points out the possible dangers which might result in case of an affirmative statement by the patient to the foregoing questions. He considers the tongue condition as of special importance. It may give valuable indications of the applicant's past life history and habits, such as a tendency to chronic alcoholism, as shown by the furred tongue inclined to tremor with a more or less characteristic odor of the breath. In chronic superficial glossitis, also, we have a complaint both common and important with its various forms or stages, as leucoma, psoriasis of the tongue, and the red glazed smooth form. Its exact etiology may be somewhat obscure, but syphilis, excess in smoking, and alcohol (especially spirits), stand out preeminently as contributors to its development, and gout and rheumatism are also believed to be factors. As regards leucoma and cancer it may be said that leucoma is a very strong predisposing cause of cancer, and if in a case of leucoma any ulceration with induration is found, we may be pretty sure that the carcinomatous stage has already been reached.

Clinical Observations on Mucomembranous Colitis.—A general description of the disease is given by J. Liddell. In considering treatment he refers particularly to that employed at Harrowgate. At the outset of treatment we must naturally eliminate any known cause. The original exciting cause may be no longer in operation. Next one must adopt the best means of overcoming the stasis of the bowel and procure a regular and complete evacuation of its contents. The necessity of this is apparent, since it is the retention of mucous secretion, feces, products of putrefaction, and microbes which causes the constitutional disturbances and increases the local irritation. Moreover, requisite means have to be taken to improve the mucous membrane and the muscular coats of the intestine. For evacuation of the bowel aperients prove unsatisfactory in colitis. They never effectually clear the bowel without producing considerable local and general disturbance, and really aggravate the condition. As they lose their power in course of time the patient requires to take larger quantities and take them more frequently, thus making the local condition increasingly worse. Probably the best means of evacuating the bowel and at the same time lessening its irritation is by colon irrigation. When this is properly administered it clears the bowel more effectually than aperients do, and instead of having a pernicious effect its action is most beneficial. A somewhat extensive experience has taught the author the value of this method and that it is by far the best way to commence the treatment of colitis. It has to be carried out with very great care and under certain restrictions, as it may do harm instead of good. But properly administered its value is undoubted. The fluid used must be of a bland unirritating nature. It must also be given under a low and equable pressure or painful spasm will occur and irritation of the colon. The temperature and the quantity of the fluid are also matters of importance. The remainder of the paper is occupied with a description of the details followed out at the Harrowgate institutions.

British Medical Journal, May 18, 1907.

Calcium Salts in the Treatment of Certain Types of Pneumonia.—J. D. Cree believes that it is quite as important to know when to withhold calcium salts in pneumonia as when to prescribe them. He gives the histories of two cases. Case 1 was that of a stout woman of thirty-eight years who was suffering from severe dyspnea, low tension pulse, albuminuria, and was raising over a pint of watery hemorrhagic sputum in twenty-four hours. The picture was that of a patient drowning in her own excretions rather than dying from a toxemia. She was of the hydremic type and her condition was regarded as due to an insufficiency in the coagulability of the blood. Diet was restricted and she was given twenty grains of calcium chloride in water by the mouth. Ten grain doses were continued hourly for twelve hours, and were then reduced to every four hours. Half a day showed a decided improvement in the patient's condition. The sputum in particular was reduced to half its previous amount, and the bright hemorrhagic appearance gave way to a dull, rusty color. In Case 2, that of a thin woman of twenty-five years, the clinical course of the disease was from the start very different, the case running throughout a "dry" course. In this case thrombosis was feared and the aim was to decrease or rather to prevent any increase in the coagulability of the blood. The patient was allowed soft diet and fruit, and was encouraged to drink lemon juice in water. The author makes a plea against the unreasoning use of the calcium salts in pneumonia. In the first type it renders great service; in the second there is no logical reason for its administration and there is one very good reason against it.

Morphinomania Treated Successfully with Atropine and Strychnine.—M. S. P. Strangman reports one case, that of a man addicted to over thirty years' use of the drug. His latest allowance was two wineglassfuls of laudanum in the day and he presented the usual symptoms of the habit. The treatment was begun with atropine sulphate 1/100 grain and strychnine nitrate 1/60 grain three times daily, increasing as rapidly as the patient could bear until on the eighth day his dosage was atropine 1/50 and strychnine 1/20, but it was soon necessary to reduce the atropine to 1/60. Under this plan of treatment immediate beneficial results were noted. Finally the atropine was stopped and the strychnine continued a while longer. The opium was suddenly withdrawn in this case with the usual result of nausea, vomiting, and diarrhea, but the patient finally weathered the storm.

Regeneration of Nerves with Regard to the Surgical Treatment of Certain Paralyses.—The observations of C. J. Bond center about the case of a man of forty-six years who had been struck in the back by the buffer of an engine twenty days previously, and sustained a fracture dislocation of the lowest dorsal and first lumbar vertebræ, with crushing of the cord and complete paraplegia. Laminectomy was performed, the neural arches of the last two dorsal and first two lumbar verterbræ being removed, and the dura mater laid freely open. Finding that (as was expected) the cord was completely divided, and acting on a previously considered plan, the reporter divided the last dorsal nerve-roots intact above the crush on the right side as low down as possible before their exit through the theca, and also similarly divided the first lumbar nerve roots intact below the disorganized portion of cord, also within the thecal canal, and turning these latter upwards he united the cut proximal ends to the cut proximal ends of the dorsal nerve roots previously divided. A corresponding junction was also made in the left side. It was hoped that by so doing a path might be provided for the possible transference of nerve impulses—afferent, efferent, and trophic—across the gap caused by the crushed portion of the cord.

The patient recovered from the operation and the wound healed. He remained in the hospital until June 24, when he left for his home, where he died seven weeks later, and unfortunately no post-mortem examination was obtained. During the three months of his stay in the hospital there was no evidence of any return of voluntary movement, though there was a transitory alteration in the level of the anesthetic area. The bladder condition remained as before.

The Physiological Action of Whiskey on the Circulation.—Experiments have been made in this direction by F. J. Charteris and E. P. Cathcart. They note that many pharmacological experiments which have influenced the ideas of physicians as to the effects of alcohol on the system have been made with pure alcohol and not with the forms in which it is employed in medicine, such as brandy, whiskey, champagne, and port wine. It is difficult to define just what whiskey is. In Scotland it is the pot-still product and not the patent-still product. The former is more complex in character and may contain secondary ethereal products; the latter is a poorer and cheaper substance. The authors made a series of experiments on three men, practical abstainers, noting the relative effects on the circulation of absolute alcohol and whiskey. The dose given corresponded to one ounce of absolute alcohol and sufficient water was added to make the dilution of alcohol one to four. The conditions under which the experiments were carried out are fully specified. In general terms it may be said that the effect upon the pulse and pressure of all three alcoholic preparations, in the above dosage, was very slight, and that after the first ten minutes practically no difference could be detected in action between the absolute alcohol and the whiskies examined. In other words, the action of whiskey on the pulse and pressure depends upon its alcoholic content and not upon any special body distilled over either in the process employed in the manufacture of pot-still whiskey or in that used in the preparation of the patent-still whiskey. The same result was obtained in a series of pneumonia cases and a series of intravenous injections on rabbits.

Berliner klinische Wochenschrift, May 13, 1907.

The Effect of Injections of Cocaine on the Sensibility of the Abdominal Organs.—Kast and Meltzer point out the apparent discrepancy between the statements of Lenander and other surgeons who have found that the abdominal viscera, even in the inflamed state, have no sensibility for painful stimuli, and the constantly occurring clinical observation of severe abdominal pain in many different conditions. By an extensive series of animal experiments the authors were able to show that while it was true that surgeons who operated under local anesthesia did not find that manipulation of the intestine or other abdominal viscera was painful, this condition was the result of the injections of cocaine used to anesthetize the skin for the abdominal incision. In animals (dogs and cats) the injection of 0.02 to 0.03 g. of cocaine sufficed to render painless stimuli to the intestine that without the cocaine would have been resented. It seemed to make little difference whether the site of injection were close to the seat of operation or at a distant part of the body, such as the extremities. Intramuscular injections were found to be more promptly effective than hypodermic injections, and the authors express the view that the mode of action is through the medium of the circulation. The sensibility of inflamed organs in untreated animals was found to be greater than that of uninflamed organs, but the action of the cocaine injections was equally pronounced in such cases. Another observation made was that the cocaine injections had a distinctly quieting effect on the post operative restlessness of animals that had been subjected to ether anesthesia.

The Nature of Carcinoma.—Westenhoeffer reviews at length some of the considerations that lead to the view that the malignant growths represent true parasitic cell colonies which are at once anarchistic and despotic in nature. While originating from the body cells, they are made up of cells which have lost the normal characteristics that belong to these and have become an entirely independent type. This change the author endeavors to explain on the assumption that there has been an atavistic reversion of certain cells which have gone back to the primitive cell type, which is the lowest form of life and is represented by the unicellular animal and vegetable organisms. In order to prove this hypothesis he has made many biological experiments, one group of which was founded on the method of anchoring the complement and by which he tries to show that the cells of carcinoma metastases are heterolytic to animal and vegetable albumin of all varieties. The manner in which certain cells are supposed to be liberated from their normal restraints and rendered capable of this reversion to the ancestral type is explained somewhat in accordance with Ribbert's view of the effect in this regard of chronic irritation and inflammation.

The Effect of Salt and Sugar Injections in Infants.—Schaps found that the infants in the Berlin Asylum for Children sometimes manifested elevations of temperature, that appeared suddenly and disappeared quickly, in conjunction with the addition of a larger quantity of sugar to the food. He was led to believe that this did not depend on any bacterial cause or the absorption of toxins, but rather was the result of the sudden increase in the carbohydrate of the diet; in other words, that an alimentary fever is possible. In order to test this hypothesis he gave infants infusions of glucose and lactose in a strength isotonic with normal salt solution. He found that a typical febrile movement followed this procedure and that even normal salt solution gave rise to an evanescent rise in temperature. He therefore concludes that an alimentary fever exists, and explains it as being due to the disorder of cellular metabolism that is temporarily caused by the alteration in the tonicity of the fluid in which the cells are bathed. The infant, with its imperfectly developed intestinal tract, is especially prone to manifest fluctuations of this nature.

Münchener medizinische Wochenschrift, May 7, 1907.

Intestinal Obstruction Due to Gallstones.—Brentano, in discussing the operative relief of this condition, calls attention to the necessity for investigating the bile passages and intestine for the existence of other calculi which might give rise to serious complications during the patient's convalescence, as was the case in an instance that he reports in which the patient died as the result of a second obstruction caused by another stone about two weeks after the original operation. He considers that in every case of gallstone ileus the proximal portion of the intestine should be palpated for the presence of other stones, and any that are found should be removed if possible through the same incision as the one that is impacted. If this segment of intestine is empty, but the gallstone removed displays facets indicating the presence of other stones in the gall-bladder the incision must be prolonged so as to give access to this viscus and permit of its being emptied. This is particularly desirable if the stone removed has a large round facet pointing to the presence of another equally large calculus. In view of the possibility that it may be necessary to invade the gall-bladder region, it is wise in cases of suspected gallstone obstruction to open the abdomen by an incision above the umbilicus. The incarcerated stone may easily be removed through this incision, as it is usually in a coil of the ileum. Longitudinal incision of the intestine is preferred to transverse incision for the removal of the stone.

Observations on Anguillula Intestinalis.—Bruns reports three cases of infection with this parasite and gives a detailed review of what is known in regard to it. His own patients were miners and apparently were not incommoded by the presence of the parasites. The manner in which these individuals became infected could not be determined. As the result of his studies of the subject, Bruns is of the opinion that it is impossible as yet to determine the relationship existing between the occurrence of intestinal disorders and the presence of the parasites, that is, whether intestinal catarrh encourages the multiplication of the organisms or whether it is itself evoked by them. In view, however, of the circumstances that the parasite lives in the intestinal mucosa, that its youthful forms may occur in the circulating blood, that infection may take place through the uninjured skin, and that in its entire biological relationships there are many points of similarity with the ankylostoma, it is hardly justifiable to regard it as entirely without pathogenic significance. All the cases that have so far been reported in Germany have been sporadic, but it seems advisable to cultivate the study of the parasite with greater interest than has heretofore been the case.

A Study of Some Tropical Ulcerations of the Skin, with Particular Reference to Their Etiology.—Richard P. Strong's observations have led him to conclude that a number of forms of chronic ulceration of the skin are to be encountered in Manila, among which (after excluding certain ulcerative lesions of syphilis, yaws, leprosy, and lupus) there still exist at least several types of different etiology. A somewhat rare form is evidently of blastomycetic origin, in which the torulæ encountered have somewhat the appearance of the forms which have been described in certain cases of Oriental boil or sore as species of protozoa related to the Donovan-Leishman bodies.—*The Philippine Journal of Science.*

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-eighth Annual Session, Held at Atlantic City, June 3, 4, 5, 6, and 7, 1907.

(Special Report to the MEDICAL RECORD)

HOUSE OF DELEGATES.

Monday, June 3—First Day.

THE PRESIDENT, DR. WILLIAM J. MAYO, OF ROCHESTER, MINN., IN THE CHAIR.

THE Committee on Credentials presented a preliminary report. The minutes of the Fifty-seventh Annual Session were read and adopted.

President's Address.—Dr. WILLIAM J. MAYO, following the custom of his predecessors, directed the attention of the house to some of the more important matters to come before it for decision. It was fortunate that as president he was relieved of the business control of the Association by the board of trustees, to whose wise control of its affairs the Association owed its place as the largest and most powerful medical organization in the world. Dr. George H. Simmons of Chicago, the general secretary of the Association, had won his admiration. Dr. Mayo spoke particularly of the success of the *Journal* of the Association; it had brought to the Association a profit of over $50,000 during the year. The president expressed his appreciation of the ability with which Dr. J. M. McCormack of Bowling Green, Ky., had performed his duties as chairman of the committee on organization. He called attention also to the evil of medical schools owned by private corporations and conducted for their own advantage, hoping that the moral force of the Association might be lent to the correction of this condition. The committee on life insurance would make a report upon the vexing question of fees for life insurance examinations, which was one causing much dissatisfaction in the ranks of the profession, affecting at least 10 per cent. of its members. The speaker thought that physicians were quite as unreasonable in the use of proprietary preparations as were the public in the use of patent medicines. The work of the Council on Pharmacy and Chemistry deserved the support and encouragement of the profession. To expedite the business of the House of Delegates, and thereby save the time of its members, the president recommended the creation of a new committee.

The president then announced the membership of committees.

Report of the General Secretary.—Dr. GEORGE H. SIMMONS presented this report. The membership of the American Medical Association on May 1, 1906, was 23,636. During the year the names of 2,135 were discontinued on account of deaths, resignations, nonpayment of dues, and noneligibility. To the list, however, had been added 6,014 names, giving a net gain of 3,879 for the year, and a present membership of 27,515. The secretary had received official advice of the amalgamation of the Oklahoma and Indian Territorial Associations. Committees had been appointed in accordance with resolutions adopted at the Boston session as follows: Committee on Tropical Medicine, Ludvig Hektoen of Chicago, Chairman; Maximilian Herzog of Chicago, George Dock of Ann Arbor, Mich., Dr. L. F. Barker of Baltimore, and Col. Wm. C. Gorgas of Panama. Committee on Ophthalmia Neonatorum, F. P Lewis of Buffalo, chairman; J. Clifton Edgar of New York, and F. F. Westbrook of Minneapolis. In his report of last year he had called attention to the ambiguity of the provisions of the by-laws with reference to associate membership, it being claimed that those eligible to full membership, wut who did not care to avail themselves of it, might acquire temporary membership. He thought it obviously unjust to active members to permit those not caring to assume the obligations of active membership to become associate members, and thus obtain special privileges. On the other hand, there was a distinct class who were not licensed to practise medicine who should enjoy the advantage of the membership without the formality of election each year. He therefore proposed the amendment of the by-laws to obviate the ambiguity and uncertainty. The relations between the secretaries of the various constituent associations and the General Secretary's office were constantly becoming more intimate. The growth of the organization involved the necessity of a more accurate registration system, which, inaugurated two years ago, was proving more and more valuable. Regular reports were received during the past year from thirty-nine State secretaries, and reports, though not regular, had been received in sufficient fullness, with one exception, from the remaining secretaries to cover all membership transactions during the year. The presidents and secretaries of county societies had been receiving the Councillors' Bulletin, which, issued at intervals during the past year, had contained much matter of importance to them. The Bulletin now had a circulation of nearly five thousand. The biographical card index of the individual members of the profession was being constructed from over sixty thousand personal biographical reports now in the hands of the Directory Department. Though the correspondence with Porto Rican physicians had been continued, no success had yet met the efforts looking toward the organization there of a constituent association. Organization matters generally had attracted increasing interest throughout the country, more attention than ever having been paid to the prerogatives and duties of physicians as members of the community.

Report of the Board of Trustees.—Dr. T. J. HAPPEL of Tennessee, Chairman of the Board of Trustees, presented their report for the last calendar year. The net revenue had been $31,915.10. The net earnings of the *Journal* amounted to $55,000 for the year. The Council on Pharmacy and Chemistry had maintained its close censorship of advertising matter, yet without an increase in the advertising space the increased circulation of the *Journal* had made possible an increase of $2,800 in the income of that department. The experience of the Association had justified the purchase of the buildings now owned by the Association. Whereas formerly $5,000 annually had been expended for rent, the Association now received the same amount from the rental of space it possessed in excess of its own needs. Thus Dr. Happel considered the Association to be ten thousand dollars a year better off than it had been before. Much money had been invested in the Directory, but its first edition having been completed and copies delivered, the Association was now recouping itself. Despite the rather favorable financial showing, the Board of Trustees felt it necessary to recommend the creation of a sinking fund of not less than a hundred and fifty thousand dollars. Debts must be discounted and bills met promptly and a margin left for emergency. Heretofore the Association at its conventions had been dependent to a very considerable extent upon the hospitality of the local body of the profession. This year for the first time it had provided its own meeting places, and had met the entire expenses of the convention, save for the entertainment of the ladies attending the sessions, for which it was indebted to the local committee. This year also the manufacturers' exhibits were closely supervised, and only such products accepted as might be admitted to the advertising pages of the *Journal*. A suspicion had existed in the minds of some that the Council on Pharmacy and Chemistry had discriminated against some manufacturers in favor of others. This feeling had been dispelled, and the success of the efforts of the Council was gratifying. Every member of the medical profession throughout the country should be

willing to lend his hearty support to the Council in this work. The Committee on Medical Legislation had accomplished much. The full report which it would present to the House of Delegates would justify the wisdom of the appropriation of $4,500 for the committee's use during the year. The Committee on Medical Legislation had kept the Board of Trustees advised of its work, which, though remaining under the supervision of the chairman of the committee, would in future be carried on largely by one of the assistant secretaries with headquarters in the building of the Association. While the Board of Trustees was prepared to furnish in detail desired information concerning the present condition of all appropriations, it would consider it poor policy to publish such details to the world. The Board had been encouraged in its work by the diminution of captious criticism on the part of those less well informed regarding the business of the Association. The Trustees had at an annual meeting extended a vote of thanks to the editor and general manager of the *Journal*, Dr. George H. Simmons, for his painstaking and efficient efforts.

Report of Committee on Senn Medal.—Dr. A. F. Jonas of Omaha, Neb., the chairman of the committee, being absent, the secretary read his report for the committee. Only two theses having been presented, neither of which the committee considered of such merit as to deserve the medal, the committee had determined to make no award. A permanent notice was recommended to be inserted in the *Journal*, setting forth the conditions attending the competition for the medal.

Of the appropriation of $5,000 for the relief of the California earthquake sufferers, only $3,000 had been called for during the calendar year. The chairman of the committee had been advised informally that the $3,000 had since been returned to the Association.

Report of the Council on Medical Education.—Dr. Arthur N. Bevan of Chicago, Chairman, presented an extended report, outlining what the Council had accomplished so far and what it hoped for the near future. The Council had been created in 1904 to take up the work which, up to that time, had been carried on with indifferent success by committees on education, which had labored under the disadvantage of a rapidly changing membership. The Council desired to see organized a permanent national bureau on medical education, with an adequate clerical force, and a permanent base. This bureau in giving publicity to the evidence which it would collect would be effective in producing reforms, even though it were without legal powers. The Council had had two conferences with representatives of State examining boards in April, 1905, and May, 1906, respectively. At the first conference the questions of a standard of preliminary educational requirement, the medical curriculum, and the relation of the college of liberal arts to the medical school were discussed. As a result of this conference the Council formulated a minimum standard for the time being: A college preparatory education, passed on by a State official, graduation from an approved medical school having a course of four years of thirty weeks with thirty hours' work in each week, and a licensing examination. The Council also formulated an ideal standard to work for in the future. At the second annual conference, May, 1906, was considered the most important subject of the relative standing of medical schools based on the success their graduates had had before licensing boards. Schools were classified with reference to the percentage of failures. Such tables, it was believed, would, if published periodically, be of much service in elevating medical standards. A personal inspection of medical schools throughout the United States had been undertaken during the past year in the attempt to ascertain the exact character of their work and to mark them on a civil service basis. The task had been found a large one, but in its value would justify itself in enabling the Council to form a better idea of existing conditions than could otherwise have been obtained. The question of increasing the requirements for matriculation had been pursued with many colleges. A year ago only seven medical schools in the United States demanded preliminary work in a college of arts. Now forty-nine schools would, by January 1, 1910, require one or more years of college work for admission. Furthermore, there were now only six States where non-graduates might receive licenses to practise. Interstate reciprocity had made considerable strides recently. Forty-five States now had State committees on medical education, which in their reports to the State Associations had done good work in several instances. It was thus that each State medical society would be kept fully informed of the relative standing throughout the country.

Report of the Committee on Medical Legislation.—Dr. Chas. A. L. Reed of Cincinnati, Chairman, outlined the influence which the Association had exerted upon Congress, resulting in the final passage of the Pure Food and Drug Bill, despite serious obstacles. Through persistent presentation of the case of Dr. James Carroll, who as the result of his experiences with yellow fever in Cuba had become largely incapacitated, had finally met success in the promotion of Lieut. Carroll to be Major and Surgeon. The project to secure an army general hospital had resulted in an appropriation of two hundred thousand dollars. The Army Medical Reorganization bill, though pressed assiduously, had met the determined opposition of the Speaker of the House of Representatives, and in the opinion of the committee had little chance of becoming law in the near future. The disparity between the professional requirement for license between the United States and many foreign countries was emphasized in the course of an investigation of a report that the Anglo-Japanese treaty discriminated against American practitioners in Hong Kong. It was learned that licenses were there granted under the Imperial Medical Practice Act of Great Britain, which required a five years' course of medical instruction previous to graduation as a prerequisite to license. Thus American physicians, though not discriminated against as Americans, suffered in competition with the men of other nationalities. The efforts which the Association had put forth in former years to have the chief medical officer on the Isthmus of Panama given coordinate rank on the Isthmian Canal Commission recently met with success when the president named Colonel Gorgas as a member of the commission in charge of sanitation. Through the assistance of medical men, members of Congress, the osteopathic practice bill for the District of Columbia, which had passed the Senate, was defeated in the House. The subject of the creation of a national department of public health was now in the hands of a popular "committee of one hundred." Other matters of legislation, National and State, were mentioned by the committee as meriting attention.

Dr. Frank S. Billings of Chicago offered a resolution to communicate to the Director of the U. S. Census the wish of the American Medical Association that an enumeration of deformed and ruptured children in the United States should be made in connection with the next census.

Report of Committee on Organization.—Dr. J. N. McCormack of Bowling Green, Ky., chairman, reported in some detail his conferences with various State officials. Interest in county societies was waning, he believed, for the need of a more systematic method of study. The committee favored the elaboration of a scheme of post-graduate work, covering an extended course of study adapted to the needs of the average county society. After a full consideration by the House, the committee hoped such a system might be evolved as to meet the needs of many practicing physicians who at present did not attend any

association meetings. The development of the idea would require the expenditure of perhaps $600, the appropriation of which the committee suggested. Dr. McCormack pointed out the fact that the antagonism between certain mercenary interests and the profession at large had resulted in a more or less open breach between the physician and the druggist, which would merit the kindly and dispassionate attention of the House of Delegates. The chairman of the committee presented a second report recommending the organization of branches of the American Medical Association, dividing the territory of the entire country into seven geographical divisions. Membership in these branches should be limited to the members of the State and County societies, and should be purely voluntary. Meetings of the branch associations should be held coincidently in time and place with those of the State societies, and should so far as possible be held in the fall, midway between the conventions of the National Association. This plan would tend to diminish rather than to increase the total number of the societies of the country, and would afford to the younger men an opportunity for activity not presented by the National Association.

Report of the Committee on Ophthalmia Neonatorum.—Dr. F. Park Lewis of Buffalo, chairman, presented a report discussing the etiology of blindness in the United States. The purpose of the committee was not to discriminate as to different methods of procedure, but to solve the problem of how best to put into execution a course of procedure of known value. That the subject of prevention of needless blindness had been sorely neglected was shown by the statement that in New York State, for instance, midwives had no legal status save in a few of the western counties, and that forty-two per cent. of the total number of births last year in Greater New York were presided over by women required to have no standard of efficiency and under no adequate supervision. The committee reminded the House of Delegates of the obvious duty of the State to protect the individual from injury through needless exposure to disease, whether it be smallpox, diphtheria, or ophthalmia, and that full responsibility must attach to any person caring for the mother and her new-born babe. Extensive popular education as to the dangers of the disease and the methods of its prevention must be undertaken. Unwilling, without further advice, to recommend a detailed plan of procedure on so important a matter, the committee recommended that its work be continued, and that it be permitted, with the advice and consent of the chairmen of the sections on Ophthalmology, Obstetrics, and Hygiene and Sanitary Science, to formulate a detailed plan of procedure, with the cooperation of committees already appointed by the Academy of Ophthalmology and Oto-Laryngology and the American Ophthalmological Society, in making effective such a plan as may be determined upon. The committee also recommended that the Health Officer of each State or Federal Territory, and the president of each State Medical Society be also invited to cooperate with the committee in carrying these procedures into effect throughout the United States. It was moved and seconded that the report of the committee be accepted and its recommendations carried out. The motion was adopted.

Report of Committee on Section on Tropical Medicine.—A communication from the chairman of the committee, Dr. Ludwig Hektoen, of Chicago, to the effect that it was not in a position to make any report, was read by the secretary, and the committee was continued.

Report of Committee on Plan of Organization of a Department of Public Instruction.—Dr. John G. Clark of Philadelphia, chairman, reported that the popularization of knowledge on scientific subjects had not extended in any marked degree to the field of medicine. Leading editors had found it difficult, largely through ethical considerations, to obtain satisfactory matter for publication. Inasmuch, however, as it was the citizen to whom we must look of assistance, through his individual effort and through legal means, to limit the ravages of disease, the layman as well as the physician must have more or less accurate information regarding its cause and prevention. The American Medical Association was competent indeed to meet this need, through the assistance of the public press. The investigations of the committee had led to the conclusion that four separate means should be followed to accomplish this education. First, the publication in the daily press of timely articles, as for instance, during a prolonged heated period caution as to how to prevent sun stroke; second, the organization of a central bureau to distribute in pamphlet form information which should be preserved by the laity for reference; third, the organization of public lectures at medical colleges, and under the auspices of the county societies, and, fourth, correspondence by circular letters with the individual members of the medical profession, thereby preventing professional lethargy. In this latter category must be included the discussion of venereal disease, uterine cancer, etc., which, from their nature, it would not be feasible to accomplish by other methods. The committee outlined the organization of a board of public education, composed of seven representatives, to be appointed by the President of the Association, and having a paid secretary to attend to editorial and executive work. The authorship of published articles, the committee thought, should not appear, the board accepting the responsibility for the publication. An appropriation would be necessary to meet the immediate expenses, and the committee suggested the sum of $3,500 per year to inaugurate the scheme, hoping that its continuance might be accomplished by aid through philanthropic channels. The report was referred to the Committee on Hygiene and Sanitation, with instructions to confer with the Board of Trustees as to the feasibility of the necessary appropriation and to make a comprehensive report upon all matter.

Dr. Craig moved an amendment to the by-laws to provide for the creation of a Board on Public Instruction on medical subjects.

Dr. Denslow Lewis of Chicago presented a resolution commending to the public authorities the exception from the category of obscene matter of all literature on matters of sexual education.

Tuesday, June 4—Second Day.

The meeting was called to order at 2:15 P.M., by the President, Dr. Joseph D. Bryant.

Report of the Reference Committee on Constitution and By-Laws.—Dr. George W. Guthrie of Wilkes-Barre, Pa., chairman, reported favorably upon amendments to the by-laws providing that the admission of dental and pharmaceutical members should be subject to confirmation by the House of Delegates, that representative teachers and students of the allied sciences resident in the United States and not eligible to regular membership might become associate members on the recommendation of the officers of a section and on election by the House of Delegates, such associate members to enjoy the same privileges and to be subject to the same conditions as regular members, and that representative teachers, students of sciences allied to medicine, and distinguished physicians of foreign countries might be invited by the general officers or by the officers of a section to attend the annual session and to take part in the scientific work. They should be designated invited guests, and should hold their connection with the Association until the close of the annual session to which they were invited. These amendments were adopted on motion.

The committee reported unfavorably upon amendments

proposed by Dr. Grosvenor of New York providing that all reports presented to the House of Delegates should be acted on seriatim, except such reports as contained only one proposition, and that in balloting for all elective officers and for the place of meeting of the Association each member of the House of Delegates should cast his own ballot. A motion was made and seconded to accept the unfavorable report of the Reference Committee.

Dr. Grosvenor then addressed the house. On the former amendment he remarked that much criticism had been heard in the past that committee reports had been made rather by wholesale. The present constitution, he said, had been adopted without consideration seriatim. To disarm such criticism, he thought the by-laws should provide for consideration of reports seriatim. Other members pointed out that the House was competent at any time to consider reports in this manner, but that a uniform rule would entail much needless loss of time. With reference to the second amendment Dr. Grosvenor believed that it should not be necessary for a member to present a formal objection to the procedure of electing officers by means of a unanimous ballot of the House cast by the Secretary—practically election by acclamation—but that he should have the privilege of balloting for whomever he chose, without appearing openly to oppose a leading candidate.

Dr. Cantrell of Texas considered the amendment entirely unnecessary, inasmuch as unanimous consent was required for the suspension of the rule on individual ballot.

Dr. Guthrie of Arkansas believed, on the other hand, in the maintenance of the utmost respect for the ballot, and approved the amendment.

The chairman of the Reporting Committee pointed out that adoption of the amendment would deprive the House of its own liberty of action. The report of the committee was adopted and the proposed amendment was defeated.

Report of the Committee on Scientific Research.—The Secretary read the report of Dr. Alfred Stengel of Philadelphia, chairman of the committee, showing that four grants, aggregating $550, had been made by the committee for the year 1907, to Drs. G. F. Ruediger of Chicago, H. T. Ricketts, Richard M. Pearce of Albany, and J. N. Wainwright of Scranton, Pa., for research work on various lines. The committee had restricted its grants as far as possible and had not used all of its funds, but requested a continuance of the same appropriation for the next year. On motion, the report was accepted and referred to the Trustees.

The Judiciary Council, Dr. G. W. Guthrie of Pennsylvania, chairman, had no report to make.

Report of the Committee on the Davis Memorial.—Dr. H. O. Marcy of Boston, chairman, presented a report showing contributions received during the last year, and asked that the committee be continued. It would make a special effort during the coming year and hoped to make a satisfactory showing next year. On motion, the report of the committee was adopted.

The resolution presented at the Monday morning session by Dr. Billings, requesting the Director of the Census to conduct an enumeration of ruptured and crippled children in the United States in connection with the next census, was reported favorably by the Reference Committee, and was adopted by the House without objection.

The Reference Committee returned to the House the report of the Committee on a Board of Public Instruction, with a favorable recommendation, save for that part relating to an appropriation, which was without its province, and asked that the question of the publication of the names of the authors of contributions to this work be laid before the House for its decision. The report was adopted on motion. Dr. Woodward recommended that the articles be unsigned, but hoped the matter would be brought before the House for a vote.

The resolution presented by Dr. Lewis of Chicago with reference to the dissemination of information on sexual hygiene and venereal prophylaxis, was reported back from the Reference Committee with a recommendation that it be referred to the Board of Public Instruction. The resolution was so referred.

The Reference Committee on Sections and Section Work reported back the proposition to insert in the *Journal* an advertisement regarding the Senn Medal award, recommending that the matter be referred to the Executive Committee of the Section on Surgery. The recommendation was adopted.

The Reference Committee on Legislation and Political Action reviewed the report of the Committee on Legislation, recommended its adoption, and that a vote of thanks of the House be extended to the Committee on Legislation. It also recommended that the House of Delegates indorse again the Army Medical Organization Bill and the bill for the restoration of the army canteen; that the matter of a department of public health be left in the hands of the "committee of one hundred," and the adoption of resolutions expressing appreciation of the efficient service to the profession rendered by the medical members of the House of Representatives. It favored the extension of the work of the Committee on Medical Legislation into the field of legislation by the several States.

The Army Canteen.—Dr. Mills recommended the adoption of the report as a whole, which motion was seconded. Whereupon Dr. Grosvenor of New York protested against the indorsement by the House of the recommendation in the report respecting the restoration of the army canteen, submitting his views and his reasons for believing such restoration to be undesirable, quoting General Sheridan and General Miles. Dr. Solis-Cohen of Philadelphia did not believe the matter to be germane to the work of a scientific organization, being essentially a moral question. Dr. Reed of Ohio, the chairman of the Committee on Medical Legislation, supported at length the recommendation of the committee. Dr. Jones of California drew a comparison of conditions at the Presidio before and after the abolition of the canteen, showing the great disadvantage, moral and physical, which had resulted from the change. Dr. Rees of New York and Dr. Guthrie of Arkansas opposed the restoration of the canteen on moral grounds, while Drs. Essig of Washington and Gile of New Hampshire were convinced that the matter was not a proper one to receive serious consideration by the House of Delegates. Dr. Chas. Richard, Major and Surgeon, U. S. Army, sought to make clearer in the minds of the House the true nature of the canteen, the advantages which the soldier had derived from its social and restraining influences, showing how the physical and moral being of the soldier had suffered since its abolition. The matter finally received a vote on an amendment to a motion to accept the report, providing that the House expressed no opinion upon the question of the canteen, and the report was so adopted.

Report of the Committee on Insurance.—Dr. John H. Musser of Philadelphia, chairman, said the committee had at present nothing to add to its report, published last December, in which it had set forth the result of its conference with the officers of the life insurance companies in New York, who, though at first

declining to meet the members of the committee in their official capacity and expressing their determination to negotiate with the individual examiners rather than with the profession as a whole, had among themselves agreed upon a common course of action. The Equitable and Mutual companies had declined to restore the $5 fee unless the New York Life did the same. There the matter stood. The committee was convinced that $5 should be the minimum fee for a life insurance examination. It had now nothing further to report and asked that it be discharged. Dr. Work of Colorado offered a resolution approving the report of the Committee on Insurance and urging action in accordance therewith upon the county societies. Upon the motion of Dr. Cantrell of Texas the matter was referred to the proper Reference Committee.

Dr. Lund announced that the Reference Committee would be glad to hear all those who wished to appear before it in connection with the report of the Committee on Medical Education.

The Reference Committee on Constitution and By-Laws presented an amendment providing for the organization of a Board of Public Instruction to consist of seven members, to be appointed by the President, the term of service to be four years.

Dr. Lewis of Chicago, on behalf of the Section on Hygiene and Sanitary Science, and by its instruction, requested a report on questions presented last year upon matters of sexual hygiene, etc., and then referred to the Committee on a Board of Public Instruction. After some discussion, on motion of Dr. Craig, these resolutions were recalled from the Committee and referred to the Committee on Sanitation and Public Health.

It was announced that the sixteenth International Medical Congress would be held in Budapest in 1909, and that Dr. J. H. Musser of Philadelphia had been appointed chairman of the American Committee on the International Congress. A motion for confirmation of Dr. Musser's appointment by the House of Delegates was adopted.

Dr. D. A. T. Bristow of New York presented a resolution providing for the appointment of a committee of five on nomenclature and classification of disease to cooperate with representatives from other bodies interested, in order to send a suitable delegation to the Paris Commission in 1909, which would revise the international classification of causes of death. The resolution was adopted.

Dr. Richard Cabot of Boston presented a resolution aimed to eradicate rabies. The resolution was referred to the proper committee.

GENERAL SESSION

Tuesday, June 4—Second Day

The meeting was called to order by the retiring President of the Association, Dr. William J. Mayo, of Rochester, Minn.

Prayer was offered by the Reverend H. M. Gessner, Pastor of the First Presbyterian Church of Atlantic City.

His Honor the Mayor of the city, F. P. Stoy, in a graceful address extended a cordial welcome to the convention, presenting to President Mayo the key of the city.

Dr. Alexander Marcy, President of the Medical Society of New Jersey, welcomed the Association, on behalf of the medical profession of the State, on the occasion of its third convention to be held in Atlantic City during seven years. Owing to the rapid growth of the Association it would soon be difficult to find elsewhere the necessary accommodations for the annual convention, and sooner or later a permanent meeting place would have to be considered. When that time should come New Jersey would offer its incomparable Atlantic City, and say to the association: "Come and abide with us forever." The time was not far hence when no reputable physician could afford not to be a member of the Association.

The President introduced to the convention the following named foreign guests: Dr. Gustav Killian, Freiburg, Germany; Dr. Charles Trow, Toronto; Dr. George T. Ross, Montreal; Professor Küster, Marburg, Germany; Professor Kocher, Berne, Switzerland; Dr. D. G. Wishart, Toronto; Professor Hess, Wurzburg; Dr. Reeves, Toronto; Professor Adami, Montreal; Mr. Herbert J. Paterson, London; Professor Schmieden.

Reports were presented by Dr. Philip Marvel of Atlantic City, Chairman of the Trustees' Committee of Arrangements, and Dr. W. Blair Stewart of Atlantic City, Chairman of the Local Committee of Arrangements, summarizing their work, acknowledging the hospitality of the city, and making necessary announcements.

Dr. Mayo then said that it was his pleasing duty to introduce the incoming President, "a man who is so well known in this country that although his home is in New York his election came, not from New York, but from the whole of America—author, teacher, and surgeon—Joseph D. Bryant of New York."

President's Address.—Dr. Bryant then delivered the Presidential Address (see page 925).

Evening Session

The second general session was held on Tuesday evening, the order of business being the delivery of the general addresses.

Oration on Medicine.—Dr. James B. Herrick of Chicago took as his subject in this address "The Relation of the Clinical Laboratory to the Practitioner of Medicine." The change that had been brought about in our conception of disease and in the manner of its detection through the discovery and invention of instruments and methods of precision and the application of improved laboratory technique was one of the most striking characteristics of the marvelous advance in medicine of the last half century. To realize what this means, he said, one had but to think for a moment how comparatively helpless we should be were we suddenly deprived of bacteriological aid in diagnosis with its attendant specific serum reactions; of the improvements in technique of the last fifty years in the way of microscopy, stains, section cutting, etc.; of the study of the corpuscles of the blood and the estimation of its hemoglobin; of our knowledge of the chemistry of the stomach; of the cytological, bacteriological, chemical, and physical facts concerning normal and pathological fluids of the body; of the means of measuring blood pressure; of the numerous electric light appliances enabling us to explore nearly all the orifices and cavities of the body; of the Roentgen ray; of the improved qualitative and quantitative chemistry of the urine and feces; of aids from physical chemistry. Nothing had given a greater uplift to medical thought and practice, and especially to diagnosis, than the laboratory. Its aid was indispensable. But it had its own proper place. The earlier tendency to overvalue its work and to undervalue that done at the bedside was having the natural result in a swing back of the pendulum, and we were now hearing voices on either side of the Atlantic cautioning against the undue magnification of the laboratory at the expense of other aids to diagnosis. In our own country several writers had recently referred to the subject, and within a few weeks a large body of select medical men—the Congress of American Physicians and Surgeons—had considered the subject in a symposium, "The Relative Value of Laboratory and Clinical Methods in Diagnosis."

Certain mistaken notions had obtained regarding labora-

tories, which had led at times to strained relations and misunderstandings between the practitioner and the laboratory expert. These were due to faults that lay partly in the laboratory worker, partly in the physician. There was often a failure on the part of the laboratory worker to acknowledge his limitations. He should bear in mind the possibility of error in technique or of false interpretation of the facts observed, and the fact that we were more or less even yet ignorant of some of the common laboratory reactions; he should ever be on the lookout for artefacts; he should hesitate to assert positively from microscopical examination alone that a smear from a throat does, or especially does not, contain diphtheria bacilli, or that a cellular form observed is the *Amœba coli*. He should always realize the gravity of the duty imposed upon him by the practising physician; he is often so remote from the patient that he does not feel the personal responsibility that weighs upon the clinician, and so, not realizing the importance which may attach to his decision, he may make it on insufficient grounds. Were he to feel the full import of this decision, in doubtful cases he might admit more frankly to himself and to the physician his inability to reach a positive conclusion. Repeated or later examinations could then be made, thus clearing up the diagnosis. Or, if the result were still inconclusive, he should be ready frankly to admit that he did not know. Finally there was a tendency for some laboratory workers to step beyond their province and make diagnoses that were unwarranted by the facts and perhaps unasked for, and even to advance a prognosis and advice as to treatment. The laboratory's function ceased when its findings were announced. The interpretation of the laboratory findings rested with the practitioner. No sharp line should be drawn here, for the man in the laboratory and the clinician should work together; but Dr. Herrick would criticise such a laboratory report which he had seen more than once, as: "This urine is from a typical case of chronic interstitial nephritis" when it was not; it was from a typhoid patient drinking huge quantities of water and passing urine of low specific gravity and of large amount, with a trace of albumin and an occasional cast. Often he had seen the positive diagnosis of pernicious or secondary anæmia made from a blood smear alone sent in to a laboratory—a possible, but risky diagnosis. And many times he had seen a report that said in substance, often in so many words on the basis of a Widal reaction: "This is (or is not) a case of typhoid fever." And when free hydrochloric acid had been found in the stomach contents the statement was returned: "This is not a case of carcinoma." Such reports were wholly unwarrantable and inexcusable. Nothing had done more to bring the laboratory into disrepute than this irrational, almost meddlesome, method of venturing a diagnosis on wholly insufficient grounds.

The physician had done his share in creating more or less prejudice against the laboratory by failing to recognize its limitations and by holding the notion that laboratory methods were infallible and rendered unnecessary careful bedside observation. Consequently misinterpretation of laboratory findings by the practitioner was common and was grave. And this was due to no fault on the part of the laboratory, but rather to the shortcomings of the methods themselves and the failure on the part of the practitioner to take cognizance of this fact. Many of the aids to diagnosis were regarded as too far-reaching and comprehensive; they were looked on as pathognomonic and as without exception infallible. This came about because earlier reports as to the value of these tests were often rosy-hued and conclusions were sweepingly and definitely stated. The later observations throwing doubt on the method were slower to get into print and were less likely to attract the attention of the busy practitioner than was the favorable report. The physician, furthermore, had no right to throw the entire responsibility of an important decision on the laboratory. The decision in a perplexing case should be a combined one, the men working as colleagues, and each man sharing in the responsibility. These faults—of laboratory worker and of medical practitioner—were not irremediable, the author maintained. The solution lay in two directions—first, in a better practical training of the undergraduate in laboratory technique and methods so that he might realize the difficulties, limitations, and possibilities of the laboratory; second, in the closer relation between the laboratory expert and the clinician and when possible their union in the one individual. The closer the laboratory and the patient the less the liability to error. The less the scattering of responsibility the surer was the responsibility to be met. To these ends there should be laboratories in our medical colleges for the training of undergraduates, and these should be as closely connected with the wards of the hospital and the clinic as possible. No modern hospital should be regarded as well equipped that did not make provision for a laboratory. The ideal would be for each practitioner to have his private laboratory, but practically for the majority of physicians this was not feasible. Groups of men might, however, combine to employ some young man to do their laboratory work. Similarly the county medical society might have its clinical laboratory under the charge of some young man, paid a salary or fees for separate examinations, who would conduct a laboratory to which any member might feel free to go for the help that for various reasons he could not get in his own office. Laboratories for counties had already been established and, if not too much entangled in politics, ought to be successful, especially in the way of guarding the health of the community and in aiding in the diagnosis of charity cases. In the same way municipal laboratories had become a recognized feature of the modern city, though the carelessness of the political appointee or his incompetence often detracted from the value of their results. Commercial clinical laboratories in our large cities were of great service and had a legitimate place, their value depending on the personnel of their staff and on how far they permitted the commercial side to overshadow the scientific. What the orator contended for, therefore, was not less laboratory work, but more, more for the undergraduate and more for the practitioner.

In concluding, Dr. Herrick said that one should not look on the laboratory as a short cut to a diagnosis. Sometimes it was, but often its workings were slow and cumbersome, and because of their complexity the results were not easily expressed in practical, every-day, usable terms, and were, therefore, inconclusive or confusing. In other words, the laboratory diagnosis was not yet one of machine-like accuracy. The time had not yet come when a diagnosis could be made without the exercise of brain power. We did not wish our professional work to be degraded by being "dementalized," to use Weir Mitchell's expression. Anamnesis, physical, and laboratory findings were to be studied and compared and a result reached that not only gave a name to the disease, but gave a conception of the disease as it existed in the particular individual, with all that such a comprehensive diagnosis implied in the way of prognosis and hints as to therapy.

Oration on Surgery.—Dr. WILLIAM H. WATHEN of Louisville delivered this oration, taking as his title "Acute Suppurative Peritonitis (Local, Spreading, Diffuse, and General)." One reason for selecting this subject for an address before a general medical audience was, he said, the fact that the essential questions involved in the study of the etiology, pathology, diagnosis, and treatment of acute suppurative peritonitis were of equal interest to the internist and the surgeon. The greatest success of surgery in saving life in these cases depended on early surgical diagnosis and timely operation, before pathological condi-

tions could develop that might so impair the vital resistance of the body tissues as to cause death of the patient with or without surgical intervention; and as these patients usually first consulted the internist, early operation was impossible unless the surgeon was promptly associated in consultation. The intrauterine life and at birth the intestinal canal was sterile and remained so until bacteria had been introduced with the food. The bacteria ordinarily found in the alimentary canal varied according to the food, but the one constant normal inhabitant was some type of the colon bacillus; in childhood the *Bacillus lactis aërogenes*, closely related to the *Bacillus coli*, was also normally present. These two germs, independently or jointly, might conduce to health by aiding digestion, antagonizing intestinal putrefaction, and inhibiting the growth of pathogenic intestinal bacteria. In splitting carbohydrates they generated acids which limited intestinal putrefaction by the proteolytic bacteria, and might prevent pathological processes which would otherwise develop in the existing alkaline fermentation. So long as there was perfect digestion, absorption, and assimilation, the great number and variety of bacteria living on the carbohydrates and proteids were not only harmless but conducive to health, but when some pathogenical condition in the gastrointestinal tract disturbed the circulation, digestion, and nutrition, they might quickly become mildly or virulently pathogenic, multiplying rapidly and generating toxic substances in the tissues of the body, or causing peritonitis by passing through injured walls or a perforation into the peritoneal cavity.

Since bacteria were introduced with the food it might be reasoned that the intestine when emptied of its contents would become sterile, and experimental investigation had shown the truth of this assumption. It was possible to utilize these facts in certain intraperitoneal operations and sterilize the stomach and some part of the upper intestine by giving the patient no food by the stomach for several days before he was operated on; or, when the patient's condition would not admit of this, by giving sterile liquid food, and have him cleanse his mouth frequently with some efficient antiseptic liquid for a few days.

The infectivity and virulence of bacterial invasion of the peritoneum was measured by the relative number and pathogenic powers of the bacteria that entered the peritoneum from the different parts of the gastrointestinal tract, the virulence being greatest when the infection occurred from the lower part of the ileum with the maximum intensity at the ileocecal and appendicular region. In perforative duodenal ulcer the leakage into the peritoneal cavity was often free of pathogenic bacteria and did not cause diffuse suppurative peritonitis, and when infective bacteria were present they were usually so mildly pathogenic that the resultant peritonitis remained local or spread so slowly as to admit of successful surgical interference. This applied also in pyloric perforation, because of the character of the contents in this part of the stomach, and also because of its relation to adjacent structures to which it might quickly form adhesions to close the perforation, or to localize the infection. It was not true, however, in ulcerative perforation of the cardiac end of the stomach, because the anatomical relations were so entirely different as to minimize the protecting influence of adhesions to adjacent structures in closing the gastric opening or in limiting the area of infection, and also because of the greater number and virulence of the bacteria in the leakage, for these perforations often occurred with food in the stomach containing bacteria that acid secretion had not destroyed.

As acute suppurative peritonitis was often caused by the invasion of pathogenic bacteria from the organs contained in the pelvis, it would be well to consider briefly the bacteriobiology of the vagina, uterus, Fallopian tubes, and urinary bladder. No pathogenic bacteria inhabited the upper part of the vagina, the cavity of the cervix or body of the uterus, or the bladder when these organs and the kidneys were in a state of health, and pathogenic bacteria were found only in diseased conditions of these structures, having been introduced from without by infected media. With an intact and normal epithelium of the urinary tract, bacterial growth was inhibited and the urine was free of bacteria and in no sense infective. But any part of the tract or the entire tract might become infected by the tubercle bacillus introduced through the kidneys, or by pyogenic germs of any degree of infectivity introduced through the urethra, and under such conditions acute suppurative peritonitis might result from perforation or rupture of the bladder. Pathogenic bacteria might be abundant at the vulva and in the lower part of the vagina, but they could not be cultivated from the secretions of the upper part of the vagina or in the neck or body of the uterus, the acid secretions of the lower half of the cervix and the vagina positively inhibiting bacterial growth. The uterus and Fallopian tubes might be infected, however, by bacteria of all degrees of pyogenic and pathogenic virulence, resulting in mild or fatal forms of toxemia or septicemia or local and diffuse acute suppurative peritonitis.

In conclusion, Dr. Wathen emphasized in a general way a few things, on the observance of which might mainly depend success in the operative treatment of all perforations into the peritoneal cavity, and in the prevention and treatment of local, diffuse and general peritonitis from any cause.

"1. Operate as soon as a surgical diagnosis is made and avoid purgation and opium before and after the operation. Give no food or liquid, and if there is no gastric perforation empty the stomach by lavage, and remove fecal matter from the colon by rectal enemata.

"2. Operate rapidly and, if possible, treat the foci of infection by suturing gastrointestinal perforations, or bladder wounds, by cholecystectomy or cholecystostomy, by appendectomy, or the removal of the uterus or its adnexa, always remembering to avoid peritoneal traumatism so as to protect peritoneal resistance to bacterial invasion and toxemia.

"3. Expose or handle the intestines as little as possible, and do not separate adhesions or irrigate or sponge the peritoneal cavity. Establish drainage from the bottom of the pelvis through a suprapubic incision, and, if indicated, also drain the site of infection, using a large split rubber tube with or without gauze, with the patient in nearly a sitting posture.

"4. Pour into the peritoneal cavity, before closing the abdominal wound, hot horse serum or saline solution to stimulate leucocytosis, and when the patient is returned to bed use saline solution by rectum, after the fashion of Murphy, and, if necessary, use the horse serum or saline solution subcutaneously.

"5. Enterotomy is never indicated, except in some delayed cases of intestinal obstruction or paresis, and it should then be performed quickly and with a minimum exposure of the intestine; enterostomy is contraindicated.

"6. Physicians should be educated to impress on their patients the fact that acute diffuse and general peritonitis may usually be prevented by the early surgical treatment of gastric or duodenal ulcer, cholelithiasis and cholecystitis, appendicitis, tubal and ovarian infections, and acute intestinal obstruction; also in many cases of gastric and duodenal perforations."

Finally, the orator insisted with special emphasis upon the fact that the treatment by purgation, opium, and delay of the pathological conditions that caused acute local, diffuse, and general peritonitis, and bacteriemia and toxemia, had caused more deaths during the last ten years than had been sacrificed on the battlefields of the world;

and that in this progressive age of civilization he who obstructed the progress of science, medicine, and surgery in the prevention and cure of disease and the prolongation of life, was committing an offense against the State, humanity, morals, and religion for which the ethics of his environment may cause the people to hold him to a rigid accountability.

Wednesday, June 5—Third Day.

Address on State Medicine.—Dr. SAMUEL G. DIXON of Harrisburg, Commissioner of Health of Pennsylvania, delivered this address, taking as his subject, "Law, the Foundation of State Medicine." On State medicine, he said, the happiness of the people and the prosperity of the nation depended, for that nation would be strong which was vigorous in the health of its individuals. The contention that the enforcement of sanitary laws could be an infringement of personal liberty was puerile, for, as Parks has said, if we would aim to render growth more perfect, decay less rapid, and life more vigorous, we must give up many primitive or individual liberties. One factor in bringing about the wonderful achievement of the Japanese army was the high rank accorded to their medical and sanitary departments. In their particular branch of the service these men were supreme. In all great movements they were consulted. Unless a military necessity prevented, they supervised routes of march, sources of water supply, and sites for encampment. So long as the medical service was made subordinate to the strictly military service in our own army, so long, the speaker said, would repetitions of the disgraceful slaughter of Camp Alger and Chickamauga be of common occurrence in our military operations. In all matters pertaining to the health of the troops the medical staff of an army should be the authority, and in all councils of war their voice should be of equal authority with those of the combatant officers. It was only the skill of the medical officers of our army that made the present occupation of Cuba by our forces possible without frightful loss of life. It was only their knowledge of the mysteries of the transmission of the *Plasmodium malariæ* and the yellow fever microorganism by mosquitos that had enabled us to undertake the construction of the Panama canal and to convert the Canal Zone from a valley of death into a region in which men could live and labor in health and safety. Our legislators, Dr. Dixon said, were in general striving to do what was for the greatest good of the community in health matters, but they could not always distinguish between the true advisers and the false, between real scientists and pretenders, and the only way was for the Government to call upon educated medical and sanitary experts for advice; better yet it would be, if, as had been so often urged, there were established a Department of Health with a Secretary, a Cabinet Officer, at its head. The keynote of State Medicine was, however, compulsion and not persuasion. Without the law to back it, State Medicine might be a beautiful science, but it could never be a practical art. Certain public health questions were of national concern, and such matters as the prevention of the pollution of interstate rivers and streams, the prevention of food adulteration, and the sanitation of public conveyances on interstate lines of travel, both by land and water, must be controlled by federal law. The author then spoke of recent sanitary legislation in Pennsylvania. The first noteworthy enactment was the substitution in place of a State Board of Health of a Department of Health with a single official at its head, having a seat in the Governor's cabinet. The same legislature which gave the commissioner such broad powers also placed under his charge all the waters of the State and laid on him the duty of reclaiming them from pollution. No new system of water works for the supply of water to the public, and no addition to a system already existing, and no new sewerage system or addition to a sewerage system already existing could be made without a permit from the commissioner, in whose office must be filed certified copies of the plans, surveys, and descriptions of such systems. Pennsylvania was until recently without a State system of registration of vital statistics, but this was now no longer the case. The legislature had passed an "Act for the Immediate Registration of Births and Deaths," and to make this law effective in the rural districts nearly a thousand local registrars and two hundred subregistrars had been appointed.

An Epitome of Sanitary Legislation in the Several States.—Dr. Dixon then presented a review of what had recently been accomplished by other States in the way of sanitary legislation, the data for which had been furnished by a special bulletin of the State Board of Health of Rhode Island and the Providence Plantations compiled by Dr. Charles V. Chapin. In 1905, which was a year of unusual activity in sanitary legislation, the matter of registration was taken up in California, Connecticut, Michigan, Minnesota, South Dakota, Utah, Wisconsin, and Nebraska. In five of these States a complete system was inaugurated. These were California, South Dakota, Utah, Wisconsin, and Nebraska. In the remaining three, the acts were intended to remedy defects in systems already existing. These were Connecticut, Michigan, and Minnesota. In California, in addition to the complete law for the registration of deaths only, the old law for the registration of births and marriages received several amendments. A law establishing a State Board of Health or considerably enlarging its powers was passed in Minnesota. Acts establishing or regulating local boards of health were enacted in Indiana, Minnesota, Nevada, New Jersey, and Oregon. In Nevada and Oregon, county boards of health were created. Legislation for the better control of contagious diseases was accomplished in California, South Carolina, Maine, Tennessee, Utah, and Wisconsin. Emergency funds were established for special use in epidemics in Maine, Pennsylvania, and Wisconsin. Hospitals or sanitoria for consumptives were projected, established, or aided in Massachusetts, Michigan, Missouri, Rhode Island, Wisconsin, Georgia, Indiana, and New Hampshire. Acts to regulate the practice of medicine were established in fifteen States—Colorado, Indiana, Michigan, New York, Missouri, South Carolina, South Dakota, Tennessee, Texas, Washington, Wyoming, Florida, Michigan, North Dakota, and Wisconsin. The action of Colorado, Michigan, Wyoming, Nevada, and Wisconsin in forbidding the granting of licenses, or certificates, or registration to persons guilty of immoral, dishonorable, or unprofessional conduct, and empowering the State boards or courts to revoke and annul any license or certificate issued to such persons, cannot be too highly commended. Laws regulating the practice of undertaking and embalming were adopted in Illinois, Indiana, Massachusetts, New York, Pennsylvania, West Virginia, Wisconsin, Minnesota, North Dakota, and Oklahoma. Cigarette smoking was considered an evil of such magnitude as to require prohibition in Arizona, Indiana, Nebraska, Oklahoma, and Pennsylvania. State laboratories for bacteriological or chemical analysis were established in California, Connecticut, North Carolina, Wisconsin, and Pennsylvania. The practice of osteopathy was legalized in Colorado, Indiana, Montana, Nebraska, Tennessee, South Dakota, and New Mexico. The examination and registration of nurses was provided for in California, Colorado, Connecticut, and New Jersey. More stringent provisions to regulate the sale of poisons and narcotic drugs were adopted in Connecticut, Massachusetts, Minnesota, Nebraska, North Carolina, Texas, and Wyoming. An act to provide a method for locating and destroying mosquito-breeding areas had been adopted by the State

of New Jersey. This list indicated an advance, but there was always need of vigilance on the part of sanitarians. Anyone who was on the ground during a session of a State Legislature could but be struck with the amount of crude, ill-digested, and even nefarious legislation of this kind which was presented, and with the necessity for having intelligent medical men on the spot who could watch purely commercial schemes presented under the guise of sanitation and science and inform the legislators of their true character. An intelligent and conscientious chief executive was, however, often the only bulwark against disaster.

The speaker then referred to the scheme now being outlined in Pennsylvania for the limitation of tuberculosis. It contemplated utilizing the great forest reservations of the State for the purpose of hospital or sanatorium treatment. It was proposed to have two colonies at widely separated points that they may be accessible from different parts of the State. Instead of large and massive structures of brick or stone, there would be erected a large number of frame cottages, each of which would accommodate a small number of patients. Somewhat apart from these would be an infirmary for those in the more advanced stage of the disease. In this building those to whom hopes of recovery could not be held out would be afforded shelter and comfort in the closing days of life, and this extension of relief would be more than justified in the fact that such patients would be removed from their confined, crowded, ill-ventilated, and often impoverished homes at the time when they would be most in danger of communicating the disease to others. In addition to this, it was planned to establish in each of the sixty-six counties of the State a dispensary for tuberculosis, under the direct supervision of the Department of Health. The object of these dispensaries will be twofold: Many patients who might be unable to leave their homes for a prolonged stay in a sanatorium could frequently go there for advice in regard to matters of diet, medication, and the open-air treatment, so far as it was possible of being carried on at home. They would also receive careful instruction in all the precautions necessary to be observed for the protection of others. In this matter of the care for the tuberculous and the limitation and prevention of the disease, the speaker hoped to see a generous rivalry between the States, so that each might deserve well of the republic.

SECTION ON PRACTICE OF MEDICINE.

Tuesday, June 4—First Day.

DR. THOMAS D. COLEMAN OF AUGUSTA, GA., IN THE CHAIR.

Early or Premonitory Symptoms of Pernicious Anemia.

DR JOHN H. LICHTY of Pittsburg read this paper, in which he said, as far as we knew, pernicious anemia is the result of a toxemia. The symptoms and course of the diseases were clearly in accord with this, and the study of the bothriocephalus anemias permitted scarcely any other conclusion. What the exact nature of this toxin was was still a matter of speculation and doubt. It was generally accepted that its origin was in the intestinal canal. In a recent paper by Dr. C. A. Herter it was shown that the *Bacillus aërogenes capsulatus* was an active hemolytic agent, and that when the *Bacillus coli* type was sufficiently meagre to permit a very large growth of the *B. aërogenes* alterations appeared in the blood similar to a secondary or pernicious anemia. The blood change was not the cause of the symptoms—it was a part of the symptom complex of pernicious anemia. Other prominent symptoms were loss of muscular power, dyspnea and cardiac oppression, pallor, edema, subcutaneous and submucous hemorrhage, loss of appetite, achylia, diarrhea or alternate diarrhea and constipation together with certain nervous manifestations. From the literature on this subject it was evident that there was no recognized regularity in the order of the appearance of symptoms. The blood picture generally gave a high color index, with megaloblasts and megalocytes, and these were pathognomonic, but before this appeared certain premonitory symptoms arose which would lead one to make a most thorough blood examination. If the blood examination was negative and other diseases could be excluded, a provisional diagnosis should be made and the patient treated accordingly.

DR. GEORGE B. HERRICK of Chicago said that it was necessary to look back into the patient's past history and find out about gastrointestinal symptoms, as well as paresthesias. In case of changes in the cord, tingling of the fingers or toes was frequently present. Hunter had called attention to the fact that these cases often have sore tongues and sore mouths.

DR. W. S. THAYER of Baltimore said that pernicious anemia was more common than was generally supposed. He spoke of the importance of the early nervous symptoms, and particularly of paresthesias of the lower extremities with ataxia, while the upper extremities showed increased reflexes.

DR. F. F. GOODWIN of Mount Vernon, N. Y., said that from a study of pernicious anemia he was led to believe that all anemias arise from some disturbance in the gastrointestinal canal, such as the fermentation of carbohydrates or the partial oxidation of protected substances like nucleoalbumin.

DR. G. W. MCCASKEY of Fort Wayne, Ind., said that all were agreed that pernicious anemia was due to a toxemia, but whether that toxin came from the gastrointestinal canal or some other part of the body was a question still unanswered. He thought it was of great importance in these cases to estimate the amount of iron excreted. If, as is usual in these cases, there is a destruction of the red blood corpuscles then there would be an increased amount of iron excreted in the urine. This also was true in most of the chronic nutritional diseases.

DR. MAX EINHORN of New York City spoke of a patient with achylia who developed pernicious anemia. For three years this condition was still unchanged. He was improved somewhat on a liberal diet, low in meat.

DR. H. S. ANDERS of Philadelphia considered floating kidney an etiological factor.

DR. N. S. DAVIS of Chicago wished to speak of early degenerative changes that took place in the spinal cord in these cases. When one met with a case of ataxia pernicious anemia should be thought of and the case should be watched to see if this condition developed, even if the blood examination showed only a moderate anemia.

DR. C. S. HOOVER of Cleveland asked whether anyone had seen recovery in a case of pernicious anemia after spinal cord symptoms had developed?

DR. FRANK SMITHIES of Ann Arbor said that many physicians were apt to neglect the blood examinations. Many cases would show cardiac disturbances. One examination of the blood was not enough, but five or six examinations must be made. He had always found oval cells in the early part of this disease. The doctor asked Dr. Lichty what was his interpretation of the so-called "megaloblastic showers?"

DR. LICHTY closed the discussion by stating that the "megaloblastic showers" were a sign of the approaching end. He agreed with Dr. Davis and Dr. Hoover in regard to the changes in the spinal cord, but did not think that a movable kidney could cause pernicious anemia. He wished to bring out one point, that of the occurrence of cardiovascular symptoms in the early cases and the great importance of blood examinations.

Some Observations on Digestive Conditions in Pulmonary Tuberculosis.—Dr. James Rae Arneill of Denver, Colorado, read this paper. He said that during the last ten years he had been greatly interested in enteroptosis and had been on the lookout for this condition in patients of all classes. The frequency of this condition in slender patients, suffering with malnutrition, psychoneuroses, and tuberculosis was decidedly impressive. Most examinations of tuberculous patients did not include an examination of the abdomen. If one palpated the kidneys, and looked for Stiller's sign, the contracted colon, and the succussion sound in the stomach and the large intestines, he would find a surprising number of enteroptosis cases. Patients born with the enteroptotic type of physique were prone to malnutrition, psychoneuroses, and tuberculosis. Analysis of the stomach contents and the motor power were very often valuable aids in treatment. The most effective treatment was fresh air, absolute rest, generous feeding, attention to the skin and bowels, optimistic suggestion, and isolation with diversion and exercise. In the consumptive the cure must be prolonged and modified to meet conditions. Notwithstanding the remarkable work done along the line of opsonic therapy, our sheet anchor in the cure of tuberculosis must be the nutrition of the patient. Gain in weight and increased adiposity were only a part of nutrition. Rest, exercise, and fresh air were all of value, because they increased the appetite and oxidation. The average case of indigestion in the consumptive could be treated on symptomatic lines. Bitter tonics, hydrochloric acid and ferments, alkalies and antifermentatives were used when indicated. Application of some form of abdominal bandage was often of value in properly selected cases. Operative interference was occasionally necessary in the tuberculous patient, such as gastroenterostomy and appendectomy, in order to correct serious digestive disturbances. The successful treatment of tuberculosis chiefly depended on intelligent guidance of spontaneous resistance and recovery.

Dr. Woods Hutchinson of New York City opened the discussion on this paper. He said that there was more in pulmonary tuberculosis than the discovery of the germ or the signs brought out by the stethoscope. The most important information was found outside of the chest. The changes in the heart and abdomen were important. Often the heart was distinctly undersized, the stomach dilated, and the colon displaced.

Dr. Judson Deland of Philadelphia spoke of the importance of the use of the *x*-rays in diagnosis and as an aid in determining whether the supporters were doing their work by holding the organ in its proper place. He said that graded courses of exercises were most beneficial.

Dr. M. G. Lichty of Cleveland brought out the relation of consumption to gastrointestimal diseases.

Dr. J. H. Wetherspoon of Nashville, Tenn., said that he thought hyperchloracidity was a much graver condition than hypochlorhydria

Dr. Arneill in closing the discussion spoke of the importance of altitude in the treatment of these cases. He referred to the experiments of four noted German physiologists who made observations upon soldiers in the Alps. They found that low barometric pressure was followed by an increased proteid metabolism, also that low barometric pressure increased the activity of the blood-forming organs A high altitude gave 20 to 30 per cent. more hemoglobin.

The Continued Fevers of Southern Georgia.—Dr. H. F. Harris of Atlanta, Ga., read this paper. He said that this continued fever was known under different names, such as "slow fever," "Wallacoochee fever," and typhomalarial fever. It lasted from one to ten weeks. It was considered by some as malarial, by others as typhoid. The onset often came with a chill, the temperature was comparatively high, and the usual manifestations of a malarial paroxysm were present, but plasmodia were not found Other cases began like typhoid. The speaker had studied forty-five cases, making observations of the blood, urine, and feces, and in seventy-five per cent. typhoid or paratyphoid bacilli were isolated. In some cases a mixed infection was present. The prognosis was good. He thought medication did not modify the course of the disease, although some believed that large doses of quinine were beneficial.

Dr. J. H. Wetherspoon of Nashville, Tenn., said these cases of continued fever were not similar to malarial fever or typhoid and that quinine was not effectual. It began with a chill, there was rapid prostration, and the patient was irritable. The tongue was not that of a typhoid case neither was the pulse, which was rapid, and the belly was not tympanitic. If tenderness was present, it was over the liver or the sigmoid. This fever was not affected by the season of the year. The patient was constantly hungry and there was a rapid change in temperature similar to that of a septic case.

Dr. Wood of Wilmington, N. C., said that these cases were mild typhoid and gave a positive Widal reaction. It was most important to teach people the great danger of these cases.

Dr. John W. Litchy of Pittsburg said that a similar discussion had taken place in Louisiana. In Pittsburg where no malaria was they had "slow fever" cases and all gave positive Widal reaction.

Dr. Alexander Lambert of New York City asked if blood cultures had been made in any of these cases which were suspected as being typhoid. He said that in Bellevue Hospital 90 per cent. of the doubtful cases gave a positive culture of typhoid fever. Of course the Widal reaction varied in individual cases.

Dr. Howard Fussell of Philadelphia said the typhoid fever varied in form, but that the name typhomalarial was a shield of ignorance and should be banished.

Dr. Harris, in closing, said he accepted the view that this slow fever, so called, was a "mild" typhoid. In a few cases blood cultures were taken and the positive reaction obtained.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Tuesday, June 4—First Day.

Dr. J. Wesley Bovée, Chairman

The Status of the Fight Against Cancer of the Uterus.—Dr. J. Wesley Bovée of Washington delivered the Chairman's address, taking this as his subject. He said that from the many articles catalogued on the subject, the observer would think it was hackneyed and that great enthusiasm existed in the professional ranks concerning the treatment of cancer. There were many remedies presented, from surgery to the use of the newer remedies, *x*-ray, radium, etc. W. Dean Bluchcr modestly claimed a curative effect of radium on cancer, but did not claim that it would benefit uterine cancer to any great extent. The great things that have been claimed for some of the new remedies were very far from the actual facts. Those who were brought into actual contact with cancer of the uterus knew that it was one of the worst scourges flesh was heir to. It appeared that in no country, race, or society were women free from this disease. Some claimed immunity for the North American Indian, the inhabitants of Africa, and the negro of this country, but such was not true. Seldom was the speaker without a negro woman in his wards with cancer of the breast or uterus. It usually occurred during the few years preceding the menopause or after. It should be remembered that cancer of the uterus, whether of cervix or the body, was a local disease in

the beginning, but soon lost its local character, passing to surrounding tissues. The cancerous tissue was often isolated and at a distance from the focal point. It was important that there be a uniform classification, and Sampson of Albany had suggested a good working classification. Much work had been done to discover the cause, but no conclusion had been reached. Much was hoped from the bacteriological theory, and while it was possible to transfer from one animal to another, it had not been proved that the origin was a bacterial one. After all the most that could be said was that it might have its impetus from a chemical irritant circulating in the blood. The cancer age was from near the menopause to the end of life. This held true in the vertebrates other than human. The element of heredity was a very important one. The question of contagion should not be overlooked, for he had cases in which there seemed no doubt that the disease was communicated from another patient. Dr. Bovée quoted from A. Lapthorn Smith, who offered many instances in which cancer was communicated from one person to another and claimed that cancer had increased thirty per cent. in a decade. The question of vital import was the cure of cancer, and since it was admitted that it started as a local disease, there was great necessity of early diagnosis. The fact that the uterus was a concealed organ, that women often hesitated to have examinations, that the disease was one occurring at times near the menopause (the physician being often misled to think it was a condition associated with that event and did not make an early diagnosis) often prevented the early radical treatment. With the many handicaps the surgeon had not been able to demonstrate to the general practitioner that he could cure cancer by radical operation if taken in the early stage, and industrious effort would be necessary for years to overcome these obstacles. Women should submit to examinations at regular intervals when they have reached the cancerous period, the same as they would consult a dentist about their teeth. In this way they might be guarded against a progressive condition that would prove obstinate and fatal. All cervical tears or injuries should be repaired and prophylactic measures be employed. Radical operations in early cases had proved quite satisfactory. In the later stages of the disease Byrne's method of the galvanocautery had been beneficial. Trypsin was now much used in nonoperable cases. The uterus seemed too deep seated for use of the *x*-rays. In conclusion Dr. Bovée said stress should be placed on early diagnosis; special care in the classification of the varieties; *x*-rays and radium were of little use, and no time should be wasted with these when the case was an operable one; the cautery should not be used as a substitute for a radical operation, and the vaginal route did not offer as good results as the abdominal. He also suggested that all rooms occupied by cancerous patients should be fumigated before being occupied by the non-cancerous, and everything possible should be done to stamp out the disease.

How Can We Lessen the Mortality of Uterine Cancer?—Dr. E. E. Montgomery read this paper. He said the bacterial origin of cancer had not been proved, but the influence of heredity was an important factor as was also the resisting power of the patient. The fact of heredity might have to do with either the cancerous tendency or diminished resisting power. Most cases of cancer were found in women who had borne children and one of the great causes was injury or long irritation of the part affected. The damaged cervix was a factor to be heeded and all such conditions should be attended to. The treatment was preventive, curative and palliative and the first two were vital. Of course the early diagnosis was all important and if the cervix or the body of the uterus was in any way affected treatment should be directed to its correction. The general health of the patient was of vital importance and all gastrointestinal fermentation and irritation should be avoided and the patient should drink large quantities of water and if necessary sleep in the open air. Experience demonstrated that the earlier in life the disease occurred the more rapid was its progress, and at all times an accurate knowledge of the disease and its early recognition were essential for its radical removal and cure.

Dr. Howard Kelley of Baltimore said he would emphasize the necessity of the early diagnosis. He thought much could be gained by systematic classification, but found many varying individual cases. He thought much harm was often done to the patient by the length of the operation. That an operation requiring two or three hours was too much of a drain on the power of the patient. By the use of long clamps in clamping of the arteries the operation had been reduced in time.

Dr. Marstey said that he was using a modification of the zinc-mercurial cauterization he presented at New Orleans with good success in two cases. Instead of using a general anesthetic he applied the cautery as long as the patient could well bear it, one-half to one hour at 200 milliamperes without great discomfort to the patient. One of the patients had been well for over three years and the other for nine months.

Dr. Margaret A. Cleaves made a plea for the use of trypsin and said she had patients who according to all rules of the disease should be dead, but were living with no symptom of the disease. She had noticed that patients in whom trypsin was injected often reacted in markedly different manner. One presenting fever, chills, and all the serious evidences of eosmophilia and the other going along in a normal way. She had found these cases were different in that the former were sufferers from a malignant condition and the latter were not, although the diagnosis had been the same in both cases. If trypsin were administered many of the cases began to improve at once.

Dr. Boldt said that in patients 30 years of age the vast majority were doomed. It was important what route should be pursued in the operation. In cases over 50 years he advised the vaginal route as there was less shock to the patient and in these cases his experience with the abdominal route had not been good. He thought that radical operation was the right method.

Dr. D. L. Craig said that three years ago he had reported an investigation of cases treated in a hospital for women and that in cases where there were no lacerations or the cervix had been repaired there was no cancer, and he thought many cases were due to some form of irritation. The general practitioner could do much toward the prevention of cancer.

Dr. Carson said there were two important things to keep in mind; how to prevent and how to save the patient. He laid special stress on the fact that at some time it was a local disease; perhaps as big as a pin point or as a pea, but it was then a local disease and it was the physician's place to keep a watch for a starting point.

Dr. Montgomery said in closing the discussion that he agreed with the majority of the speakers and that other methods than the radical operation might in time prove to be preferable, but at the present and with the light we now had he held to the radical operation in all operable cases.

Parasitic Uterine Myomata.—Dr. Thomas S. Cullen said that by the term he meant myomata that had become completely or partially weaned away from the uterus and got their blood supply from another source. These might get the greater part from the omentum, the large or small bowel, the bladder, mesenteric vessels, or Fallopian tubes, or from several sources at the same time. In many cases the omental adhesions were associated with pelvic adhesions or with pus tubes. Sometimes the peduncle became very small and most or all of the blood supply came from some

other source. In cases where the blood supply was from the omental vessels they became very large and tortuous, but as a rule there were large arteries each accompanied by two veins. At first there might be but little omental change when the blood supply was from that source, but as the tumor increased the omental fat gradually disappeared. The function of the omentum seemed marvelous in some cases, as in one where the tumor weighed 89 pounds and was attached to the uterus by a very small pedicle, its chief supply coming from the omentum. In the operative treatment of these tumors one of the first things to do was to control the omental vessels. This could be done by tying off the omental vessels on the proximal and once on the distal tumor side. They were so delicate that they should be tied instead of using forceps. The arteries should be tied under sight and one should not attempt to liberate adhesions far under the abdominal wall as they might contain blood-vessels that would give trouble. Dr. Cullen showed illustrations of myomata and insisted that the greatest care be exercised in the operation lest a blood-vessel be ruptured.

Dr. Isaac S. Stone said that ten years ago he had written on that subject, but it had been passed in the way of many things. He thought it a most interesting subject and the writer had presented the subject most interestingly. He supposed that when a fibroid started on its way it might take an exceedingly varying course.

Dr. Boldt said the important point was the blood-vessels and the greatest care should be taken that they be not injured or the tumor removed until all were secured.

Prevention of Peritoneal Adhesions by Adrenal Salt Solution, with Especial Reference to the Pelvis.—Dr. Emery Marvel presented this paper. He said peritoneal adhesions resulted from a pathological process active within or adjoining to the peritoneum. Their formation was Nature's effort to combat an injurious process in which adhesions were good and a protection to the organs. In many cases they were injurious and it was desired to prevent them. The thin-walled vessels of the peritoneum favored free exudation of serum and became the agent by which the surfaces were united. Now in an operation the dilated blood and lymph vessels gave a leaking orifice with exudation that meant adhesions. To prevent adhesions the purpose was to dilute the serum and thus hasten absorption and prevent further exudation. Then too the irritated surfaces should be kept apart until partial repair had taken place. In order to remove the irritant and release the parts salt solution might be used, and then should be added to this for the purpose of preventing further exudation adrenalin chloride. The salt solution aided absorption of the secretions and the adrenalin prevented the exudation of further secretions. The bulk of the fluid kept the surfaces apart and thus the threefold purpose was accomplished.

Dr. Lawrence said much of the trouble from adhesions was due to the methods of operations. Too much was done in the abdomen and with all the drainage tubes, the sponges, the handling of the parts traumatism resulted and adhesions. Much of the adhesion was defensive and Nature's method of protecting herself, and as for himself he did not look with great favor upon the method advocated by the writer

---

SECTION ON SURGERY AND ANATOMY.

Tuesday, May 4—First Day.

Address of the Chairman.—Dr. Arthur Dean Bevan of Chicago spoke on the importance of a further study of anesthetics and anesthesia, and, after commenting on the value of the findings of the British Commission, urged the creation of a similar body in this country. The use of gas as an anesthetic, he said, had until very recently been relegated to the dental fraternity, in the more progressive surgical centers this was now very generally being recognized as a great mistake. Cases of aneuria, among many others, were singularly suitable for the induction of anesthesia by gas—there was indeed a very long list of capital operations in which for a half hour or more anesthesia might, without detriment to the surgeon and with lasting benefit to the patient, be used to the exclusion of ether or chloroform. Operations in two specific regions, namely, the perineum and within the abdomen, were not favorably conducted under gas. One objection to the employment of gas lay in its relatively great cost. It averaged about two dollars an hour. Certain savings in this cost might be effected, however, if hospitals were to make their own gas—a plan that was practical to follow.

Dr. Powers of Denver made a motion embodying the suggestion of the chairman and requesting the section to create a Commission on Anesthetics which should consist of three or five men—one of them to be the chairman of the section, the others prominent men qualified specially to carry on investigations along the lines of interpreting and correlating the great mass of information regarding anesthetics now available at every hand, but not made the fullest use of. This commission was to have the power to create sub-commissions in special regions and was to report to the Section on Surgery and Anatomy the result of its findings every year. Its expenses were to be paid by an appropriation to be voted by the trustees.

Dr. Rodman of Philadelphia seconded the motion—said he regarded the creation of an Anesthetic Commission similar to that of the British Empire, and especially its reporting to the surgical section, as a most important and valuable departure.

Intestinal Perforation in Typhoid Fever; Its Surgical Treatment, with Report of a Case.—Dr. J. E. Allaben of Rockford, Ill., read this paper. He gave a full but concise summary of the literature of the subject. He spoke of the improvement in the death rate, which had been lowered by about ten per cent. during the past four years. Fully ninety-five per cent. of the perforations occurred in the ilium, although there were a sufficient number in the colon to make every search which did not fully include that organ incomplete. Coma had, in earlier days, been considered a valuable point diagnostically, but it was now well established that to wait for its appearance in a suspected case was to sacrifice all hope of saving the patient. Pain, rigidity, and tenderness to pressure were the cardinal symptoms calling for operation. The value of the leucocyte count to which Cushing had called attention was lessened by the fact that it frequently occurred in transient waves. Buxton's experiments, which showed the importance in germ absorption of the lymphatics of the diaphragm, proved that flushing of the abdominal cavity after operation was not alone not indicated, but was evidently positively dangerous, for it carried the germs to the diaphragm whence they might easily be absorbed.

Dr. Murphy of Chicago laid great stress on the need of early operation. Hyperleucocytosis was frequently absent. He urged the importance of washing the system out by properly conducted and continuous proctolysis. This to be well done should be induced by saline flowing continuously from a level just high enough to overcome intra-abdominal pressure—not from a considerable height—with the tube clamped so that the saline might run in drop by drop. He urged, further, the wisdom and necessity of a careful examination of the colon for perforation.

Dr. L. J. Hammond of Philadelphia spoke of the value of surgical prophylaxis. Most cases of perforation, he thought, were due to the preexistence of some lesion—such as adhesions or ulcers in the typhoidal bowel. He believed that perforations in typhoid rarely occurred ex-

cept in the presence of such antityphoid lesions and advised, therefore, that in all individuals whose history was known well enough to justify the supposition that lesions, non-typhoidal, existed, should be subjected to operation at once. Such lesions he thought were indicated by the appearance of abdominal symptoms very early in typhoid fever.

Dr. Allaben in closing said that collapse was due to the liberation of endotoxins in the blood due to breaking down of the bodies of bacteria.

An Operation for Exstrophy of the Bladder.—Dr. JOHN T. BOTTOMLEY of Boston read this paper. He discussed the shortcomings of the three classic types of operation for this abnormality and showed that in each there seemed to be an insuperable difficulty yet to be overcome. The first was the plastic, in which substitutes were made for the deficient wall of the bladder. The second was the making of a new receptable. The third was the diversion of the urinary stream. The operations on the pelvic girdle, many of which were brilliant, were nevertheless attended with a mortality of twenty-eight per cent. As to the employment of the rectum as a reservoir of urine, he said that even after the brilliant work of Madyl we were still unable to do it satisfactorily and without great danger, either of intestinal leakage or of ascending infection. For nothing could be more surgically unclean than the sigmoidal mucosa. Eight per cent. died of peritonitis and the operation was dangerously long. It was to be borne in mind, however, that by no means all cases of pyelonephritis were due to operative intervention, for the very nature of the abnormality itself predisposed to such a condition. Patients suffering from it rarely attained to their twentieth year. He urged the transplantation in certain selected cases of the ureters to the loins and the utilization by the patient of a well fitting rubber girdle which kept the skin dry and was eminently practical. Loin skin, he said, could be kept clean and thus much less septic and unsurgical than sigmoidal mucosa.

Dr. H. H. YOUNG of Baltimore said that the subject was still an open one, whether it were better to employ a permanent drainage tube from the kidney, as he had frequently done, or to make use of ureteral transplantation to the skin.

Dr. BOTTOMLEY in closing said that he never intended to suggest that this operation should supersede certain others, but that it be employed in specific chosen cases which were suited to it.

How May Our Present Methods of Medical Illustrations Be Improved?—Mr. MAX BRÖDEL of Baltimore read this paper. He contrasted the excellent character of some of the illustrations in the lay press with the inferior work frequently appearing in the medical publications. An important reason for this law in the inability or unwillingness of the artist thoroughly to familiarize himself with the subject of his work from both physiological and pathological standpoints. The artist should know more of science and the scientist more of art. He showed how outline illustrations of specific regions might be useful to surgeons in presenting important details to artists for their elaboration.

Dr. WILLIAM MAYO said that the entire profession owed Mr. Brödel a debt of gratitude for his development of an entirely unique school of artists. He said that much of the medical literature which had been so ably illustrated by Mr. Brödel had been intelligible to him only after a study of the illustrations.

Gall-Duct Obstruction Caused by Movable Kidney.—Dr. MARTIN B. TINKER of Ithaca, N. Y., read this paper. He referred to the known frequent association of biliary tract affections with diseases of the stomach, pancreas, and appendix. The connection between these lesions and movable kidney had, however, but in rare instances been dwelt upon. His personal experience had led him to the conclusion that the movable kidney, pressing upon or adherent to the duodenum and common duct, was a not infrequent cause of biliary obstruction. He recited in detail the history of two cases which illustrated and supported this belief. He believed that nephropexy combined with cholecystostomy would almost always afford relief.

Bier's Treatment in Chronic and Acute Surgical Affections.—Dr. WILLY MEYER of New York read this paper. He said that even to-day, more than ten years after its discovery, this admirable addition to the prophylactic treatment of wounds had been but little employed in America. During the past few years, however, its advantages seemed to have become more generally appreciated and as a consequence the literature of the subject was growing at a very rapid rate. He considered that the results following its employment in chronic bone disease might be simply astonishing. He had seen a tuberculous elbow recover in a few months under moderate elastic compression of the arm and the results were equally gratifying when the method was employed to combat acute local extremity infections which were tending to become generalized. He concluded that, however applied, whether by compression by cups or by hot air, hyperemia was a most valuable aid to surgical therapeutics.

Dr. SCHMIEDEN of Berlin, one of Bier's assistants, spoke of the very general manner in which the treatment was employed in Germany and expressed the hope that all the American hospitals would give it a trial.

Dr. HOLLISTER of Chicago said that hyperleucocytosis was by no means so important a factor resulting from the hyperemia as was hyperobsination. He cited a most instructive series of cases in which experimental observation had proven that the opsonic index of the serum exuding from a sinus was below ONE, while after treatment it rose to ONE or plus ONE. Further, the series showed that by combining the congestion treatment with vaccine therapy the best results were obtained.

Dr. SMITHIES of Ann Arbor said that there were very marked limitations to the compression treatment—that it was capable, if not properly employed, of causing much damage. This was particularly to be feared in anemic cases, such as arthritis deformans and chronic rheumatism.

SECTION ON DISEASES OF CHILDREN.

Tuesday, June 4—First Day.

The Status of the Child.—Dr. J. ROSS SNYDER of Birmingham, Ala., presented the Chairman's address. Certain changes in our way of living would seem imperative if the integrity of the nation was to be preserved. The rapid increase in the number of defective and degenerate persons called for the better safeguarding of the children of to-day in order to insure an oncoming generation of well-equipped individuals. Some of the evils that beset children were associated with their home life, and in this connection the physician could render lasting service to the country. The position assumed by modern society with reference to the unborn child had been such that physicians rather shrank from approaching the subject. This should not be so, however, and physicians should instruct the prospective mothers under their care in matters pertaining to the care of the child. Enough consideration was not given by physicians to the conditions which surrounded the mothers of the country. Attention was called to the increasing tendency on the part of women to adopt measures for the prevention of conception—a tendency born, many times, of fear engendered in the minds of newly married women by stories told by older women of the horrors of child-bed. It should be the duty of the physician to overcome this fear in the minds of women, and to so educate and prepare the expectant

mothers in matters pertaining to the child's needs that her later duties will be less arduous. A failure on the part of the mother to furnish her child with a sufficient supply of natural food tended to make motherhood burdensome. A large proportion of defectives and degenerates in America came not from homes of poverty, but from homes of wealth, for the thoughtless care of children was confined to no status of society. A strong plea was made against child labor. Physicians took just pride in the part they had played in bringing about various reforms with reference to children; in the direction of suppressing obscene literature, however—chief and probably most harmful of which is the modern newspaper—it would seem that all efforts were unavailing.

Some Needs of Institution Children.—Dr. JOHN RUHRÄH of Baltimore, Md., read this paper, in which he outlined the general causes which led to failure on the part of institutions to raise children coming under their care. Certain requirements should be adhered to. First of all, the matter of ventilation should be looked after. One thousand cubic feet of air space should be provided for a child under one year of age. Under no circumstances should admission to the institution be allowed to exceed the capacity of the wards. Children should be kept out of doors as much as possible. A strong plea was made for the separation of sick from well children and for the prompt isolation of infectious diseases. A special ward, kept at a higher temperature than the others, should be provided for congenitally weak children. Each ward should have a competent trained attendant. Babies should not be kept in bed all the time, and should not be fed in bed. The nurses should be allowed ample time for that most important factor in the care of children in institutions—the "mothering" of the child. He advocated simplicity in diet.

Dr. GRAHAM of Philadelphia emphasized the importance of the requisite air space, and of out-door life. This had not been appreciated in institutions until within the past few years. He wished, also, to emphasize what the reader of the paper had said about nurses. In very few hospitals and institutions devoted to the care of children would it be found that nurses were allowed sufficient time for "mothering" the children under her care, yet he considered this a very important factor. The feeding of the infant in hospital and institutional practice was a subject to which much attention had been directed, and he was surprised to hear what Dr. Ruhräh said on this subject.

Dr. SHAW of Albany, N. Y., thought Dr. Ruhrah had idealized the requirements for the institutional care of children. One thousand cubic feet of air space might be provided and yet the ward not have sufficient fresh air. In the institution with which he was connected, which received only children under one year of age, in some of the wards there was not more than three hundred feet of air space, yet results were very good, the mortality being not more than seven per cent. All of the children were artifically fed. Great importance was attached to ventilation in this institution. In the upper sash of each window the glass was replaced by cheesecloth, which was true in winter as well as in summer, and the difficulty had been not in keeping the wards warm, but in keeping them cool in winter. The smallest ward accommodated three children and the largest nine. In summer the children were kept out of doors. He considered the separation of the sick from the well children of the utmost importance. The individual needs of the child should be studied with reference to diet, as had been suggested by Dr. Graham, but he agreed with Dr. Ruhrah with reference to simplicity in the matter of feeding.

Dr. KNOX of Baltimore, Md., advocated wards for not more than three children, and as far as possible that each infant should be in a separate room. Children slept much better in small wards. In summer they should be kept in the open air practically all the time.

Dr. C. G. KERLEY of New York City agreed with the preceding speakers as to the importance of air space, ventilation, attendance, out-of-door air, etc., but the feature which seemed to him of the utmost importance was the complete emptying of the ward during the day. Places should be provided for the day and sleeping rooms for the night. In institutions with which he had been connected the mortality had markedly decreased under this régime.

Dr. Ruhräh, in closing the discussion, said that the point he wished to make with reference to feeding was that it was much easier to feed a child who is well taken care of than one who is not.

The Relation of the Physician to Defective School Children.—Dr. W. C. HOLLOPETER of Philadelphia, Pa., in this paper contrasted the requirements for the fourth grade child in the public schools of Philadelphia in 1888 with those for 1907, and showed that the school life of the child of to-day is so complex that it leads to great tension on the body as well as the mind. He considered this ever-increasing strain a menace to the child's natural mental development and the cause of serious impairment of health. This condition of affairs was in a large measure the result of the modern tendency to "child study"—a tendency which he was inclined to deprecate. He agred with the statement that much of the delinquency of our time was the result of what had been characterized as the "grinding monotony of school life." He emphasized the fact that perfectly normal children develop different faculties at different ages, and that this should be taken into account in the grading of school children. The personal equation should be more fully studied as to physical and mental development. The danger of overreaching the child's capacity should be borne in mind. The power of fixing the attention was an important factor in the process of mental development, and should really be the true standard of grading, regardless of the child's age. It was only within recent years that the physician had anything to do with the grading of school children. Only within recent years had any effort been made to deal with the distinctly defective classes. This was a step in the right direction. Medical inspection should be more thorough and the mental and physical defects of school children should be removed in early life.

Dr. A. C. COTTON of Chicago thought the Section should go on record as formulating some plan for rectifying the abuses of modern education. He deprecated the inefficiency of medical inspection of school children as it is usually practised. He considered it the duty of every medical organization that deals with the disorders of children, particularly if it deals with the hygiene of the developing period, to make itself heard on this subject. It was the part of true economy to weed out the defectives and place them in special grades to which they properly belonged. He believed the time would come when honest medical inspection will include the fitness of the child for the mental work expected of him and his readiness for promotion to a grade requiring different work.

Dr. A. W. FAIRBANK of Boston, Mass., gave a preliminary statement of the results of a clinical study of fifty backward girls between the ages of twelve and sixteen, forty-six per cent of whom showed a marked discrepancy between

the actual age and the development. Ninety-two per cent. were of the age when puberty develops, yet in fifty-two per cent. there was no evidence of such development. Only four out of the fifty showed definite anatomical stigmata.

Dr. BROWN of Elmira was of the opinion that the nervous breakdowns in school children were not attributable to the school work alone, but to various outside factors,—social duties, music lessons, etc.

Dr. HOLLOPETER, in closing the discussion, expressed the opinion that teachers and boards of education were not to be too severely criticised, as much of the fault of the present conditions of affairs rested with physicians. He advocated paying more attention to physical development.

A Preliminary Report on the Etiology of Infantile Atrophy.—Dr. A. H. WENTWORTH of Boston, Mass., said, in this paper, that the etiology of infantile atrophy had long been a mooted question, which is still far from settled. He reviewed briefly the various theories, and outlined his investigations, which were undertaken upon a functional basis. This series of comparative experiments consisted of twenty observations. Cots were used for the purpose and the experiments were conducted after Heidenhain's method. Within a minute or two after the injections of secretin pancreatin flowed out through the cannula. The total time that the pancreatic juice ran was as important as the quantity thereof. This varied from nine to fifteen minutes. The theory upon which these experiments were based was that in infantile atrophy the digestive functions are not normally activated because infants do not obtain suitable food at an early age, and that the derangement of one function upsets another, and this in turn still another, until nothing goes right.

Dr. A. W. FAIRBANKS of Boston, Mass., reviewed briefly Edsall's theory which, he thought was reasonable. It was based upon the fact that protein is more complex than formerly thought, and that its end products constitute the building blocks, so to speak, of the proteid molecule. Syphilis was thought to be a factor in producing infantile atrophy, and in all these cases this should be borne in mind. He cited illustrative cases.

Dr. GRAHAM of Philadelphia said it was not uncommon to find cases in which the amount of atrophy was out of proportion to the failure of digestion and absorption, and it was interesting to note that autopsy in such cases gives nothing upon which to base a diagnosis. He hoped Dr. Wentworth would continue his experiments along this line.

Dr. WENTWORTH, in closing the discussion, said the *motif* of the whole subject was to give the child suitable milk.

The Ferments of Milk and Their Relation to Pasteurization.—Dr. ROWLAND G. FREEMAN gave, in this communication, a brief résumé of the history of the pasteurization of milk, calling attention to the supposed injury to milk by high temperatures. He emphasized the indisputable advantage of breast milk. Escherich's theory of the ferments was outlined and tables were presented showing the ferments of breast milk and cow's milk, and the temperatures that destroy each. These facts were applied to pasteurization.

This paper was discussed by Dr. KERLEY, Dr. COTTON, and others, and the discussion closed by Dr. Freeman.

A New Form of Amputation Stump.—Vanghetti has successfully employed a new method of forming the stump in two cases of amputation. The procedure consists in fashioning a loop lined with skin from the tendons of the stump, through which loop a cord can be passed that is fixed to the prosthesis and in this way a certain amount of voluntary control over the latter may be secured. In one case the tendons of the biceps and triceps were united and the loop so formed converted into a permanent opening by the transplantation of a skin flap, and in the other the flexor and extensor tendons of the forearm were made use of in a similar way.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.*

INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

October 23, 1906.

CHEMISTRY.

1. What is carbolic acid? Give antidote.
2. What is calomel?
3. What is the specific gravity of healthy urine? Give test for albumen, sugar, blood.
4. What is double decomposition?
5. What is the difference between the mercurous and the mercuric compounds?

MEDICAL JURISPRUDENCE.

1. What is rigor mortis? How soon after death does it begin?
2. How would you determine whether an infant was still born or had been killed after birth?

NEUROLOGY.

1. Give cause, symptoms, and diagnosis of epilepsy.
2. Give the definition of dementia.
3. Give difference between concussion and compression of the brain.

OPHTHALMOLOGY AND OTOLOGY.

1. How do you distinguish whether deafness is due to nerve lesions or aural lesions?
2. Give etiology, diagnosis, terminations, and treatment of chronic inflammation of the membrana tympani.
3. Give etiology, symptoms, and treatment of iritis.

PEDIATRICS.

1. Give cause and treatment for intestinal worms.
2. Give cause and treatment of nystagmus.

PHYSICAL DIAGNOSIS.

1. Define the "Argyll-Robertson" pupil. In what disease is this condition often found?
2. How would you ascertain the shape and position of the stomach?
3. At what age is the pulmonic second sound more intense than the aortic? At what age does the aortic second sound predominate?
4. Give causes and symptoms of pulmonary atelectasis.
5. How would you diagnose alcoholic coma from the coma of epilepsy?

PHYSIOLOGY.

1. Explain cell division.
2. What are the elementary tissues or structures of which the human organism is composed?
3. Give the physiologic composition of the blood with the function of each part.
4. If a sympathetic nerve be divided, what is the effect upon the blood-vessels in the parts to which the nerve is distributed, and why?
5. How long will an animal survive deprived of water?
6. Give the manner of the transmission of motor impressions.
7. Give the origin, course, and distribution of the motor impressions that effect respiratory movements.

RHINOLOGY AND LARYNGOLOGY.

1. Give some of the constitutional causes of epistaxis.
2. Give symptoms and treatment of chronic rhinitis.

ANATOMY.

1. Give diagram or brief description of (a) simple tubular, (b) simple convoluted, (c) compound racemose, and (d) compound tubular glands.

***It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.**

2. Give the boundaries of the thorax.
3. Give the muscles of the orbital region.
4. Give, in the order of their origin, the branches of the external carotid artery.
5. Give, in the order of their origin, the branches of the femoral artery.
6. From what regions do the lymphatic vessels convey lymph to the axillary glands?
7. Give the openings communicating with the pharynx.
8. What muscles attach to the trochanter major?
9. Give general description of the spinal cord.
10. Give the principal nerve trunks of the arm, with location of each.

ETIOLOGY AND HYGIENE.

Give cause and hygienic measures for the prevention of (1) tuberculosis, (2) typhoid fever, (3) diphtheria, (4) scarlatina, (5) variola (smallpox).

GYNECOLOGY.

1. Give pathology, etiology, and treatment of pelvic peritonitis.
2. How would you conduct a physical examination? In what position would you place your patient?
3. Describe the operation of trachelorrhaphy.
4. What are the indications for dilatation of the uterus? Give technique of dilatation.
5. Give after-treatment in major operations (abdominal sections).
6. Define chronic metritis. Give etiology and pathology.

INTERNAL MEDICINE.

1. Define inherent body resistance to disease, and state how it may be increased.
2. Give source, habitat, symptoms, and treatment of tænia solium (tapeworm).
3. Give symptoms of true angina pectoris, and the pathological conditions causing it.
4. Give clinical history of gastric ulcer, and differentiate from (a) gastric carcinoma, (b) duodenal ulcer.
5. Give causes, symptoms, remote results, and treatment of cirrhosis of the liver.
6. Define hematuria, and state how you would determine the probable source of the hemorrhage.
7. Give cause, means of prevention, and treatment of bed sores.
8. In what class of diseases is general aching a pronounced symptom?
9. Give etiology, symptoms, and treatment of dysentery occurring in the temperate zones.
10. Give diagnosis and treatment of pertussis (whooping cough).

MATERIA MEDICA AND THERAPEUTICS.

1. Define preventive medicine, and give illustration of its application.
2. Give derivation of ichthyol, and its therapeutic application.
3. Give technique of introducing medicinal agents into the organism hypodermatically.
4. Name three therapeutic agents which increase the renal function.
5. Name three therapeutic agents which increase the hepatic function.
6. Name some therapeutic agents which promote constructive metabolism.
7. Name some therapeutic agents which promote destructive metabolism.
8. Name some therapeutic agents which excite the functions of the spinal cord and sympathetic.
9. Name some therapeutic agents which depress the functions of the spinal cord and sympathetic.
10. Name some therapeutic agents which are germicidal in their action.

PATHOLOGY AND BACTERIOLOGY.

1. Explain the difference between active and passive hyperemia.
2. Give the modes of infection by the tubercle bacilli; by the malarial hematozoa.
3. To what pathological conditions may passive hyperemia of the stomach be due, and to what may it lead?
4. What pathological conditions may result from abnormal conditions of the thyroid gland?
5. Give the conditions of the urine in nephritis.
6. Describe in detail the various forms of bacteria which are known to be the cause of pneumonia.
7. Name the bacteria which may cause meningitis.
8. What tissues are usually invaded by the typhoid bacilli during typhoid fever?
9. How would you prepare Löffler's blood serum?
10. Describe the staining properties of the smegma bacillus.

OBSTETRICS.

1. Describe the fetal circulation.
2. How and when should the umbilical cord be ligated and cut?
3. State causes of the rupture of the perineum and how prevented.
4. Give diagnosis and probable cause of tubal pregnancy.
5. Name diseases most commonly affecting the mammæ of the nursing mother.
6. Give cause and treatment of aphthæ.
7. Give indications and contraindications for the employment of chloroform in labor.
8. When should ergot be employed in obstetric practice?
9. State cause, diagnosis, and treatment of porrigo larvalis, or crusta lactea.
10. Give cause and treatment of vomiting of pregnancy.

SURGERY.

1. What is a compound fracture?
2. Give diagnosis of inguinal hernia.
3. What is an aneurysm?
4. Give diagnosis and treatment of appendicitis.
5. What conditions justify amputation of a limb?
6. Give symptoms and treatment of intestinal obstruction.
7. Give a description of Chopart's operation.
8. What are the symptoms and treatment of depressed fracture of skull?
9. Give symptoms and treatment of hydrocele.
10. Give symptoms and treatment of downward dislocation of head of humerus.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

Indiana State Board of Medical Registration and Examination

October 23, 1906.

CHEMISTRY.

1. Carbolic acid is phenyl hydroxide: C_6H_5OH. Its antidote is alcohol or magnesium sulphate.
2. Calomel is mercurous chloride: Hg_2Cl_2.
3. The specific gravity of healthy urine is from 1015 to 1025.

Test for *Albumin.*—The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for *Sugar.*—Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for *Blood.*—To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced. (Witthaus' *Essentials of Chemistry.*)

4. Double decomposition is a reaction in which both of the reacting compounds are decomposed to form two new compounds.

5. The *mercurous* compounds contain the bivalent group $\left(\begin{matrix}Hg\\|\\Hg\end{matrix}\right)''$ or $\left(Hg_2\right)''$, whereas the *mercuric* compounds contain the single, bivalent atom Hg″. They also differ in their analytic characters; thus with potassium hydroxide the *mercurous* salts give a *black* precipitate, and the *mercuric* salts a *yellow* precipitate.

MEDICAL JURISPRUDENCE.

1. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours.

NEUROLOGY

2. "*Dementia*, when confirmed, consists in a total absence of all reasoning power, and an incapacity to perceive the true relations of things; the language is incoherent, and the actions are inconsistent; the patient speaks without being conscious of the meaning of what he is saying; memory is lost, and sometimes the same word or phrase is repeated for many hours together; words are no longer connected in meaning, as they are in mania and monomania." (Taylor's *Medical Jurisprudence.*)

3.—

CONCUSSION OF THE BRAIN.	COMPRESSION OF THE BRAIN.
Unconsciousness is incomplete; patient can be made to answer, though it may be briefly, and in simple words.	Complete unconsciousness; may scream into patient's ear at the top of the voice, but will receive no answer.
Special senses, though greatly blunted, are not abolished.	Special senses entirely suspended.
Power of movement not destroyed; if the position of a limb be changed the patient will resist or bring it immediately into the original position.	Complete or partial paralysis; in most cases hemiplegia.
Respiration is quiet and feeble.	Respiration full and noisy.
Pulse feeble, frequent, and intermittent.	Pulse full and slow, and sometimes laboring.
The stomach sickens and rejects its contents.	The stomach is insensible to any impression; no nausea or vomiting.
The feces may be discharged incontinently, as may also the urine, though not usually.	Bowels are torpid, and the bladder incapable of emptying itself, though the urine may escape by overflow.
Deglutition little impaired.	Deglutition difficult or impossible.
Pupils variable, though generally contracted; the eyelids somewhat open.	Pupils variable, though generally much dilated, and the eyelids closed.
Temperature of the body less than natural.	Temperature almost natural, a little below the normal standard.

(From Treves' *Manual of Surgery.*)

OPHTHALMOLOGY AND OTOLOGY.

1. "If the ticking of a watch or the vibrations of a tuning fork are heard faintly or not at all when held at varying distances from the ear (aërial conduction), but become distinctly audible when the watch or the handle of the fork is placed in contact with the skull or mastoid process (bone conduction), the deafness is of the ordinary variety and due to aural disease. If, on the other hand, watch and fork are heard indistinctly or not at all, both in contact and at a distance, the deafness is due to some lesion of the nerve or its connections. In the first case the nerve is normal and can appreciate vibrations brought by the bone, while, through some fault in the mechanism, aërial vibrations are not transmitted to the nerve endings. In the second case the nerve is at fault and cannot appreciate vibrations, no matter how well they may be conducted." (Butler's *Diagnostics of Internal Medicine.*)

PEDIATRICS.

1. *Tapeworm* is *caused* by eating raw or insufficiently cooked meat containing cysticerci. *Treatment*: Give a dose of castor oil at night, and the following morning give half a dram of freshly prepared extract of male fern, and a few hours later give another dose of castor oil.

Roundworm is *caused* by swallowing with the food the ova of the ascaris lumbricoides. *Treatment*: A dose of santonin and calomel should be given at bedtime for a few nights, and a dose of castor oil the morning after the last powder.

Seatworm, or *Pinworm*, is *caused* by swallowing the ova of the oxyuris vermicularis with the food or water, or it may be conveyed to the mouth by the fingers. *Treatment*: A large enema of a cold infusion of quassia. Care must be taken to prevent reinfection.

2. *Nystagmus* is *caused* by some irritation affecting the muscles of the eye. It may be vertical or lateral, and may be due to the eye or to the central nervous system. The cause can only be determined by a study of the other symptoms associated with it. *Treatment*: Tonics or bromides are sometimes useful. Remove the cause if possible. If due to occupation, the work must be changed; strabismus, or errors of refraction, must be corrected.

PHYSICAL DIAGNOSIS.

1. *Argyll-Robertson pupil* is a condition in which the pupil accommodates for distance but not for light. The condition is chiefly found in locomotor ataxia and paretic dementia.

3. The pulmonic second sound is more accentuated in childhood; the aortic second sound is more accentuated in adult life.

5. *Alcoholic coma*: The patient can generally be aroused; the coma is not, as a rule, complete; the face may be flushed; the pupils are normal or dilated; the respirations are normal in frequency, but deep; the skin is cool and moist, and the body temperature may be below normal.

Coma of epilepsy: History of attack, with previous convulsion; the coma is of brief duration, and the unconsciousness gradually becomes less; there may be a bitten tongue or other scars.

PHYSIOLOGY.

2. Epithelial tissues, connective tissues, muscular tissues, and nervous tissues.

3. *Physiological composition* of the blood:

1. Plasma.
2. Corpuscles { Colored. Colorless. Blood-plates.

Functions:

Plasm conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

Colored corpuscles carry oxygen from the lungs to the various tissues of the body.

Colorless corpuscles act as a protection against bacterial invasion.

Blood-plates are supposed to take some part in the process of coagulation.

4. If a vasoconstrictor nerve is divided, the arteries supplied by it are relaxed, more blood flows to the part, the blood current is accelerated, and congestion results. If a vasodilator nerve is divided, there is little or no change in the blood-vessels supplied by it.

5. From seven to ten days, without either water or food.

6. Motor impressions travel from the cortex of the cerebrum, through the corona radiata, internal capsule, crus, pons, medulla, crossed or direct pyramidal columns, to the motor cells in the anterior horn of the spinal cord; thence through the motor nerves to the muscles indicated.

7. The origin of the impulses is at the respiratory center in the medulla. The phrenics and intercostals are the chief nerves conveying the impulses; and they are distributed to the diaphragm and intercostal muscles, respectively.

RHINOLOGY AND LARYNGOLOGY.

1. Some of the constitutional causes of epistaxis are: Hemophilia, pernicious anemia, leukemia, scurvy, purpura hæmorrhagica, cerebral congestion, hypertrophy, and valvular lesions of the heart.

ETIOLOGY AND HYGIENE.

1.—

	Caused by.
Tuberculosis	Bacillus tuberculosis, of Koch.
Typhoid fever	Bacillus typhosus, of Eberth.
Diphtheria	Bacillus diphtheriæ, of Klebs-Loeffler.
Scarlatina	Microorganism not yet ascertained.
Variola	Microorganism not yet ascertained.

INTERNAL MEDICINE.

2. *Tænia Solium. Source*: The encysted larvæ or scolices, which come from the proscolices, which in turn are derived from the ova of the tapeworm. *Habitat*: In the larval state this parasite exists in the hog. *Symptoms*: Often there are no subjective symptoms; there may be dyspepsia, emaciation, ravenous appetite, nausea, vomiting, colicky pains, vertigo, chorea, itching of the nose. The diagnosis is made from finding segments or eggs in the dejecta. *Treatment*: The patient should be limited to a liquid diet for two days; salines should then be administered; then the oleoresin of aspidium in a dose of one to two drams, followed in a few hours by another saline. The treatment can only be considered successful when the head of the worm is found in the dejecta.

3. The *symptoms* of true angina pectoris are: Excru-

tiating pain radiating from the heart to the neck, shoulder, and arm (generally the left); a sense of impending death; cardiac constriction; the face is anxious and pale; cold perspiration and sometimes dyspnea.

The pathological conditions causing it are: Arteriosclerosis, chiefly of aorta and coronary arteries; there may be myocarditis and endocarditis, chiefly associated with aortic regurgitation or adherent pericardium; the predisposing causes of arteriosclerosis may also be present, chiefly syphilis, alcoholism, and gout.

4. *Diagnosis*: *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

Gastric carcinoma does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

In *Duodenal ulcer* the pain is apt to be more to the right, and to occur at an interval of two or three hours after meals; the hemorrhages will be intestinal, and the blood will be passed by way of the bowels, and not vomited. In many cases the symptoms are identical with those of gastric ulcer.

6. *Hematuria* means blood in the urine. In *renal* hematuria the blood and urine are intimately mixed, tube casts are apt to be present, and there may be renal colic or pain in the lumbar region. In *vesical* hematuria the blood and urine are not so well mixed, and pure blood is apt to be passed at the end of urination. In *urethral hematuria* the urine first passed is bloody.

7. *Bedsores* may be caused by undue pressure and irritating secretions; a crease or fold in a sheet, a crumb of bread, a feather, or a bit of string on the sheet may cause them. Especially is this so when the skin is irritable from excessive perspiration, inefficient washing, or involuntary passages of urine. Bedsores are particularly common in spinal affections and in wasting diseases.

Prevention consists in reducing the pressure, careful repeated washing, drying, and dusting with zinc oxide, and subsequent protection with lint or cotton-wool, etc. Leather-backed adhesive plaster may be applied over bony prominences, or, if seen early, collodion may be used. Frequent rubbing with alcohol may prove a preventive. When congestion appears, a water-bed or air-cushion may be used. Spirits of camphor or glycerol of tannin may be rubbed in twice daily, to harden the skin. Salt and alcohol (two drams to the pint) may also be used.

Treatment: A solution of silver nitrate may be used when the skin is about to break, in the strength of gr. 20 to the ounce; and in solution of gr. 10, daily, when the skin breaks. The sloughs should be removed as fast as they form. Stimulation, good nourishment, and sleep are valuable in treatment. (From Gould and Pyle's *Cyclopedia of Medicine and Surgery*.)

8. General aching is a pronounced symptom in some of the acute infectious fevers such as influenza, dengue, and smallpox. It may also be present in tonsilitis, rheumatism, and syphilis; also in poisoning by lead or mercury.

MATERIA MEDICA AND THERAPEUTICS.

1. Preventive medicine is the application of medical science to the task of preventing or mitigating disease. *Example*: Vaccination to prevent smallpox.

2. Ichthyol is obtained from ichthyosulphuric acid, which comes from a crude oil obtained by destructive distillation of fossil fish found in the earth in the mountains of Tyrol. It is used in inflammatory conditions generally, erysipelas, rheumatism, and certain chronic skin diseases.

4. Three therapeutic agents which increase the renal function: (1) Water, (2) alcohol, (3) spirits of nitrous ether.

5. Three therapeutic agents which increase the hepatic function: (1) Sodium salicylate, (2) corrosive sublimate, (3) podophyllin.

6. Some therapeutic agents which promote constructive metabolism: Iron and its preparations, potassium permanganate, bismuth, arsenic, cinchona and its preparations, mineral acids, phosphorus, massage, fresh air.

7. Some therapeutic agents which promote destructive metabolism: Iodine, potassium, sodium, lithium, mercury, calcium, barium and their preparations; vegetable acids.

8. Some therapeutic agents which excite the functions of the spinal cord and sympathetic: Alcohol, strychnine, electricity, massage, ether, camphor, digitalis, sparteine, ergot.

9. Some therapeutic agents which depress the functions of the spinal cord and sympathetic: Opium, belladonna, large quantities of alcohol, chloral hydrate, aconite, physostigma, pilocarpus, tobacco, amyl nitrite.

10. Some therapeutic agents which have a germicidal action: Oxygen, sulphur, corrosive sublimate, carbolic acid, iodine, chlorine, staphisagria, heat, formaldehyde, creolin.

PATHOLOGY AND BACTERIOLOGY.

1. *Active hyperemia* means that there is an excess of arterial blood in a part, and is generally accompanied by an increase in the rate of blood flow. In *passive hyperemia* there is still an excess of blood, but it is in the veins and capillaries; and the blood flow is retarded.

2. Modes of infection by the *tubercle bacilli*: (1) By inhalation, (2) by inoculation, (3) by being taken in with food.

Mode of infection by the *malarial hematozoa*: By the bite of the anopheles mosquito.

3. Passive hyperemia of the stomach may be due to cirrhosis or other hepatic diseases causing portal obstruction, also to some pulmonary disorders which interfere with the flow of blood from the right ventricle. It may lead to chronic gastritis.

4. Cretinism, goiter, myxedema, cachexia strumipriva.

5. "*Acute Diffuse Nephritis*.—The urine is greatly diminished in amount (four or five ounces in twenty-four hours), or is even totally suppressed. It is smoky, blackish, or of a chocolate color. The specific gravity is high. Albumin is found in large amount, and the heavy deposit contains abundant red corpuscles, blood, hyaline, and epithelial tube casts. The total urea is lessened.

"*Chronic Diffuse Nephritis*.—The quantity of urine is diminished, it is cloudy from urates, the specific gravity may be high in the early, but is low in the later stages. Albumin is abundant, sometimes more so than in any other disease. The heavy sediment contains large numbers of nearly all the varieties of tube casts, hyaline, epithelial, granular, and fatty. The latter are especially characteristic. Occasional red corpuscles, many leucocytes, and numbers of degenerated epithelial cells are also found. The amount of urea is decreased.

"*Chronic Interstitial Nephritis*.—The urine is increased in quantity, light yellow, clear, with a persistently low specific gravity. Albumin is scanty, occurring in traces, and is sometimes absent. A few narrow hyaline casts are almost constantly found in the very small deposit. Cellular elements are as a rule no more abundant than in normal urine. Polyuria, persistent low specific gravity, and the presence of a few hyaline casts constitute the urinary signs of this disease. Albumin may or may not be present in small quantity." (Butler's *Diagnostics of Internal Medicine*.)

7. The bacteria which may cause meningitis are: (1) *Diplococcus intracellularis meningitidis*, (2) the pneumococcus, (3) *Streptococcus pyogenes*.

8. The tissues usually invaded by the typhoid bacilli during typhoid fever are: The lymphoid tissue of the small intestine, lymph nodes of the mesentery, the spleen, gall-bladder, urinary bladder.

9. Löffler's blood serum consists of one part of bouillon (containing one per cent. of glucose) and three parts of liquid blood serum. This should be well mixed, poured into tubes, and sterilized, or raised to 65° C. one hour a day for three days.

10. The smegma bacillus is like the tubercle bacillus in that it stains with carbolfuchsin and resists the decolorizing action of dilute mineral acids. But it is decolorized by absolute alcohol.

OBSTETRICS.

4. *Diagnosis*: "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2

are *presumptive signs*;. Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetrics.*)

Probable cause: Some pathological condition in the Fallopian tube which obstructs the passage of the fecundated ovum. The most common condition is salpingitis, especially of the gonorrheal variety.

5. Sore nipples; caked breast; mastitis, which may be subcutaneous, parenchymatous, or submammary; galactocele.

6. *Cause of Aphthæ*: Predisposing causes are uncleanliness, lack of hygienic conditions, improper feeding. The exciting cause is unknown; various microorganisms have been found in this condition, but none of them is recognized as the etiological factor.

Treatment: Cleanliness, proper hygiene, proper feeding, mouth wash of salt solution or boric acid; the ulcers may be brushed with a nitrate of silver solution (5 to 10 grains to the ounce), and a dose of castor oil or a few grains of calomel (in divided doses) should be administered.

SURGERY.

5. Conditions which justify amputation of a limb are: "Any injury, disease, or malformation rendering retention of the limb incompatible with life or comfort; avulsion of limb; compound fracture; compound dislocation; fracture with great comminution of bone; laceration of important vessels; extensive contusion; extensive laceration; gunshot injuries; aneurysm; effects of heat and cold; gangrene; extensive bone disease; tumors; elephantiasis; tetanus; snake bite; deformities." (Bickham's *Operative Surgery.*)

BULLETIN OF APPROACHING EXAMINATIONS.†

AUTOINTOXICATION IN ITS MEDICO-LEGAL ASPECTS.

BY HEINRICH STERN, PH.D., M.D.,

NEW YORK.

To my knowledge, autointoxication has never been the subject of medico-legal inquiry; however, a number of pathological states, the origin of which has been assigned of late to intrabiontic poisons, have frequently found forensic consideration. Modern toxicology has begun to conceive certain conditions and diseases as expressions of autointoxication; medical jurisprudence, slowly but inevitably, will also come to recognize autointoxication as a possible factor in the causation of abnormal physical and psychical states and of death. Many a toxicologist prophetically, if not clearly, foresees the importance of the intrabiontically formed poisons in forensic battles of the future. Says Lewin, in the preface of the second edition of his "Lehrbuch der Toxikologie": "The time will arrive when it will have been definitely settled that intoxication is a local or general disease, and that genuine disease is a local or general intoxication."

However, it is a melancholy fact that the experience and the knowledge of a period is but rarely reflected in the prevailing law; that the law is behind the spirit of the times, hardly ever taking into full account the scientific acquisition of to-day, is a circumstance only too well known to the legal practitioner. We cannot often subscribe to Samuel Johnson's affirmation, "The law is the last result of human wisdom acting upon human experience for the benefit of the public," but are inclined to side with Goethe, himself a jurist, who puts in the mouth of Mephistopheles the poetic words:*

> Like a disease of infinite duration
> Custom and laws descend from race to race,
> Clinging to each succeeding generation,
> And creeping stealthily from place to place.
> Reason to nonsense they distort, to blame turn charity.
> Woe to thee if thou a grandson art,
> For rights, which thy time should award,
> Remain unborn to serve posterity.

Autointoxication as a disease has become a fad with many. I do not believe in fadism, hence the conservative standpoint from which I shall view the legal aspects of autointoxication. I shall not attempt to bring the ptomaines and other poisons of bacterial origin, or the so-called intestinal poisons, which are mostly derived from without, in connection with genuine autointoxication. I limit myself to a consideration of the catabolic poisons, as far as they have any bearing upon legal medicine.

The most simple and yet the most authentic of the catabolic, hence of all autointoxications, is the retention of carbon dioxide in the blood and tissues of the organism. It is characterized by cyanosis, slowing of the pulse, difficulty in breathing, and convulsions. In extreme instances death will ensue. Death by strangulation or uncomplicated suffocation is preeminently a death by carbon dioxide poisoning. However, there seems to exist a form of carbonic acid intoxication which does not depend upon an obstruction in some part of the respiratory organs but upon the non-liberation of the carbon dioxide from a combination into which it has entered. This form of carbon dioxide poisoning may be at the foundation of some of the well-known pathological states and may thus attain importance quite frequently. Suppose now, an individual who is living near the gas works or some chemical factory, chances to become affected with carbon dioxide retention. Is it not likely that he, his family, and the attending physician attribute his untoward symptoms to the noxious fumes coming from these places of industry, when, as a matter of fact, not sufficient carbonic acid gas to produce intoxication is found in these vapors? Is it not likely that the average jury will render judgment for the plaintiff if he sees fit to sue the owners of these manufacturing establishments? Are they not known to be public nuisances the world over? Ergo, they must be the cause of the plaintiff's suffering and inability to earn his livelihood.

Carbon dioxide retention without the occurrence of a respiratory obstruction is, indeed, a very interesting phenomenon, which is destined to alter our views as regards the etiology of a number of affections. At the bottom of certain chronic diseases, as well as of many instances of so-called heart failure, apoplexy, and other forms of sudden death, we may find carbon dioxide retention in various degrees. The importance of this simple form of autointoxication for all the branches of legal medicine ought not to be underestimated.

The condition known as *acidosis* should command the earnest attention of the medical jurist. Under acidosis, or acid intoxication, is understood poisoning by overproduction or deficient neutralization, or abnormal retention of normal, or by pathological, acid principles (Stern). Catabolic acidosis supervenes in some pathological states characterized by loss of body substance. Its most frequent occurrence is in the later stages of diabetes. The acetone bodies, betaoxybutyric acid, acetoacetic acid, and acetone, are always present in the urine of persons with acidosis, and are therefore pathognomonic of the condition, but they are not the cause of the peculiar train of symptoms, as I have pointed out on various occasions. The following instance of this type of autointoxication requiring legal inquiry came under my observation:

About ten years ago a diabetic patient of mine, exhibiting acetoacetic acid and acetone in his urine, on his way from my office to his home became suddenly vertiginous and took refuge in the rear room of a liquor saloon. When he was found by the barkeeper he was in a deep stupor, his clothes were

* Translation by Selma Stern.

disarranged, and his cuffs, minus the buttons, were lying in a corner. A search plainly revealed that a robbery had been committed; policemen and detectives declared that the victim had received "knockout drops" and that he was still under their influence. The patient being well known in the neighborhood, his family, when notified, insisted upon his transportation to their home. A short time afterward I was summoned to the house. There a policeman informed me that the ambulance surgeon had already administered an antidote for the "knockout drops." The patient, true enough, presented the more prominent symptoms of poisoning with chloral hydrate. There were the stupor, dyspnea, diminished cardiac action, and lowered temperature. I was satisfied that a large dose of chloral hydrate had been administered to the patient, and I prescribed accordingly. On my way home it struck me that the symptoms displayed by the patient were also those of acid intoxication (diabetic coma). Early the next morning I found the patient greatly improved, but dull and aphasic. In the afternoon of the same day the patient became very restless and irritated. Afterwards he had some attacks of vertigo, which were followed by delirium of a low degree. A slight stupor persisted throughout the afternoon and evening. The urine continued to exhibit glucose, acetoacetic acid, and acetone, and also contained betaoxybutyric acid (polariscopically determined), and large amounts of ammonia. In view of the urinary findings I now considered his condition as one of acid intoxication. This diagnosis was positively confirmed by the subsequent behavior of the patient: frequent recurrences of the phenomena just described, and lethal exit in fully developed diabetic coma after five days.

The facts in this matter proved very simple: The patient, in a bewildered and staggering condition, was followed by two toughs when he entered the liquor saloon by the side door. They took his valuables when he began to become stuporous, and neither handled him roughly nor used "knockout drops." Had the victim died then and there, the people, without a shadow of a doubt, would have charged the thieves with murder in the first degree, and the electric chair, in all likelihood, would have expedited them into a better world.

To this instance of unrecognized autointoxication jeopardizing the life of the supposed murderers I could add another similar case of personal experience when the accused was actually convicted of murder on his first trial, but—for some altogether extraneous reasons—was found not guilty on a subsequent trial in another county.

The so-called *constitutional diseases*, originating from or giving rise to autointoxication, interest not only the physician but the surgeon as well. The surgeon, for instance, is loath to operate upon a hemophilic; he takes special care when he has to perform a bloody operation upon a rachitic or scorbutic child; he prefers to limit his work, both in extent and duration, when his patient has diabetes, and he may refuse to operate altogether when confronted with a condition of acetonemia.

There are a number of autotoxic conditions which may more or less interfere with the repair of tissues after accidents and operations. The surgeon frequently receives the blame when injuries do not heal properly, or when operations are not followed by the desired results. As a matter of fact, the cause for the defective repair of the body structures oftentimes originates within the organism. Were it known by the legal profession that catabolic substances could exert a similar influence upon the healing process, as does the syphilitic poison, the number of suits for malpractice would dwindle rapidly and different verdicts would be rendered in many instances. The following instance will illustrate my contention:

Some years ago, on the instigation of his lawyer, a man about forty years old consulted, among some other physicians, also me. He had sustained an oblique fracture of the tibia and fibula about nine months before; however, perfect bony union had not as yet taken place, and he suffered much pain at the seat of the fracture. The patient, contending that unskillful management of his fracture prevented complete bony consolidation, contemplated suing for damages the surgeon who put up the injured limb. The presence of syphilitic disease being positively denied, I questioned the patient as to his medical history. I elicited, among other facts, that he *had been rachitic in childhood,* and that he had a tendency to "gout" during the last two or three years. We know that rachitis affects detrimentally the formation of the granulation substance by which the fractured bone ends unite. This man, it is true, had no noticeable rachitic symptoms any longer, but a nutritive disorder like rachitis may, in a modified form, appear also in adult life, especially when callus production is taking place. The defective callus formation in this particular instance, however, I concluded was due almost entirely to abnormal nucleolysis, or, better, to deficient dissolving qualities of his blood serum, which permitted the deposition of purins and xanthins at the seat of the fracture. These catabolic substances perhaps prevented the osteoblasts from engaging in a normal process of cell proliferation. Undoubtedly, however, they disturbed or checked the chemical processes which lead to ossification. The pains at the location of the injury I attributed to the selfsame causes. I pointed out to the man that the delayed union of the bone ends was very likely due to systemic conditions, preeminently to that which he called his "gouty" affection, and that he had no case against the surgeon. My supposition as to the causative factors of the delayed ossification proved only too true after treatment for perverted nucleolysis, consisting in the main in the administration of potassium iodide and colchicum, had been instituted, for the pain ceased very soon, the patient began to feel more cheerful and became stronger from day to day, the callus material became more abundant, and complete bony union was secured after about fourteen weeks. When we remember the long row of discrepant diseases which have been, and still are, ascribed to uric acid and its salts, or to the alloxur bases, there can be no doubt that nucleolytic autointoxication offers many other medico-legal aspects besides the one just alluded to.

The last word concerning all those occurrences which we classify as histoenzymic autotoxicoses has as yet not been said. Much that has been advanced during the last decade which bears upon the connection of certain abnormal bodily conditions with pathological histoenzymes or perverted "internal secretions," is undoubtedly premature, hypothetical, and nonconvincing. One "internal secretion," however, the one of which least has been written, namely that of the ovary, seems to stand in causative relationship to many ills, and hence to many abnormal mental conditions of womankind. The perverse psychical states so often supervening during the adolescent period, the hysterical and epileptiform

attacks of middle life, the mental aberrations of the menopause point to the ovary as a principal participant in their production.

It would be carrying coals to Newcastle were I to recount on this occasion specific instances of disease or crime which could be adduced to a faulty ovarian internal secretion. The frequency of psychoses, the number of wrong and rash acts attributable to this one cause, is verily appalling. The legal bearings of this undisputable autotoxic factor are so numerous and manifold that one is astonished to see the entire question ignored in the courts of justice.

That which I have termed "physical autointoxication" is the consequence of the retention in the blood of *normal* products of dissimilation. It finds its principal expression in the so-called uremic state. Again, it may give rise to various other abnormal conditions, for instance to narcolepsy. This is a sudden uncontrollable inclination to sleep, recurring at irregular intervals. One of the most interesting cases of narcolepsy on record, which, however, did not then offer any medico-legal aspects, was reported by me some years ago.* Another instance of the same affection, a phase of which is related in the following, should prove very interesting to the medical jurist.

The patient, forty-three years old and weighing about 278 pounds, consulted me first in October, 1904. He was then a well-known member of the San Francisco bar. He had been affected with sudden sleeping seizures for a number of years. He would be seized by this uncontrollable desire to sleep at any time of the day. He would fall asleep in the restaurant, but also while pleading a case in court. I refrain from going into the details of the history of the case at this time, nor is this the place to give an account of the pathological findings. Suffice it to know that it was an instance of well-defined physical autointoxication. The patient acted as legal adviser of a former champion pugilist in a suit which the latter had won against a dishonest referee. This referee, a notorious character, wanted to have it out with the victorious lawyer, and, with his six-shooter in his hip pocket, he went to look for him in the evening. He found him in the hotel, called him to a side room, pulled his revolver, aimed, and at the sight of the gun the lawyer, still standing on his feet, began to sleep and to snore sonorously. At this unprecedented miracle the would-be murderer took to flight and was not heard of for many a day.

Thus far the facts in the case. Now let us consider some of its medico-legal aspects. Suppose the narcoleptic attacks of the lawyer had not been the talk of the town, what conclusions would the police have drawn when they found him unconscious and in apparent stupor after the attempted murder?

I have put this question to a number of experienced police officials and the answer of each and every one was that impulsively he would have looked for the marks of another weapon which kills without making noise; failing to find any, he would, at first, have thought of poison, and then of apoplexy or something similar. Supposing that the lawyer, when seized by the morbid sleepiness, should have fallen on his head in such a way that he had fractured the base of the skull, would not everybody have been convinced that the ill-reputed referee had actually committed a crime? Supposing again that the lawyer (whose weight, we must not forget, amounted to 278 pounds), when seized by the narcoleptic fit, had fallen upon the revengeful referee in a manner so that the latter's pistol had gone off, thereby discharging a bullet which had penetrated the lawyer's heart or lungs, would any district attorney have given credence to the statement of the malicious referee that he meant only to frighten the lawyer? This case of narcolepsy offers still more hypothetical suppositions from which the possible legal consequences may be deduced. All the possible legal inquiries which may arise out of the type of autointoxications occasioning morbid sleepiness have their analogues in the forensic questions pertaining to the toxic states underlying epilepsy and epileptiform conditions.

On the hand of our present, still meager, knowledge concerning pathological physiology it is, of course, extremely difficult to prove the connection of a given instance of a neuropathic or psychopathic state with a catabolic poison or with a disturbance of the intrasystemic osmotic equilibrium. That we may have epileptic conditions without anatomical substrates is a fact known for many years. Certain forms of alcoholic epilepsy, for instance, are the direct consequence of alcohol or its normal or abnormal decomposition products. If we are satisfied that certain substances introduced into the organism may occasion epileptic or epileptiform attacks, why should not we also accept that certain toxic states of intrabiontic origin may manifest themselves by similar nervous phenomena?

At any rate, the medical jurist who holds that a specific instance of epileptic equivalent or of acute or cyclical insanity, proceeded from a well-defined autotoxic condition, stands on much firmer soil than the one who nonchalantly asserts that a "nerve crisis," or a "brain storm," is due to a family taint.

Chronic renal disease is sooner or later followed by a general autotoxicosis of the organism. This toxic state is due to the relative impermeability of the kidneys and the synchronous incompetence of the other emunctories. The substances accumulating in the blood serum exhibit little or no chemico-toxicity; they exert a noxious influence simply by their retention. The long-continued poisonous state arising on the basis of histolytic retention is generally referred to as chronic uremia. This condition, with its protean symptoms, offers ever so many and manifold legal aspects and complications. I know of a case of chronic uremia which was diagnosed as "ptomaine poisoning" by one of our leading physicians. An acute exacerbation of the chronic condition was pronounced a case of opium poisoning in the absence of the regular attendant by the hurriedly summoned physician of the neighborhood, with the result that the former had a suit for malpractice on his hands for over a year. I have seen uremic poisoning to be taken for fusel oil intoxication, and for poisoning with belladonna and aconite.

Some of the gastrointestinal concomitants of chronic uremia—nausea, vomiting, and diarrhea—are often referred to the ingestion of tainted food; disturbances of the nervous system as headache, vertigo, insomnia, are frequently looked upon as the result of medication; neuralgia, muscular cramps, and paresthesia are in many instances ascribed to injuries received lately or in years gone by.

Every one of these symptoms is a manifestation of the specific autotoxicosis, and, if the circumstances arise, each one may prove of decided medico-legal interest. However, of still greater importance for forensic medicine are the cerebral symptoms such as mania, melancholia, and delusional insanity, which are apt to accompany chronic uremia.

*A contribution to the Pathogenesis of Narcolepsy and other Forms of Morbid Sleepiness; MEDICAL RECORD, January 11, 1902.

These cerebral manifestations occur principally in uremia on the basis of chronic parenchymatous nephritis, the only renal affection which should be designated as Bright's disease. Among all mental diseases the psychoses of Bright's disease alone are truly autotoxic in character. They are the expression of a poisonous state of autochthonous formation and are not the result of morphological changes in the brain.

The delusional insanity of Bright's disease, the *Folie Brightique* of the French, has undoubtedly a greater forensic bearing than any of the other uremic psychoses. Instances of *Folie Brightique* occur in the practice of almost every physician, but are often overlooked in the milder forms, or not recognized as such when the insanity attains a severer degree.

This specific mental aberration of Bright's disease which, in the majority of instances, is delusional in character, is not due to molecular changes in the brain matter, but due to the impairment of the physico-electric conditions in the body liquids, an autotoxic state, the minute etiology and pathology of which I described some years ago.* However, the average alienist, although admitting a toxic insanity, has not progressed far enough to recognize an autotoxic insanity. Says Hamilton in his "System of Legal Medicine" (Vol. II., p. 120):

"Such somatic insanities as that due to Bright's disease are frequently referred to, but often great stress is laid by counsel upon the existence of the cerebral symptoms of this and other diseases, and their effect upon the conduct of the individual..... Beyond the irritability, stupidity, aphasia, and very rare epileptic conditions, nothing can be shown; but when we consider the renal disease, with cardiac disease, as precursors of actual degeneration of the cerebral vessels, it has a decided importance." He concludes as follows: "The demonstration of the connection between embolism, or cardiac disease, with cerebral softening and dementia, of syphilis with paretic dementia, or epilepsy, is of the greatest moment."

These statements are utterly devoid of any insight into the nature of chronic uremia, that is into the latter phases of Bright's disease. Cases of uremic insanity with lethal exit show cerebral changes only in the very rarest of instances. Even the edema of the brain, by which Traube wanted to explain the uremic phenomena, is wanting in many cases. A degeneration of the cerebral vessels has nothing whatever to do with the *Folie Brightique*, the delusional insanity of Bright's disease, which is and remains an autotoxic phenomenon. If we wish to study the delusional insanity of Bright's disease we have to view it as a manifestation of an autotoxic process; analogously do we have to treat it as an expression of an autotoxicosis when we make use of it as a defense or when we question the individual's testamentary capacity. Cellular pathology has still a *raison d'être* in surgery, for the scientific investigation of many psychoses it is absolutely useless. Were the mental aberrations of Bright's disease explained on the autotoxic basis, I am satisfied there would be fewer petitioners sadly wending their way homeward from the Surrogate's Court.

It is a fact, which is ever corroborated, that the individual with uremic delusions is easily influenced by his latest acquaintance to whom he has taken a liking. This explains in a measure why the chronic nephritic so often disposes of his property in an erratic manner, why he leaves the bulk of his estate to his nurse or the chance companion of his latter days. As the law holds in great esteem the right of an individual to make his own will—requiring, for instance, less mental capacity to make a will than to make a contract—it is in almost every contest a difficult task to disprove the testamentary capacity of the deceased. But why, we may ask, should not a person with uremic delusions while alive be adjudged non compos mentis? An individual thus afflicted, of course, has relatively lucid intervals, on which, according to law, the testamentary capacity may depend; however, the autotoxic process underlying the mental aberration is chronic and its fluctuations, as far as they pertain to its diminution, are only limited in degree. Thus the chronic uremic is always kept in a more or less abnormal state of mind, which fact ought to be taken into consideration at the inquest.

This brings to a conclusion my discourse on the forensic importance of the autotoxicoses. I have dwelt upon the topic in a brief and conservative manner; some subjects, I am fully aware, have been treated rather fragmentarily, others I have purposely refrained from entering into on this occasion. I believe, however, to have demonstrated:

1. That certain pathological conditions as well as certain forms of death demanding legal inquiry are due to autotoxic processes of catabolic origin.
2. That the catabolic autotoxicoses offer many and discrepant legal aspects.
3. That the time has arrived when the catabolic autotoxicoses should obtain legal status and citizenship in our courts of justice.

SOME OBSERVATIONS ON THE TREATMENT OF GRAVES' DISEASE.*

By J. ARTHUR BOOTH, M.D.,

NEW YORK.

In a paper which was read before the American Neurological Association in June, 1894, I presented certain views, which were in support of the theory that the symptom complex of Graves' disease obtained its fullest explanation by the presence of some morbid change in the thyroid gland or its secretion, this important advance in our knowledge of the interesting and puzzling malady having been brought to our attention by the very valuable contributions of Victor Horsley, Moebius, and Kocher. Within recent years still further evidence has accumulated, so that at the present time it is the general belief that the thyroid gland dominates the disease. Permit me now to ask your attention to a brief review of some of this evidence, together with the results of my observations in twenty-five patients, who presented the different clinical types of the disease. The changes in vascularity and consistency of the gland were first noted and then followed the observation that there were also certain specific changes in the parenchyma and secreting cells, differing somewhat in degree in the various stages of the disorder. This enlarged, vascular gland, then, with its vesicles assuming other shapes than the round or square, together with a most marked development in the epithelium, now cylindrical instead of columnar, seems to justify the view that there is an increased or altered activity of its parenchyma and secreting cells.

*Read before the Philadelphia Neurological Society and the New York Neurological Society, March 16, 1907.

These changes will be readily appreciated by comparing a section from the normal human thyroid gland (Fig. 1) with that from a case of Graves' disease (Fig. 2). The specimens removed by thyroidectomy in my cases varied in vascularity and consistency. Microscopically the alveoli were distended

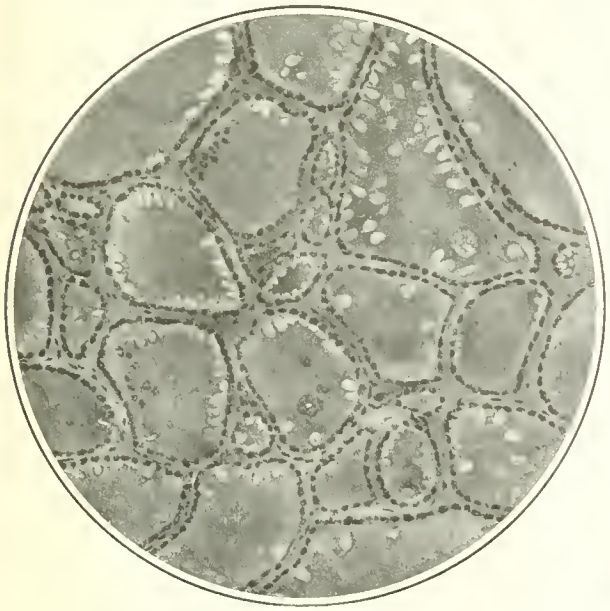

Fig. 1.—Section of normal human thyroid gland. (Kocher.)

with hyaline material and the tissue thickly crowded with round cells both in the alveoli and stroma. This evidence is satisfactory except in those patients who do not show any visible enlargement of the gland; and here we may assume that there is too slight an enlargement to be positively made out, or that the above morbid changes may be present without increase in size. Personally I have found it quite difficult to discover a slightly enlarged thyroid and in several of the operative cases noted how

Fig. 2.—Section of thyroid gland in Graves' disease. (Kocher.)

much larger the gland really was after exposure by the incision. It is believed that this changed gland produces an increased or perverted secretion, which, being absorbed into the blood by the veins and lymphatics, acts as an irritant directly or indirectly, like many other poisons, upon the heart, the nervous system, and upon the nutrition of many tissues in the body. What it is that starts the hypertrophy of the thyroid and neighboring glands, or what part the parathyroids or persistent thymus plays, are questions yet to be answered. Perhaps fright, some shock, emotion, microbic infection, or some heredi-

Fig. 3.—Case I.

tary taint may prove to be the exciting cause. In the present series of cases emotional disturbance seemed to be the exciting factor, as there was a distinct history of fright from burglars and fire in ten patients, and from first menstruation in one. Three patients had a good deal of mental worry.

Fig. 4.—Case II.

Three had chorea in childhood. The symptoms followed an attack of rheumatism in two patients. In four there was a family history of the disease, and in two there was a record of simple goiter in the family. Our former knowledge being deficient concerning the etiology and pathology of the affec-

tion, necessarily made the treatment difficult and uncertain; now, however, with the results of recent investigation before us, we are in a position for a more intelligent treatment both by therapeutics and surgery. Bue even at the present time, when an attempt is made to outline any specific line of treat-

Fig. 5.—Case III.

ment, one of the difficulties met with is the fact that the disease is represented by so many different types. For example, in the present series of cases there were three males and twenty-two females; seven were married and eighteen single. The average age

Fig. 6.—Case IV.

was twenty-one, the oldest being forty and the youngest twelve years of age.

Enlargement of thyroid, followed by tachycardia and exophthalmos, in ten. Tachycardia, followed by exophthalmos and thyroid enlargement, in seven. Exophthalmos, followed by enlargement of thyroid, in four. Tachycardia and nervous symptoms alone in four. Tremor was present in ten. Intestinal disturbances in only four patients. Fever was present in ten; noted as absent in six and no record in the others.

Assuming the truth of the thyroid theory, it is

Fig. 7.—Case V.

probable that these different clinical types represent various degrees of intoxication and thus explains this diverse symptomatology. These different clinical types being recognized, it is necessary and of great importance to have some form of classification as an aid to prognosis and the proper treatment of the disease; so with this object in view a division into three classes has been suggested,

Fig. 8.—Case VI.

which I will now give, illustrating the same with a few photographs.

First Group.—Here the clinical picture indicates a mild form of the disease. Marked toxemia is absent, as well as one of the cardinal symptoms, usually the exophthalmos; and we find a slightly en-

larged thyroid, with a moderately increased heart action. Many of these cases do well under treatment by rest and drugs and a few are cured. In those in which this method of treatment fails, operative treatment should be considered.

Case I.—Enlargement of thyroid and exophthalmos slight. Tremor; edema of the eyelids. Pulse,

Fig. 9.—Case VII.

100 to 118. Thyroidectomy. December, 1895. Cured.

Case II.—Exophthalmos and enlargement of thyroid slight. Pulse, 98 to 110. Thyroidectomy. April, 1893. Cured.

Second Group.—Simple chronic exophthalmic goiter or thyroidism of moderate severity, with all the symptoms which give origin to the name. The clinical picture is that of an advanced stage, and here medicinal measures give only temporary relief, but by thyroidectomy and the use of serum good results are obtained. In these cases it is not wise to delay operation too long.

Case III.—Decided exophthalmos and enlargement of the thyroid. Tremor and all the nervous symptoms. Pulse, 140 to 160. Thyroidectomy. November, 1893. Cured.

Case IV.—Patient is only twelve years old, and has all the clinical symptoms of the disease. Pulse, 120 to 140. Exophthalmos and enlargement of thyroid marked. At present under treatment by rest in bed and ice bag to chest. Medication, antithyroid serum and phosphate of soda. Is more comfortable. Pulse rate reduced to 110-118.

Case V.—Enlargement of thyroid and exophthalmos marked. Pulse, 120 to 140. Tremor and all the nervous symptoms. Thyroidectomy, November, 1895. Cured.

Third Group.—In this class we find a still further advance in the intoxication. Fever is a prominent symptom and may be quite high. The circulatory and nervous system are also markedly involved. Here operation is not profitable, as they are poor subjects for a shock of any kind, especially from an operation under general anesthesia. Dr. Rogers reports good results from the use of a cytotoxic serum in this class, but my experience in its use is too limited to give any definite conclusions.

Case VI.—This patient had all the symptoms of the disease in a severe form and finally died in an attack of acute mania.

Case VII.—Had all the symptoms of the disease for many years, with attacks of fever and a history of diabetes. Thyroidectomy, October, 1894. Death twenty-four hours after the operation.

Case VIII.—The advanced stage of the disease is well shown in this patient. Bilateral exsection of the sympathetic was performed by Dr. Curtis in January, 1893. There was rapid improvement in the exophthalmos and a reduction in the pulse rate to 100. She unfortunately died from pneumonia and nephritis two months after leaving the hospital.

The diagnosis of Graves' disease being made, the following details of treatment should receive attention:

(1) Rest; (2) electricity; (3) medication; (4) the consideration of operative interference by partial thyroidectomy, ligature of arteries, and sympathectomy; (5) the use of cytotoxic serum.

It is not necessary to consider here in detail the first three means of treatment, except to say that perseverance and strict attention to detail, placing the patient under the best hygienic conditions, with rest and plenty of fresh air, will accomplish a great deal towards mitigating the intensity of the symptoms and a cure may result in a certain number of patients, especially when the diagnosis is made early in the disease. In a record of eighteen cases, three were cured, five improved, and ten received no benefit from the treatment.

Operative Interference.—If as a result of our present knowledge we are justified in believing that a changed or excessive secretion is the causative factor of Graves' disease, then a rational therapy would seem to turn itself into one or two directions: either towards a positive limitation of the secretion by the partial resection of the gland, or a neutraliza-

Fig. 10.—Case VIII.

tion of the toxins by the use of an antitoxic serum. By the first method we have now sufficient data to clearly show that a more rapid and greater benefit occurs in a larger number of cases through operation than under medicinal treatment, and this is especially so in those patients who show the marked

symptoms of Group 2 in the above classification. Nine of my cases were treated by operation; thyroidectomy being performed in eight patients and bilateral exsection of the sympathetic in one. The operative work was skilfully performed by Dr. B. F. Curtis, with the following results: In the thyroidectomy cases the right lobe was removed in five and the left in three cases. Six were permanently cured, one was improved, and one died twenty-four hours after the operation with symptoms of acute toxemia. (Case VII.) Two of the operations were done in 1893, two in 1895, one in 1896, and one in 1897; being thirteen, eleven, ten and nine years ago respectively. Four of the patients have been seen and examined quite recently and are well, though in two of them there is still present a slight prominence of the eyes. The other two patients were well two years ago.

Antitoxic Serum.—From recent clinical studies of the thyroid gland in simple goiter and Graves' disease, there have been found some definite indications for serum therapy and good results have been reported by a number of writers. Recently Drs. Rogers and S. P. Beebe have introduced a specific serum and the results they have obtained by its use in over ninety cases warrant the conclusion that it is an agent of great value, especially in those patients showing symptoms of marked toxemia. One of the patients recorded by me as improved by thyroidectomy relapsed after a time and later was treated by Dr. Rogers. No improvement followed and the result was a failure in this case.

Conclusions.—(1) Although Graves' disease is recognized by the prominence of four symptoms, tachycardia, exophthalmos, goiter, and tremor, this symptom complex may be incomplete in the developmental stage of the disease and here the other symptoms are sufficient for the diagnosis. (2) At the time of the first examination the degree of thyroid intoxication should be noted and the patient then placed if possible under one of the three clinical groups. (3) The prognosis depends upon the hereditary, the social position of the individual, the type of the disease, and its early recognition. All these conditions being favorable, with good care and perseverance, there is a fair chance of recovery in those patients classed in the first group. The more advanced cases stand a better chance of recovery by operation, but this must not be delayed too long when organic changes have already set in. (4) Recent clinical and experimental data still further emphasize the general belief that overactivity of the thyroid gland is quite sufficient to explain the appearance of the symptoms of Graves' disease and their disappearance after operation. (5) Thyroidectomy should be the operation of choice, as giving the best results. (6) Death following operation is due to shock and the use of a general anesthetic; therefore this should be placed in only expert hands and local anesthesia employed when possible. (7) The introduction of the cytotoxic serum marks an important advance in the treatment of the disease, and perhaps may ultimately prove to be the only rational therapeutic method.

Stricture in Children.—The possibility of congenital stricture in young children suffering from urinary disturbances (frequent micturition, vesical tenesmus, retention of urine, etc.) should always be considered even in the absence of a traumatic cause or gonorrheal infection. Internal urethrotomy followed by systematic dilatation is as successful in these cases as in older persons.—*International Journal of Surgery.*

INDICANURIA, ITS ETIOLOGY AND PRACTICAL SIGNIFICANCE.*

By WILLIAM HENRY PORTER, M.D.

PROFESSOR OF PATHOLOGY AND GENERAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SHOOL AND HOSPITAL; ATTENDING PHYSICIAN TO THE POST-GRADUATE HOSPITAL, ETC.

At the present time there is no condition in pathology and general medicine the interpretation of which is of greater importance to the general practitioner and surgeon than that of indican in the urine. While indican, like the overproduced uric acid[1] found in the urine, is a symptom only, it is highly important that we should correctly apprehend its true significance. To accomplish this necessitates a clear and comprehensive understanding of the method of its formation and the various conditions that give rise to its presence in the system.

As early as 1840 Prout[2] discovered a blue coloring material in the urine, to which he gave the name indigo, hence to him is due the credit of discovery. Long before this date, however, and for several years thereafter, many observations are recorded in reference to finding blue urine, and of sediments in the urine having a decided blue coloration. Even from the time of Hippocrates and Galenus down, similar observations are recorded.[3] It was not, however, until Prout announced his discovery, that indigo became a recognized factor in connection with the urine.

From 1840 to 1857, many observers recorded similar cases, but all were of the opinion that the blue coloring material discovered by Prout was identical with the indigo blue or indican found in plant life.

Schunck,[4] in 1857, demonstrated, as he thought, the constant presence of a substance in the urine which yields indigo blue on boiling the urine with mineral acid. This substance he called indican, and was of the same opinion as previous observers—that it was identical with vegetable indican.

Baumann,[5] about 1879, first demonstrated that no sugar was formed by the decomposition of animal indican, but that there was formed sulphuric acid and a compound belonging to the indigo group.

Prior to this, however, Nencki[6] had demonstrated the fact that indigo was one of the decomposition products of a still more complex body.

It was not, however, until the researches of Baumann and Breiger[7] that the exact composition of the urinary indican was first accurately determined. They proved that urinary indican was a combination of the conjugate sulphur of a hydroxylated indol with an alkali (potassium), to which they gave the name indoxylsulphate, and suggested that the term indican be restricted to the indigo-yielding substance of plant life. This suggestion, however, does not appear to have been adopted.

Shortly after this, Baeyer[8] demonstrated that a more simple substance was the antecedent to the more complex body indoxylsulphate of potassium, $C_8H_6NO\ SO_4K$. This simple mother substance, indol or indole, C_8H_7N, is formed in the lumen of the intestinal tract. It has since been demonstrated, beyond a question of doubt, by Nencki[9] and other observers, that indol is produced always and only by bacterial putrefactive decomposition of the proteid elements of the food stuffs during their passage through the alimentary tract. It has also been shown that the animal proteids are more likely to undergo this change than are the vegetable class. This is due to the fact that the animal proteid is a free and single molecule, one easily acted upon, both

*Read before the New York Medico-Surgical Society, March 16, 1907.

by the unorganized and the organized ferments. On the other hand, the vegetable proteid is a multiple molecule, and is encased in a capsule of cellulose, neither of which is easily acted upon either by the unorganized or the organized ferments. Hence the vegetable proteid passes through the alimentary tract in a large measure untransformed, acting simply as an irritant to the mucous membrane of the intestinal tract. As a natural sequence, the animal proteid is easily acted upon in the one case by the unorganized ferment, yielding a large quota of nutrition pabulum; on the other hand, if acted upon by the bacteria of putrefaction, it yields a large percentage of indol, and subsequently of indoxylsulphate of potassium.

As the vegetable proteid is not easily acted upon by either form of ferment bodies, it is difficult of digestion; it is also less likely to be acted upon by the bacteria of putrefaction, hence it decreases the

tendency to the formation of indol and subsequently the formation of the indoxylsulphate of potassium. While it does cut down the tendency to the formation of indol, it does not prevent it absolutely. Further than this, the overtaxation of the digestive system, when on a purely vegetable diet, and the reduction in the supply of the nutritive pabulum cause profound disturbance in the metabolic cavity of the system, which is often more detrimental than the toxemia of the indicanuria.

Hopper-Seyler and his pupils[10] were of the opinion, from their observations, that indol could be produced by the action of the unorganized, as well as the organized, ferments. They also claimed that indol was produced in the intrinsic proteid tissues of the body, as well as from the extrinsic proteid contained in the food stuffs in the lumen of the alimentary tract.

The observations of Senator,[11] in connection with the urine and meconium of newly-born children, support conclusively the contention of Nencki that bacterial action is required for the production of indol. Hence indol cannot be formed in the intrinsic tissues of the body except through the action of the bacteria of putrefaction. That this does occur in some rare instances cannot be doubted.

Just how and when indol is joined to the sulphurous acid molecule and the potassium atom, is not clearly stated by any of the investigators. Neither are we informed fully as to when the sulphurous acid molecule takes its origin from the proteid molecule. All observers agree, however, that it comes from the sulphur of the proteid molecule, and that it enters into the formation of the indoxylsulphate. One thing seems to be certain, that it is not formed in the renal structures.[12]

Baumann,[13] having found a much larger amount of ethereal sulphates in the liver than in the blood, was of the opinion that the synthesis of the indol into an ethereal sulphate took place in the hepatic cells. The larger amount of ethereal sulphates in the liver as compared with the blood does not prove conclusively their formation in the liver. The ethereal sulphate being a foreign substance to the normal physiological economy, the liver in its sentinel-like function may exercise its guardianship over the general circulation and, in a measure, prevent the passage of the ethereal sulphates into the hepatic blood stream; hence the finding of the larger amount in the liver. Thus we have a logical and well-founded physiological explanation for the larger amount in the hepatic organ without assuming that it is produced in the liver cells.

On the other hand, it seems hardly possible that such active chemical action as the splitting off of the sulphur atom from the proteid molecule, with the formation of sulphurous acid, the decomposition of one of the stable potassium salts, and the synthesis of these three simpler elements (sulphurous acid, indol, and potassium) into the highly complex indoxylsulphate, could occur in the protoplasm of the hepatic cell without destroying its functional activity. If the change occurred at the edge, or bile-duct surface, of the hepatic cell, and the newly formed compound was at once discharged into the lumen of the bile duct, such a theory might be accepted, especially as it has been proven that sulphuric acid is so formed in the cells of the mucous membrane of the stomach[14] in the production of the HCl.

Viewed in this light, there are two theories to choose from regarding the formation of the sulphurous acid and its combination with the simple compounds, indol and potassium, to form the more complex substance, the etherial sulphate.

First: The sulphurous acid may be formed primarily by the same bacterial action that decomposes the proteid molecule to form the indol in the intestinal canal, following which the acid attacks one of the potassium salts, liberating the potassium atom to enter into combination with the acid and indol to form the indoxylsulphate of potassium in the intestinal tract. When thus formed this ethereal sulphate obeys the law common to all mineral salts. The indoxylsulphate is absorbed unchanged into the enterohepatic circulation, passes on to the liver, then to the general circulation, and finally reappears without being changed, and under its own form, in the urine. When this occurs the presence of the ethereal sulphate is easily demonstrated in the urine by its oxidation into indigo blue by some one of the various methods recommended.

The following method has proved the most reli-

able in the hands of the author. Add in a test tube equal quantities of urine and chemically pure hydrochloric acid. To this mixture add three drops of a ½ per cent. solution of potassium permanganate. If indican is present in the urine, there will be formed a purplish cloud in the fluid in the test tube. Then add a few drops of chloroform, then one drop more of the permanganate of potash solution, and a few more drops of the chloroform; then shake vigorously. As a result this purplish coloration will be replaced by a deep blue, which is due to precipitation of the indican by the chloroform. The amount and intensity of the precipitated indican determine the extent of the putrefactive changes going on in the alimentary tract. (See the accompanying illustration.)

One other point should also be noted in this connection, which is that the shade of color varies very much—ranging from a deep blue to a decided greenish, or even black, coloration, the later colorations being found in connection with varying degrees of interlobular compression jaundice. It has also been found that a close analysis of the color enables one to judge quite accurately regarding the varying metabolic conditions of the system.

There is still one other fact of especial importance in connection with this test, which is, that the associated toxicity of the system is not always in direct proportion to the intensity of the indicanuria. For it often happens that a considerable portion of the indican escapes with the feces, while the toxins are absorbed into the circulation.

On the other hand, a close analysis of the different shadings in the color reaction, when correctly interpreted, is a very close guide as to the intensity of the associated toxemia.

Second: The indol formed in the intestinal tract is absorbed as such from the alimentary canal, and carried by the entero hepatic blood stream to the hepatic glands. Having reached the liver, the indol is drawn from the blood stream of the intralobular plexus of capillaries into the protoplasm of the hepatic cells. At the same time, proteid molecules are also drawn into the protoplasm of the same cells, together with oxygen. This results in a splitting off of a sulphur atom and the oxidization of the same into sulphurous acid, while the remainder of the proteid molecule breaks up into other forms of byproducts. The sulphurous acid now combines with the indol and the potassium atom, but where the potassium atom comes from is not indicated by any of the observers. If this theory is accepted, the sulphurous acid must decompose a potassium salt, thus liberating a potassium atom before the synthesis is completed. Having formed the idoxylsulphate of potassium in this manner, instead of flowing out of the cells with the bile, what would be the natural course for an oxidation product to pursue? It is dropped back into the intralobular capillary blood stream, or the lymphatic channels. From this point it flows out of the liver, in either the blood or lymph, and ultimately reaches the general circulation. Finally the renal glands are reached, by which organs it is excreted together with the urine.

Neither of these theoretical methods of formation has been actually proved. The intestinal theory of formation is the more probable one, from the well-known fact that the intestinal tract is the great chemical beaker of the system; that in this intestinal beaker chemical activity of a high order is constantly occurring, while there is no proof that such action occurs in the deeper structures of the body."*

Neither does it seem possible to have the formation of sulphurous acid in the hepatic cells, the splitting of the fixed potassium salts, and the combining of these three substances into one complex whole in so delicate a protoplasmic substance as that of the hepatic cells. Were this to occur, we should expect an absolute destruction of the protoplasm of the cell structure and the formation of a permanent lesion of the liver cells, the same as occurs in the joint structures in gout when the proteid molecule is vicariously oxidized into uric acid in the cartilage cells.[45]

By either method of formation the chemical evidence proves conclusively that the other by-products formed by the decomposition of the proteid molecule are varied and often highly toxic in nature. It is also probable that in connection with these abnormal chemical changes in the contents of the alimentary tract, many of the undecomposed proteid molecules are isomerically transformed and converted into toxalbumins. The reason for this latter assumption is the great difficulty of recognizing the toxin in the blood. Were the toxin in all cases a by-product of proteid decomposition, judging by those that we are more familiar with, it ought to be easy of recognition. As the toxins are not easily recognized, only two methods of explanation are left: one, that the toxin is unstable and volatile in nature; or that it is an isomeric form of the proteid molecule—both of which are difficult to recognize and analyze accurately.

When these toxic substances, no matter how formed, reach the general circulation, and finally the nervous system, they give rise to an almost endless variety of symptoms, depending upon the nature and the amount of the poison entering the animal economy, and the inherent ability of the system to resist their toxic action. The intestinal method of formation conforms more closely to the general plan of chemical activity constituting animal life than does the hepatic theory. In all probability the intestinal explanation for the synthetic formation of the indoxylsulphate and the associated toxic products is the correct solution of this problem. As the indoxyl potassium sulphate is produced by the action of the bacteria of putrefaction only, its presence in the system and urine must be regarded always as a pathological product, and can never be classed as physiological and normal in amount. No deviation from an ideal standard can be classed as normal. The chemical processes of animal life must be perfect, and any deviation therefrom is indicative of an abnormal state. Evidence of this kind must be classed as a danger signal, that indicates the necessity for speedy correction if more serious deviations are to be prevented—such as may be recognized as absolutely pathological conditions.

With this conception of the production of ethereal sulphate or indican, as it is more commonly classified, we are in a position to consider the conditions that favor its production and the correct interpretation to be placed upon its presence in the urine.

As the production of the ethereal sulphates is always due to the action of the bacteria of putrefaction, we must determine the conditions favorable to the growth and development of these microorganisms. As a first promise, it may be stated that so long as the digestive secretions are normal in amount and composition, a decidedly restraining action is maintained over all forms of pathogenic bacteria, without inhibiting those that are essential

* At the time that the author penned the above sentences he was not aware that Neumeister had in a large measure advanced the same theory in regard to the synthesis of this simple substance.[4] He therefore calls attention to the fact that Neumeister was of the opinion that the ethereal sulphate was formed in the intestinal tract as the result of synthetic action excited by the bacteria.

for the normal digestive action. Therefore, it is common to speak of the gastric juice, the bile, and pancreatic secretion as being antiseptic in their actions, although this is not true in the stricter sense if closely applied to any single constituent of these secretions. But taken as a whole, this is unquestionably true; therefore, anything that tends to decrease the total quantity or the perfection of the digestive secretions, favors the growth and development of the bacteria of putrefaction and the formation of the ethereal sulphates.

The three fundamental factors in predisposing or leading up to a state of the alimentary tract favorable to the growth of pathogenic bacteria that give rise to the condition classed as indicanuria are: First, eating and drinking too much, or taking food of a faulty composition; second, a decrease in the amount or perfection of the digestive secretions; and, third, a faulty innervation of the glandular system as a whole.

Eating too much of any kind of food, or too largely of the vegetable class, simply overtaxes the digestive powers and ultimately decreases the so-called antiseptic qualities of the secretions poured into the intestinal tract. Too free use of the vegetable class, coupled with the fact that many are highly fermentable, causes undue irritation; all due to their great indigestibility—which ranges from 10 to 80 per cent—are highly irritable on account of this large undigested residue, and therefore prone to excite putrefaction.

This continued irritation of the intestinal tract tends also to produce an excessive secretion of a thick, tenacious mucus, instead of the normal amount, which is just sufficient to act as a natural lubricant. When the secretion of mucus is overabundant and viscid, it acts as a culture medium for the growth of the bacteria of putrefaction, and thus we have developed a putrefactive fermentation of the proteid constituents of the food, the formation of indol, phenol, skatol, etc., and finally the ethereal sulphates derived from indol.

The constant overtaxing of the digestive organs by simple overfeeding ultimately results in a defective secretion of the ferment substances, even though the food be of good quality and composition. When this occurs, the intestinal canal contains an undue amount of undigested material, which now acts upon the mucous membrane in a manner similar to what is noticed when too much food is taken of the vegetable class, or the food is imperfect in composition. In one case there is no defect primarily in the output of the digestive secretions; while in the other, the primary fault is more particularly in the secretions of the digestive glands.

When for any reason the nervous system becomes overtaxed and poorly nourished, there may be defective innervation of the digestive organs, and this is at once followed by a decrease in the quantity and composition of the digestive ferments poured into the alimentary canal. This in turn is followed by all the changes already described. Overeating at a time when one has for a long time used the nervous or muscular system unduly, is often the cause of an incomplete innervation of the digestive system, and produces changes which permit of the action of the bacteria of putrefaction. Simple overworking of the nervous mechanism, and particularly prolonged and severe mental activity, is often the only apparent cause of the incomplete innervation, decreased digestive secretions, and putrefactive changes in the intestinal tract.

But even in these instances a careful analysis of the case almost always reveals a preceding period of faulty feeding, an imperfect digestion, a faulty metabolism, and especially so in connection with the nervous mechanism. In cases of this nature, even after the indicanuria has been brought under control, and when every function of the body is being perfectly effected, any severe or prolonged mental exertion will speedily arrest the perfection of the digestive secretions and the indicanuria will at once recur, even though the patient strictly adheres to a well-regulated diet and may be still taking the requisite amount of out-of-door exercise.

The one exception to the almost universal rule that there must be errors in diet and a faulty digestion before the disturbances in the nervous mechanism will excite indicanuria, is in connection with those instances in which the nervous system has been subjected (when the whole system is otherwise in an apparently normal state) to a severe injury or shock. When this occurs there may be almost complete arrest of nerve innervation to the digestive organs, at a time when they are acting normally. In such an instance the primary defect may be traced to the nervous mechanism, and, secondarily, to the digestive organs. As a rule, however, the primary defect is found to be in connection with the diet and digestive system, and, secondarily, in the nervous mechanism. In most instances it is very difficult to draw a sharp line of demarkation between the two systems, yet the distinction can be made if each case is accurately studied by itself.

From this it is easy to see that we are dealing with a very complicated situation, one that gives rise to an endless variety of symptoms, one in which, at the beginning, so far as the deeper structures are concerned, no microscopic lesions can be detected. Later on, if the conditions persist, the development of easily recognizable lesions in one or all structures of the animal economy is of frequent occurrence. Whichever organ of the body is the most vulnerable will be the one to give way to the prolonged toxemia.

Before actual changes are developed in the anatomical structures of the body, the symptoms associated with the presence of indican in the urine are largely nervous in character and often very poorly defined. This is undoubtedly due to the large variety of toxins that are developed in connection with the putrefactive changes going on in the intestinal tract. There may be vague and ill-defined manifestations at various parts of the body. There are often neuralgic symptoms. There may be convulsions, coma, and even death in some rare instances. Not infrequently there are convulsive attacks that so closely resemble those of the so-called central epilepsy that it is almost impossible to distinguish the one from the other, except as the result of treatment. There are often headache, vertigo, insomnia, —an endless train of symptoms. When there is an associated intralobular compression jaundice, there is apt to be a persistent nausea.

There are no specific symptoms that can be classed as distinctive of indicanuria save the presence of indican in the urine. Considerable emphasis is given by some observers to the absence of free hydrochloric acid in this class of cases, as a causative factor in the development of the putrefactive changes in the intestinal tract. On the other hand, others claim that the presence of indican in the urine is evidence of free hydrochloric acid in the gastric secretion. The author is of the opinion that free hydrochloric acid is not always absent from the gastric secretion in these cases, and that when it is absent it is a secondary and not a primary condition, except in so far as all the digestive secretions are

decreased in quality and quantity, as already explained.

From these data it is clearly apparent that indican in the urine is always secondary to the action of the bacteria of putrefaction, acting usually upon the proteid elements contained in the alimentary tract; that the conditions favoring this abnormal fermentation are varied and multiple; that every case must be studied by itself and the relative importance of each one of these predisposing factors taken strictly into account; if absolutely perfect success is to follow our therapeutic endeavors. Owing to these varied conditions it is no easy matter to correct these defects when once well established.

The diet must be regulated in accordance with the well-known physiological law, so that the food taken will not be unduly irritative or fermentable. It must be of an easily digestible character, so that digestive energy will be conserved in the highest degree, and everything must be done to secure a perfect nerve innervation of the glandular system when it is below the normal standard. It is unwise—even if it were possible as some have claimed—to render the alimentary canal antiseptic. Much can be done in the line of decreasing the excessive fermentation of the viscid mucus, which is the medium that supports the growth of the pathogenic bacteria. This can be accomplished by the judicious administration of tanalbin. In so far as we succeed in this line, do we bring about practically a condition which is equivalent to rendering the alimentary canal antiseptic.

When these varied conditions are kept constantly in mind and each one given its proper importance, and treatment instituted to correct each one in the order of its importance, some wonderful cures are effected, and many serious chronic affections are prevented.

Time will not permit taking up every little detail of treatment, nor can a general detail be given of all the medication which can be brought into play in the management of these cases, for the simple reason that no two cases are alike. For this reason, what will give good results in one case may fail in another, and vice versa. Therefore, all that can be done is to point out, as we have attempted to do, the various methods by which the abnormal conditions lead up to and produce this complex condition covered by the simple term indicanuria, and to suggest from the data the general lines of treatment that must be followed to secure the desired results.

The minute details of treatment, such as the selection of the medicinal remedies and diet to be employed, must be left to the judgment of the individual practitioner, for each case must be studied separately and treated according to the special indications presented by the individuality of the patient.

The chief points in this discussion are as follows:

1. Indicanuria is one of the most important conditions in connection with clinical medicine.

2. Indican was discovered by Prout in 1840.

3. Blue substances have been recorded in the urine from the time of Hippocrates to the present.

4. Baumann and Breiger were the first to determine accurately the composition of indican.

5. Baeyer demonstrated that a more simple substance, indol, was the antecedent of the more complex body known as indican.

6. Nencki and others demonstrated beyond a question of doubt that indican is always the result of putrefactive fermentation.

7. Animal proteids are more likely to undergo putrefactive fermentation than the vegetable class.

8. Vegetable proteids are much more difficult of digestion than are the animal class, hence they are less economic, and often detrimental to the system.

9. Senator has proved conclusively that bacterial action is required to produce putrefactive fermentation in connection with the production of indican.

10. The sulphur atom in connection with the formation of indoxyl potassium sulphate comes from the proteid molecule as the result of its oxidation reduction.

11. Indican is primarily formed in the intestinal tract, and not in the liver.

12. Numerous toxins are formed at the same time that the indican is produced.

12. These toxins are absorbed into the circulation from the alimentary tract, and by their action upon the nervous system excite an almost endless variety of symptoms.

14. The conditions favoring the production of indican are errors in diet, lack of outdoor exercise, defective digestive secretions, and profound disturbances in the working of the nervous mechanism.

15. Indican in the urine is never normal, but always indicates an abnormal condition, because a putrefactive process can never be regarded as a normal or physiological phenomenon.

16. Successful treatment of these conditions depends absolutely upon an accurate apprehension of the etiological factors entering into the production of indicanuria, and also the best methods for the removal of those factors.

LOCOMOTOR ATAXIA; A NEW THEORY AS TO ITS CAUSE.*

By L. N. DENSLOW, M.D.,

NEW YORK.

THERE has, as yet, been no explanation as to the exciting cause of the changes that take place in the nervous system in this disease. It is in the hope of throwing some light on the subject that the present article is submitted.

In the light of my clinical experience I am of the opinion that the changes that occur in this disease are due primarily to irritation of peripheral nerves, producing reflex disturbances in the spinal cord and brain, and that such irritation kept up continuously for a sufficient length of time can and does produce pathological changes in the cord, although such irritation it has been supposed could only bring about functional disorders.

Under certain conditions of tissue either syphilitic or non-syphilitic pathological changes do begin and continue until grave conditions exist. It would seem that the nerve tissues are subject to degeneration from peripheral irritation only under certain conditions and exempt from it in others. From the fact that almost all authorities agree that there is a primary or inherited syphilitic history in the greater number of cases of tabes, it is possible that that disease is most frequently responsible for tissue condition necessary for its development.

The highly neurotic temperament would seem also at times to furnish a fertile soil, it having been met with in my experience in such cases a number of times and in those where there was no history of syphilis either acquired or hereditary, but always a positive peripheral irritation.

Exposure to cold, overexertion, sexual excesses, and alcoholism all have been given as contributory causes, but when one takes into consideration the thousands who suffer from all these occurrences and the comparative rarity of the disease, it would seem that there must be some other necessary factor.

In all my cases some source of peripheral irritation was found, and wherever corrected marked relief ensued. This would lead one to infer that, no matter what the condition of tissue, without the addition of the peripheral irritation, and that long continued, the tabes was not set up.

Trauma has been found in several instances to have been followed by tabes with more or less serious symptoms supervening very early in the disease. It has been thought that in such cases the shock of the injury only precipitated the disease, as irritation was always found and the symptoms yielded quickly upon relieving the irritation.

It was not the writer's experience to find a syphilitic history in every case, but in all without exception some source of peripheral irritation was found, and when amenable to treatment more or less relief was experienced.

According to Tuczek chronic ergotin poisoning induces a degeneration of the posterior columns of the cord in all points analogous to that which constitutes the anatomical lesions in tabes. This would appear to have a special bearing on the theory in hand from the well-known action of ergot on the unstriped muscular fibers; there from their general distribution over the body in the skin, could so be acted upon by the drug as to set up a general peripheral disturbance by their alternate contractions and relaxation acting upon the nerves and capillary vessels. The writer's article, "The Etiology and Treatment of Acne" (by Ergot), *New York Medical Journal*, February, 1881, bears directly on this subject. The observations of Dejerine have shown that a neuritis of the peripheral nerves may produce a symptom complex very similar to that of tabes dorsalis (peripheral neurotabes).

Thus we have two exciting causes of tabes: (1) Long continued peripheral irritation causing it with and without a prior syphilitic infection, and (2) chronic ergotin poisoning; and there is also a third cause, peripheral neuritis, producing a symptom complex very similar to that of tabes dorsalis.

From this would it not be fair to presume that in the case of a disease which is produced by agencies quite other than syphilis, and where syphilis is known not to have entered into the condition, and where the pathological changes do not resemble in their inception, course, or form any of the manifold and characteristically usual ones of syphilis, the disease is not primarily due to syphilis, but that other agencies enter into its causation.

*Read before a stated meeting of the New York Academy of Medicine, Thursday, May 16, 1907

If we allow for the present that peripheral irritation is the cause of the changes in tabes, I would submit a possible explanation of the mode whereby these changes may be accomplished. It is known that the conducting nerve substance is a very simple tissue, almost protoplasmic, being little more than highly phosphorized fats in a weak saline solution. In other words, this portion of the nerves consists of colloid particles in suspension. Now, if we apply Prof. Mathews' theory that when a nerve is stimulated electrically the colloid particles of these fats are precipitated and that coagulation to a certain extent takes place, we have a working hypothesis.

The peripheral irritation referred to in this article is that which is and has been constant for a period of time longer or shorter, as the case may be, but above all persistent and producing continuous, unconscious nervous stimulation. This irritation may exist for years without being known to the patient; in other words, without ever producing any local symptom. Such nervous action would keep up a condition of chronic coagulation, which in time would become permanent. This condition accords well with the actual first change that is found. Given this change the subsequent alterations of nerve tissue are but natural sequelæ, for with the increased sensory irritability consequent upon such coagulation, and the disturbance of the orderly action and balance of both the sensory nerves and their ganglionic cells, with their trophic connections, and given the continued persistence of the initial peripheral irritation, it would seem that there was sufficient to account for the perpetuation and progress of all the pathological changes that take place in the disease.

In connection with the foregoing theory it is interesting to note that it does not conflict with Marie's view, modified by Oppenheim,* that "the exciting cause of tabes acts upon the spinal ganglia and their homologues and injures them without at first altering them structurally," and that "this is sufficient to cause atrophy of the sensory fibers of the spinal cord, of the medulla, and of the periphery, which come from the ganglia. This atrophy gradually ascends, *i.e.* towards the ganglion cells, until their fibers are also involved." Also of special significance is the fact that Wollenberg and Stroebe discovered degeneration changes in the nerve-cells even in incipient cases of tabes.

I believe this theory of the etiology of tabes to be correct. It is based upon a considerable clinical experience. I am further of the opinion that if this is found to be the case it must create a basis for a new etiology in tabes, and possibly for other nervous diseases of unknown origin.

It has been considered by the writer sufficient at the present time simply to advance his theory in general. But in order to give other investigators the benefit of his experience he would state that the location of the irritation was genitourinary in both sexes in the cases examined, although it is believed that the causes may be as varied as those known to produce the wide range of functional disorders.

It would be of interest to know whether eyestrain was the primary cause or perhaps a contributing cause in those cases of the disease in which atrophy of the optic nerve takes place. It is proper to add that the theory advanced and these views are the result of clinical experience with a number of cases which have been observed and treated for a siderable period—some of them having been relieved in varying degree of their distressing symptoms, while others have been apparently cured, in so far at least as that all symptoms disappeared and that health and strength were regained, enabling them to return to their former mode of life and occupation.

This would lead us to infer that symptoms occur in many cases of this disease with a severity out of all proportion to the actual change in the cord and consequently that there must be a wide sphere of functional disorder in these cases beyond such change.

THE MILK SUPPLY OF VIENNA.

By ERNST J. LEDERER, M.D.,
VIENNA.

The dairy company of lower Austria which supplies the greater amount of the milk consumed in Vienna is subject to control by the provincial diet of lower Austria. The central depot in Vienna receives the milk from seventy-six affiliated dairies throughout the province, and these in turn receive the daily supply from a total number of 5,222 individual producers. The principal aim of the organ-

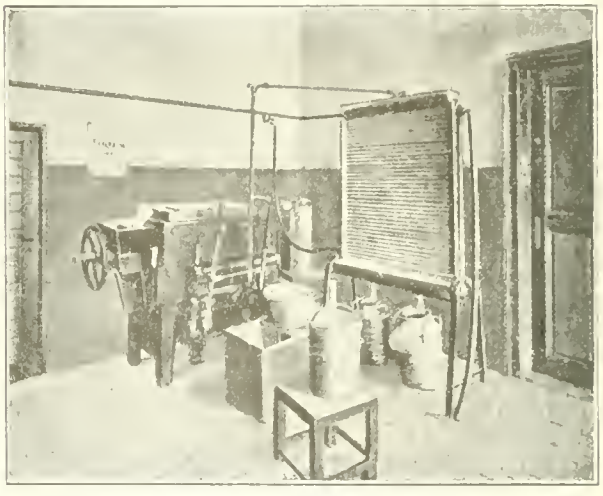

Fig. 1.—Cooling apparatus of a milk receiving station in the country

ization has been to regulate the methods of obtaining and handling the milk at the various places of production, an object which experience has shown to be especially important since farm milk, although superior in other respects, lacked that keeping quality which is one of the essential requirements in milk intended for city consumption. This aim was attained by making it immediately incumbent upon the directors of the affiliated dairies to inspect the milk at the sources of supply according to definite instructions given them by the Government Inspector of Dairies. The inspectors visit the various stables, criticise the condition of the stock and the cleanliness of the barn, etc., and make the owners remedy any existing defects or introduce needed improvements. They also supervise the feeding and care of the cows, as well as the milking. The fundamental principles which must govern the manner of feeding, tending, and milking the cows are thoroughly explained by the Government Inspector to the members of an affiliated dairy when such a one is established. Each member is supplied with a book in which is entered the daily amount of milk delivered, and to this book is appended a printed list of regulations, compliance with which is legally obli-

gatory. The Government Inspector further has the duty of visiting and inspecting the various dairies at regular intervals, and of rendering reports of such visits both to the provincial diet and to the directorate of the Dairy Company of Lower Austria. Veterinary inspection of the milch cows has likewise been introduced.

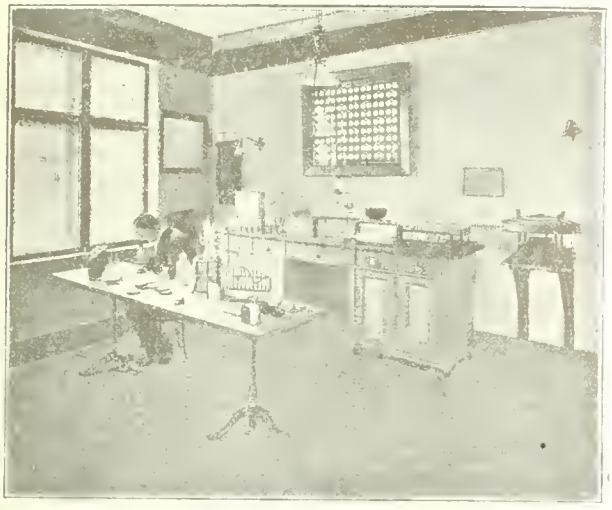

Fig. —2. Laboratory.

The new-drawn milk must be delivered at the local depot after each milking, if possible while still warm from the cows. It is then measured, tested, purified, and cooled, and if not sent off immediately it is placed in the front compartment of the refrigerating room until shipped. The local depot in which the milk is received and treated is a building which in every particular conforms to modern requirements. Each affiliated dairy has such a depot, which comprises ice-house, cooling compartment, wash-house, and the necessary apparatus, such as pipe systems for cooling, strainers for purifying the milk, apparatus for determining the percentage of fat, lactometers and thermometers for testing the milk, as well as centrifuges and the requisite appliances and apparatus for butter-making. Since the milk delivered to the local depots by the various members must be transported to the railway station to be shipped to the central depot in Vienna, the affiliated dairies have wagons which can be covered to protect the milk against the heat of the sun. The value is fixed according to quantity and percentage of fat, the latter being determined by the Government agricultural chemical laboratory in Vienna. The average contents of fat, according to the laboratory's findings, are as follows:

AT EASTER.

No. of Affiliated Dairies.	Percentage of Fat.
5	3.57
5	3.61
5	3.95
5	3.60
5	3.65
Average	3.62

AT CHRISTMAS.

No. of Affiliated Dairies.	Percentage of Fat.
5	4.11
5	4.00
5	4.12
5	3.97
5	3.80
Average	4.02

The amount of impurities contained in the milk from each producer furnishes a criterion by which are judged the care and cleanliness observed in milking. The high state of purity in which the milk from the various dairies reaches Vienna may be seen from the following table, which gives (in milligrams) the amount of impurities contained in one liter of milk, and showing comparison with various German cities. These investigations were likewise conducted by the agricultural chemical laboratory in Vienna:

	Minimum.	Maximum.
Vienna	0.5	7.5
Würzburg	3.02	8.10
Leipsic	3.80	11.50
Munich	9.00	27.90
Berlin	10.30	50.00
Halle	14.92	72.50

In the central depot, however, the milk undergoes still further purification, so that on reaching the consumers it contains only a mere fraction of a milligram of impurities per liter.

When the milk reaches the central depot in Vienna, it is poured into a large vat and weighed. The vat is provided with a system of strainers and close-meshed gauze for purifying the milk. The gauze is renewed every time after it has been used, and before being used again it is carefully washed and sterilized in live steam. The purification process gives very gratifying results. The milk, which is already in a high state of purity when it reaches the central depot, contains only from 0.3 to 1 milligram of impurities per liter after having undergone the additional purifying process in the central depot. From the weighing-vat the milk is led into the pasteurization apparatus where it is heated to 70° C. The receiving hall contains three such pasteurizers.

Although the control exercised by the affiliated dairies, the government inspector, and the veterinary surgeons aims at excluding milk from farms or barns in which contagious diseases prevail, it is not impossible, in view of the great prevalence of

Fig. —3. Pasteurizing room.

tuberculosis among milch cows, that milk from diseased cows may reach the dairy. For this reason the *entire* quantity of milk intended for direct consumption is pasteurized at 70° C., whereby all disease-producing organisms that may be present, but especially the tubercle bacillus, are rendered harmless without the milk undergoing any essential

changes, either physically or chemically. After pasteurization the milk is pumped on to the pipe coolers, where it is rapidly chilled to from 2° to 4° C. (35.6° to 39.2° F.) and thoroughly aired. From the coolers the milk is run into large galvanized-iron vats, from which it is poured into

FIG.—4 Hall for reception and distribution of milk.

cans or bottles. The latter process takes place by means of bottling apparatus. Immediately after having been filled the bottles are stoppered—by means of machinery—with paraffined paper stoppers which bear the date of bottling.

After pasteurization a certain quantity of the milk is creamed through two centrifuges, and divided into whipping cream (30 per cent. fat), tea cream (16 per cent.), and coffee cream (10 per cent.), as well as skimmed milk. These products are each cooled to a low temperature in separate apparatus immediately after the centrifugal process. The various kinds of cream are bottled by machinery, while the skimmed milk is led into a separate compartment and poured into cans which are plainly

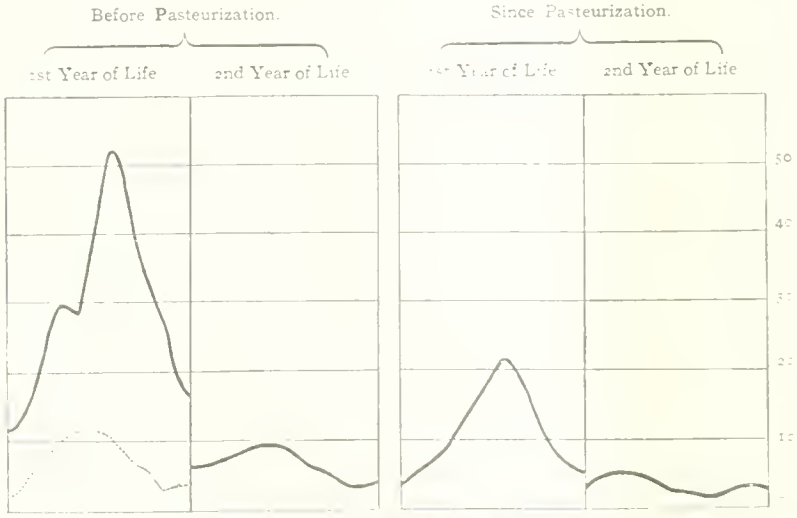

Chart showing the mortality of bottle-fed [illegible] Year before and since the system of pasteurization was introduced. The [illegible] column indicates the mortality of breast-fed children.

marked "Skimmed Milk" in red labels. The skimmed milk is utilized by bakers in the making of fine pastry, etc., any surplus amount being made into whey cheese. Unsold cream is made into butter.

The central depot contains bathrooms, and a medical examination room in which all employees who handle the milk are periodically examined by a municipal health officer. Persons suffering from tuberculosis or other contagious diseases are excluded. Both male and female employees are enjoined to bathe regularly.

Separate from the other departments is the room in which the milk for children is handled. For this purpose is used the milk from only one dairy, the cows supplying which are tested with tuberculin to make certain that they are free from tuberculosis, and kept under rigid inspection by the Veterinary Board of Lower Austria. This milk very closely resembles human milk in its chemical composition. It is sterilized at 102° C.

The process of pasteurization has absolutely no effect on the nutritive value of the milk, while rendering its taste more pleasant. Neither does it affect the formation of cream. The system has been in use for seven years; and the beneficial effects of the improved milk supply, especially with regard to the feeding of infants, are demonstrated by the statistical data. (See Chart.) The proportion between the mortality rates for breast-fed and bottle-fed children was formerly (especially in the summer months) 1:20, while it is now from 1:5 to 1:8. The circumstance that bottle-fed children are given better milk reduces the rate of mortality for those in the second year of life also. Regarding the cost of the milk, the process of pasteurization increases the price from 3-10 to 1 heller per liter (1-13 to 1-4 cent per quart).

PILOCARPINE AS AN ADJUVANT IN THE TREATMENT OF SYPHILIS.

BY WILLIAM J. ROBINSON, M.D.,

NEW YORK.

THE use of pilocarpine in the treatment of syphilis is probably not entirely unknown. But the drug is so seldom mentioned in treatises on the subject and it has given the writer such remarkable results in certain cases which refused to be further influenced by the mercurials and iodides that he considers it his duty to bring it before the notice of the profession in this preliminary note, in advance of a more detailed contribution.

I have not the slightest intention, of course, of recommending pilocarpine as a *substitute* for mercury and iodine. But there are certain cases of lues which seem to be supersaturated with mercury and which no longer respond to the drug. We may change the combination of the mercury, we may change the method and avenue of introduction—the symptoms fail to be influenced, or even become aggravated. The submaxillary, axillary, and inguinal glands instead of diminishing in size uder the influence of mercury, as they generally do, become larger and even painful. Such cases are particularly apt to be met with in patients in whom sufficient attention has not been paid to gastrointestinal elimination, to hepatic, renal, and dermic activity. Almost every physician has come in contact with such cases in his practice.

Now, try in such cases a few doses of pilocarpine and you will be gratifyingly astonished at the results. Most remarkable is the effect of pilocarpine on salivation and stomatitis. One might think it rather strange to administer a powerful sialogogue in salivation. But the fact remains that nothing will stop mercurial salivation so effectually as will small doses—say two milligrams—of pilocarpine. It is much more efficient in this respect than atropine or potassium chlorate. And the rationale is not difficult to understand. Salivation and stomatitis are caused by an excess of mercury, imbedded in the glands and acting as a toxic foreign body. Pilocarpine, being one of our most powerful glandular eliminants, acting both as a sialogogue and a diaphoretic, removes the useless excess of mercury, and thus cures the trouble by removing the cause. (Atropine, on the other hand, merely masks the symptom of mercurial salivation.) Another fact of which the writer has convinced himself again and again: Cutaneous syphilides which will obstinately resist the persistent administration of mercury will disappear rapidly, if pilocarpine be administered for several days, either in addition to the mercury, or even if the mercury be discontinued altogether (provided of course the patient has had sufficient mercurial treatment). I explain the modus operandi of pilocarpine in such cases as follows: In most cases the greater part of the mercury administered is eliminated through the bowels and kidneys. If the amount to be eliminated is too large or if the ratio of elimination is too rapid, we get cramps and diarrhea on the one hand and mercurial nephritis on the other. Very little or no mercury is eliminated through the skin and sudoriparous glands, unless special care is taken to keep them at a high state of functional activity. The pilocarpine does just that. The system may be "saturated" with mercury, but the mercury may remain dormant and therefore useless. The pilocarpine, increasing enormously the activity of the skin, brings the mercury to the surface, the skin lesions are directly affected, and the syphilides therefore disappear. If pilocarpine be given for a week or two and then discontinued, it will be found that much smaller doses of mercury will be necessary in order to produce the desired effect.

Method of Administration.—The pilocarpine should never be prescribed in combination with other remedies—always alone. We can then increase or diminish the dose, or discontinue it altogether, at pleasure. I prescribe the alkaloidal salt either in the form of pills, containing two milligrams each (1-32 grain), and of these I order two pills three times a day, sometimes increasing to three or four pills per dose; or I prescribe it in the following solution:

Pilocarpinæ hydrochlor	0.12	(2 grs.)
Aquæ chloroformi	120.0	(4 oz.)

Detur in vitro nigro.

S. 3i to 3ii t.i.d.

In not a single case have I observed any undesirable by-effects, and in no case could I find, though I carefully watched, symptoms of cardiac depression.

I have careful notes of a rather considerable number of cases, in which the beneficial effects of pilocarpine were unmistakable; and I guarded carefully against falling into post hoc-propter-hoc fallacy. But I will report those cases at a later date. In the meantime, asking the profession to give pilocarpine a careful trial as an adjuvant in the treatment of syphilis, I will lay down the following propositions:

1. Pilocarpine is a most remarkable glandular eliminant, and glandular elimination is one of the most important factors in the successful treatment of syphilis.

2. Pilocarpine is of value in all secondary manifestations of the disease.

3. There are many cases which become intolerant to the further use of mercury; the system seems supersaturated and continuing the mercury in such cases means injuring the patient. Discontinuing the mercury, giving pilocarpine in the interval, enables us to resume the former drug with excellent effect.

4. Pilocarpine should be prescribed alone, either in pills or solution, and should be given in doses of two to eight milligrams (1-32 to 1/8 gr.) two to three times a day.

12 Mount Morris Park West

Two Hundred Scopolamine Narcoses.—Parlavecchio reports 200 cases of operation under narcosis with scopolamine, many of them being of grave nature. The technique of Tuffier was used in all cases by the author, three injections being given during two hours before operation, of three millegrams and a half of the drug. Often after the second injection, sometimes after the first, anesthesia was complete and continued for from six to ten hours. Scopolamine should not be used under the age of ten years, while it is well tolerated by persons of advanced age, by those with nephritis, arteriosclerosis, and other conditions in which ether is contraindicated. The advantages of scopolamine are that it avoids the vomiting which is present after ether or chloroform, and permits of operation in persons of small vitality. It is convenient to operate in the lateral position or on the back, as may be desired, and is especially valuable in operations on the head or neck.—*La Riforma Medica*

The Saturday Night Tub.—Mr. Sidney Young has recently delivered an interesting lecture on the "Relations Anciently Existing Between Barbers and Surgeons." From the facts adduced one learns that it was the custom of no less a person than King Henry VIII. to perform partial ablutions on occasional Saturday evenings. The "King's barber," one John Pen, Penn, or Penne, an ancestor of the famous Quaker of that name, was expected to be present at these august ceremonies, when the Defender of the Faith was pleased "to cleanse his head, legs, or feet." The regulation requiring the barber's attendance was a standing order, dating apparently from the reign of Edward IV. It is preserved in the "Liber Niger Domus Regis" (Harl. MS., 642), and its wording seems to imply that the solemn washings were partial and special rather than thorough, and that the king's majesty often did without them. The royal barber, who was also a groom of the privy chamber and one of the fifteen persons allowed to enter it, was also required to shave the king daily, "having in readiness his water, basons, knives, combs, scissours, and such other stuffe as to his roome doth appertaine for trimming and dressing of the king's head and beard." He was further required to "take a special regard to the pure and clean keeping of his own person and apparel, using himself always honestly in his conversation without resorting to the company of vile persons," and so on. Thus we have the beginning of asepsis. When he was shaving the king a knight of the chamber or squire of the body, or both, were required to be present in order to prevent foul play. The portrait of Pen figures prominently in Holbein's famous picture of Henry VIII. delivering a charter to the barbers and surgeons on the occasion of their union in one body.—*The Lancet*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 15, 1907.

PASTEURIZED MILK.

It has been decided by the New York City Board of Aldermen that the pasteurization of the substandard milk offered for sale in this city is neither necessary nor desirable, and the importation and distribution of various pathogenic microorganisms will therefore go on for the present. The agitation of the subject has, however, already borne fruit in opening the eyes of the public and directing more forcibly the thoughts of the profession to the vital importance of a pure milk supply. The first requisite to this is cleanliness at the source, for no amount of pasteurization or even of boiling will convert a milk full of gross impurities into an acceptable food. All that pasteurization aims to do is to destroy the germs which even the best of milk contains in greater or lesser numbers, and with which milk, carelessly handled, drawn from diseased cows, or carried in imperfectly sterilized bottles or cans, actually swarms. Therefore, if the immediate result of the agitation in and out of the public press is only a more careful inspection of the farms and creameries at the source of our milk supply, it will not have been in vain.

The opponents of pasteurization contend that the process renders milk unfit, or at least less fit, for consumption, since it destroys the contained enzymes and so causes a deterioration in its nutritive qualities. Without attaching too much importance to this theoretical objection, it may be conceded that untreated milk, if absolutely free from the germs of tuberculosis, pus cocci, and other pathogenic microorganisms, is preferable to the sterilized (boiled) or even pasteurized fluid. Doubtless raw meat from the recently killed animal contains certain nutritive principles which are destroyed by heat, but there are advantages in cooking meat which by universal consent outweigh the loss in nutritive properties which it may sustain in the process. It is also alleged, as though this were an argument against the principle of pasteurization, that the agitation is furthered by the makers of pasteurizing apparatus. It is not unlikely that these manufacturers are alive to the possible benefit they may derive therefrom, and if they are thereby stimulated to perfect their apparatus the community will profit as well as themselves. The fundamental question is whether pasteurization does or does not prevent disease, and its determination can be arrived at only by discussion and study, so that the present agitation of the subject, even if it were of purely commercial origin, as it is not, can but be productive of good.

In the present issue of the MEDICAL RECORD are three articles bearing on this subject which are worthy of attention by those interested. In the Copenhagen letter our correspondent describes the measures which have been taken to procure a pure milk supply for that city. There is probably no large city in the world which can boast of a purer raw milk supply than Copenhagen, and it is interesting to note that this has been brought about by private initiative, the milk merchants having had the wisdom to see that it was to their own advantage to supply their customers with the best wares procurable. Concerning the London supply, little need be said; the milk is neither pure nor purified, although there is a prospect that the present public discussion started by the *Lancet* investigation may result in some improvement. On page 986 a Viennese contributor describes the measures that have been taken to protect the inhabitants of that city from milk poisoning. There pasteurization is now the rule, and the comparative infant mortality curves show what the saving of life has been since a system of general pasteurization was instituted. But infants, although the chief, are not the only sufferers from an impure milk supply. In a recent report on the milk problem issued by the Washington, D. C., Milk Commission it is stated that during the past twenty-five years the medical journals have published the histories of 105 epidemics of typhoid fever, in addition to 69 of scarlet fever and 36 of diphtheria, traceable to milk. One can imagine, though exact statistics are wanting, how many deaths, how much suffering, and how many unproductive days of illness might have been saved had the germs of typhoid fever, scarlatina, and diphtheria been destroyed by pasteurization before this poisoned milk was ingested. To this may be added the fact, demonstrated by E. C. Schroeder, Calmette and Guérin, and others, that one of the most potent sources of infection by tuberculosis is milk drawn from tuberculous cows.

Referring to the milk supply of Washington, this Commission reports: "It must be apparent that it will require time and education to secure compliance with even reasonable safeguards, and it is equally evident that the number of dairy farms now in a position to live up to sanitary requirements will supply but a small percentage of the population, although it is hoped that they will be stimulated into existence by trade competition and the refusal of the public to buy dirty milk at any price. Until this is accomplished, the committee, in the interest of public health, strongly advocates clarification and pasteurization of all milk; this, to be sure, will not make bad milk good, but it will at least destroy its power to transmit disease germs." The men who have signed this report are not uninstructed laymen or persons interested in the manufacture of pasteurizing apparatus, but men who know whereof they speak. The constitution of the committee is as follows: Dr. George M. Kober, Chairman; Emil Berliner; Dr. G. L. Magruder; Dr. C. F. Mason, U. S. Army; Dr. A. D. Melvin, Chief of the Bureau of Animal Industry; Dr. J. R. Mohler of the Bureau of Animal Industry; Dr. M. J. Rosenau, Director of

the Hygienic Laboratory of the Public Health and Marine Hospital Service; Col. R. G. Smith of the U. S. Army, and E. H. Webster, Chief of the Dairy Division of the Department of Agriculture. The conclusions of this committee apply with equal force to the milk supply of New York and all other large cities, and they add weight to the arguments of those who believe that the only safety for all consumers of milk in this city, for many years to come, will lie in the pasteurization of the bulk of milk offered for sale, only excepting that supplied by dairies certified by the Milk Commission of the County Society or some other competent authority.

This is not in disparagement of the laudable efforts of the Health Commissioner of this city to better the milk supply by a system of inspection of the dairy farms. Such inspection is absolutely necessary, but it will be many years before perfection can be secured in this way. Moreover, political considerations may at any time lead to the supersession of the present Commissioner by one more subservient to the demands of the "district leaders," and when this change comes, what will become of the elaborate system of dairy inspection which he is building up? Unfortunately, little confidence can be placed in the permanence of any efficient system of inspection under political control. The present Commissioner of Health is doing what he can, with about one-tenth of the necessary force of inspectors, to insure a pure milk supply, but no man knows what his successor will do. Until the political millennium, and until model dairies can be conducted as cheaply as ordinary cow farms, the only safety for the mass of milk consumers will lie in public or private pasteurization.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

The Atlantic City meeting of the American Medical Association, held last week, was quite successful, and, excepting a personal encounter in one of the Section meetings, fairly harmonious. The scientific work in the various Sections was up to the average, though it suffered somewhat from the fact that the Congress of American Physicians and Surgeons, held a month before in Washington, had taken the cream of what those who are members of both organizations had to offer. The weather was cold and did not tempt to board-walk life, but this served to increase attendance at the Section meetings, so, in the interest of the scientific work, it was perhaps not to be regretted. The public addresses were good, that on State Medicine being especially interesting, and the thoughts expressed in the President's address were sound. The suggestions as to reform in the management, foreshadowed in Dr. Bryant's address to the Medical Society of the State of New York in Albany last January, were for the most part omitted at Atlantic City. The President did, however, offer what may be construed as a protest against the suppression of criticism in the columns of the official *Journal*, and he hinted that there might be danger in the wording of the constitution, which declares one of the objects of the Association to be "to safeguard the material interests of the medical profession." "It requires no special discriminating sense," he said, "to foresee the devious interpretations which eager desire might willingly give to the phraseology of this declaration."

The protest of the Medical Record last year against secrecy in the financial affairs of the Association has borne some fruit, for the Trustees announced that all details of the expense account will be furnished verbally on request, though they said it was inexpedient to state what wages are paid the linotype workers or the girls employed in wrapping the *Journal* for mailing. The three Trustees whose terms of office expired this year were re-elected, somewhat to the disappointment of those who do not favor the close corporation principle in the management of scientific bodies. It was urged that the members of the Association give their cordial support only to those journals which carry the advertisements approved by the Council on Pharmacy and Chemistry. This suggestion, if acted upon, would exclude from favor all the independent journals, among them several edited by members of the Board of Trustees, as well as a number of the best of the State journals.

Dr. Burrell of Boston was elected President of the Association, to take office at the next annual meeting, which will be held in Chicago. This is doubtless in recognition of Dr. Burrell's excellent work in connection with the Boston meeting in 1906, one of the largest and best conducted meetings in the history of the Association. The choice is in every way most commendable. The selection of Chicago for the next place of meeting was wise, for it will give the members in attendance the opportunity to see the headquarters of the Association and to gain an idea of the practical workings of the business part of the organization.

On the whole, the meeting gave evidence that the Association is prospering in material affairs and that its membership is increasing satisfactorily, notwithstanding the defection of over two thousand during the year. This is a matter of congratulation to all loyal members, even to those who believe that a still greater measure of prosperity would follow upon a change in men and methods which would recall those who have left, prevent future defections, and bring into the fold the great mass of the profession of the country which is opposed to the system of oppressive paternalism against which the President of the Association so eloquently warned his hearers in the New York State Society a few months ago.

The Coronary Arteries.

The literature relating to the anatomy and physiology of the coronary arteries represents an unusually extensive field of investigation, but the results have so far been more or less unsatisfactory in that they have been full of contradictions. The ordinarily accepted view that the coronary arteries are end arteries—if not in the strict sense of Cohnheim, at least from a functional standpoint—has been contested by numerous observers, and in a recent contribution by Hirsch and Spaltcholz in the *Deutsche medizinische Wochenschrift*, May 16,

1907, appears to be definitely disproven. Spalteholz, who studied the problem from the anatomical standpoint, by means of a specially devised injection method combined with a process for rendering the tissues translucent, comes to the conclusion that the coronary arteries, far from being end arteries, possess numerous anastomoses both on the surface of the organ and in the substance of the myocardium. Each papillary muscle is supplied by several afferent vessels communicating with each other by numerous branches. These studies for the most part were made on the hearts of dogs and monkeys, but comparisons showed that the results could legitimately be transferred to the human organ as well. The fact having been established that the heart is not deficient in arterial anastomoses, but, on the contrary, is remarkably rich in these, the clinical application of this observation had to be determined by experiments on the living organ. Bier has already shown that the different organs behave very differently in regard to the consequences of ligation of their arterial trunks and that the anatomical picture alone does not suffice to explain the results of the occlusion of the afferent vessel. This part of the investigation was conducted by Hirsch, who found by work on dogs that in the heart muscle the conditions attending coronary obstruction or occlusion depend largely on the anatomical or functional state of the vessels, and to a still greater degree on the *vis a tergo* or cardiac power. The sudden blockage of a coronary artery is therefore a particularly serious occurrence, if the vessel is arteriosclerotic, and observations of the blood pressure in these cases are practically important as affording an insight into the force of the heart's action. In angina pectoris associated with a low blood pressure the use of rapidly acting heart stimulants is likely to restrict the dimensions of a resulting infarct, but if there is increased vascular tension any further elevation of pressure must be avoided and morphine and the vasodilators are indicated.

Hypertrophy of the Prostate.

The operative treatment of hypertrophy of the prostate has now, at least in the hands of certain operators, reached a highly satisfactory state of development—so much so that a German surgeon of international reputation is reported to have said that now that prostatectomy is available it is a pleasure to grow old. None the less the mortality of the operation is still comparatively high and there are many contraindications to its performance, so that nonoperative measures must continue to bulk largely in the treatment of the condition. Among these, permanent drainage of the bladder by a soft rubber catheter is highly commended by Vogel (*Berliner klinische Wochenschrift*, May 20, 1907), who says that the results of the use of this procedure in the stage of congestion are often astonishingly good, particularly if the patient is in the stage of congestion. In these cases there is a vicious circle in which the enlargement of the gland causes retention of urine, and this in turn occasions congestion of all the pelvic viscera and so contributes to the increase in size of the prostate. Continuous catheterization by relieving the vesical distention brings about a general improvement, which often continues for a considerable length of time, and even in the later stages of the malady great relief may attend the occasional resort to this measure. The patient may in this way reacquire the power of emptying his bladder unaided, or if the improvement is of short duration benefit may follow leaving the catheter in place for an hour or two a day, or every other day. It is of great importance that the catheter be inserted into the bladder only far enough to allow its eye to be just beyond the sphincter, and it must be firmly fixed in this position. Numerous methods have been suggested for this purpose, but the one preferred by the author is as follows: Two strips of adhesive plaster about .5 cm. in width and 15 cm. in length are applied at their middles to the catheter at the meatus in such a way that their ends form a cross. These four ends are fastened to the glans, and are further secured by a strip passing circularly around the coronary sulcus, though this must not constrict the organ. The dangers of cystitis must of course be reckoned with in resorting to this method, and the most scrupulous asepsis is an essential.

Protection Against Infection from the Intestinal Canal.

A problem that has been made the subject of much research is that of determining the conditions under which the passage of bacteria from the intestinal tract into the blood stream is facilitated or impeded, but the results so far have not been very conclusive. A recent contribution of considerable interest is that of Uffenheimer (*Münchener medizinische Wochenschrift*, May 14, 1907), who found that the intestinal tract of the new-born guinea pig is resistant to the passage of all bacteria and genuine albumins, except the tubercle bacillus and antitoxins. On repeating the experiments with new-born rabbits, however, it was found that these animals exhibited a greater degree of susceptibility to the passage of bacteria and albumins through the gastrointestinal mucosa. By a series of ingenious experiments the author was led to the conclusion that this disparity depended in general on a fundamental difference in the bactericidal properties of the blood, and particularly on the amount of alexin in the serum. On removing the alexin from the serum of rabbits by saturation with goat erythrocytes he uniformly succeeded in causing the passage of prodigious bacilli into the blood of the experiment animals, and he expresses the conclusion that the amount of alexin in the serum of an individual is the decisive factor in determining whether or not bacteria gaining access to the intestinal canal are to succeed in gaining a foothold in the circulating blood. If this conception proves to be well founded, its bearing on the mechanism of infection in such diseases as typhoid fever is self-evident, and additional light is thrown on the protective agencies of the body.

Chemically Treated Roadways.

A recent issue of the *Lancet* calls attention to a practice, evidently extensively followed in England of sprinkling roadways with a solution of calcium chloride. The increasing motor traffic has made the question of dust a more pressing one than ever before, and the immediate results of the new practice seem very satisfactory. The roadbed thus sprinkled is converted more or less into a permanently moist state on account of the hygroscopic properties of the salt. The latter is cheap and its

supply abundant. But, as the *Lancet* states, we have yet to learn of the permanency of its good effects and have yet to find if it has any drawbacks. Is it free from corrosive properties? Our contemporary asks: "Will it affect the feet of the horse, sheep or ox? Will it attack the rubber tire? Will splashings containing calcium chloride corrode clothes, the skin, woodwork, and so on? Perhaps also some risk may be involved in inhaling a dust impregnated with an irritating salt. As is well known, a solution of calcium chloride practically acts as an acid and readily attacks iron and other metals, so that it is possible that the use of calcium chloride as a dust preventer on the roads may prove to be a remedy worse than the disease. A shower of rain, of course, is calculated to wash out the calcium chloride, so that the moment dry weather succeeds wet the application of the salt would have to be renewed." The problem of the new dust-layer is manifestly not yet reduced to its lowest terms.

News of the Week.

Red Cross Congress.—The formal opening of the eighth international Red Cross conference took place in London on June 11. Lord Roberts welcomed the delegates and read communications from the Queen, from the Dowager Empress of Russia, and from the Florence Nightingale Assembly. The congress closes to-day with a reception to the delegates at Buckingham Palace, at which the King and Queen, General Robert M. O'Reilly, U.S.A.; Col. William C. Sanger, and naval and military attachés will be present. The United States, in addition to General O'Reilly, is represented officially by Medical Director John C. Wise, U.S.N., while the American Red Cross delegates are Colonel Sanger, Miss Mabel T. Boardman, and Ernest P. Bicknell.

For a National Department of Sanitation.—At the banquet of the Practitioners' Club of Jersey City, held in this city on June 11, Congressman Eugene Leake of Jersey City announced that at the next session of Congress a bill would be introduced providing for the establishment of a Federal sanitary bureau to take over the health problems now scattered among several departments, and to centralize and coordinate the work of public sanitation. The bill will probably include the appointment of a medical member of the Cabinet.

The Correction of Medical Nomenclature.—The Medical Society of Athens, in the endeavor to assist in the formation of a system of classical Greek medical nomenclature, for the guidance of men of science who use chiefly the Greek language for scientific terms, has appointed a committee, of which Professor S. Mangina is chairman, entrusting this committee with the collection of the classical Greek definitions to be proposed as substitutes for irregular terms newly introduced into medical literature and in use both in Greece and in foreign lands. Dr. Achilles Rose of this city has been unanimously elected a member of this committee.

Coroner's Physicians Bill.—Governor Hughes has vetoed the bill increasing the number of Coroner's physicians in Brooklyn. In doing so he points out that if the law is to be amended at all it should provide that the number of Coroner's physicians within the Greater New York should be fixed by the local authorities and not by the Legislature.

Suicides in Chicago.—An unusually large number of suicides was reported in Chicago during the past month. January had twenty-five cases of suicide, February twenty, March thirty-seven, April forty-six, and May fifty-five. In the first five months of the year there were seventy-five murders, twenty-two of which were committed in May.

Hygienic Cigars.—Cigars are now made in Germany which are free from the danger of transmitting infectious diseases from the workman to the smoker through the practice of gumming the wrapper. In the new method the wrapper is held in position by a tinfoil ring, removable before smoking.

A Conference of Physicians Interested in Hydrotherapy was held at Atlantic City on June 4, 1907. Dr. Simon Baruch was called to the chair and Dr. Frank E. Brown appointed secretary. Representative physicians from several States discussed the importance of furthering the study, teaching, and practice of hydrotherapy and other physiological methods. A committee consisting of Drs. Hare of Jefferson, Thayer of Johns Hopkins, Baruch of Columbia, and F. E. Brown of Baltimore were appointed to formulate a symposium on these subjects for the next meeting of the American Medical Association.

Louisiana State University Medical School.—At a recent meeting of the Board of Supervisors of the Louisiana State University, held in Baton Rouge, the charter and by-laws of the new medical college of the University, to be established in New Orleans, and the contract of assimilation between the University and the Medical Department were submitted to the Supervisors and approved. It is the general understanding that this medical department is to be ready for opening during 1908.

McGill University Medical Building.—It is planned to rebuild the medical building of McGill University, which was recently destroyed by fire, on a plot of ground immediately opposite the Royal Victoria Hospital. The ground is owned by Lord Strathcona, who bought it for the purpose of preventing residences being built opposite the hospital, and is believed to be willing to place it at the disposal of McGill. The laboratory, which practically escaped the flames, will remain where it is, but the plot on which the medical building proper stood will be cleared and left for the general beautification of the grounds.

Columbia University.—On the recommendation of the faculty of medicine, Dr. James D. Voorhees has been made adjunct professor of obstetrics, Dr. Royal Whitman adjunct professor of orthopedic surgery and Drs. George R. Lockwood, William K. Draper, and Van Horne Norrie adjunct professors of clinical medicine. Plans have been filed for the partial remodeling of the Vanderbilt Clinic building of the College of Physicians and Surgeons at the southeast corner of Amsterdam avenue and Sixtieth street for the establishment of a department of hydrotherapy.

The New Civic Health Commission of Chicago, recently appointed by Mayor Busse, is composed of the following: Mrs. Marshall Field, Dr. Nicholas Senn, Dr. Frank Billings, Dr. C. E. Kahlke, Dr. W. E. Quine, and Dr. C. H. McKenna. During periods of high mortality in the city Dr. Evans, Health Commissioner, will consult with the commission as to the best means of checking the death rate.

For a Street Cleaning Commission.—Mayor McClellan has asked the Board of Estimate to appropriate $10,000 to be used for the expenses of

a commission of three engineers whom he will appoint to investigate and report at an early date on an improved system of street cleaning, and a better method of disposing of the city's waste. The following are suggested by the Mayor as suitable members of such a commission: H. de B. Parsons, Esq., S. S. Whinery, Esq., and Rudolph Hering, Esq.

Chicago Death Rate in May.—During May there were 3,028 deaths reported in Chicago from all causes, this being equivalent to an annual death rate of 10.91 per 1,000. Pneumonia led the death causes with 685; consumption, 352; heart diseases, 243; nephritis, 215, and violence (including suicide), 201.

New Nursery and Hospital for the Cribside Society.—The new building for the nursery and hospital for the Cribside Society, to be erected at Fullerton avenue and Orchard street, Chicago, will be ready for occupancy January 1. This building will be a two-story red brick structure, built on strict colonial lines. Its dimensions will be 41 by 37 feet.

Quarantine Against Cuba.—Passengers arriving in this port from Cuba now have their temperatures taken at Quarantine and if thought advisable are kept under observation for a day or two at Hoffman Island. An arrangement has been made in Havana under the sanction of the United States Marine Hospital Service to enable passengers to the Southern States to avoid detention on landing by spending several days under observation in a quarantine camp before sailing. It is planned to centralize the sanitation of the whole island under Major Kean, United States Sanitary Supervisor. An executive department of sanitation may be created later.

Plague in Trinidad.—Two fatal cases of bubonic plague in negro children have been officially reported from the Island of Trinidad. The health authorities have cabled to this city a request for antiplague serum.

Gifts to Hebrew Charities.—The will of the late Louis Josephthal, filed for probate last week, leaves $5,000 to Mount Sinai Hospital to found a bed in his memory, and $2,500 to the Montefiore Home for Chronic Invalids.

The British Royal Institute has awarded the Actonian prize of one hundred guineas to Madame Curie, in recognition of her researches in the field of radiology.

Illinois Bill against Cigarettes.—Governor Deneen has approved the Berry anticigarette bill, forbidding the use of cigarettes in public by minors under eighteen years of age, and also forbidding the sale of cigarettes to minors under that age. A fine of $100 or jail for thirty days is provided for those who adulterate cigarettes.

Japanese Gastroenterological Association.—Dr. J. Takamine and Dr. Max Einhorn, both of this city, have been made honorary members of this Association.

Optometry Bill.—The bill permitting the practice of optometry under certain restrictions having passed the Legislature, a hearing on the bill will be held by Governor Hughes on June 17, before he takes final action on it.

Bequest to St. Luke's Hospital.—The will of Mr. James Morris of Ridgefield, Conn., which was probated last week, leaves $18,000 to St. Luke's Hospital, the income to be used in providing rides for sick children in Central Park. Another bequest of $10,000 is also made to the same hospital, to be added to $6,000 already given, in memory of the testator's son, Marion Gray Morris. The income from this is to provide for the services of a voice to sing hymns in the children's ward. Mr. Morris and his wife had already given $2,000 to provide rides for sick children.

The Eleventh Antialcoholic Congress will be held at Stockholm, Sweden, July 28, 1907. These meetings, held in different cities of Europe during the past few years, have attracted a great deal of attention. The Swedish Government, through its State and Educational Departments, has taken full control of this Congress and formally invited every country in Europe, as well as the United States and Canada, to send representatives and eminent persons interested in and acquainted with the subject. The State Department at Washington has appointed as delegates to this Congress, for the Government, Surgeon-General O'Reilly of the U. S. Army and Medical Inspector Beyer of the Navy, Drs. T. D. Crothers of Hartford, Conn., and T. A. McNicholl of New York City, to represent the medical profession, and Mr. B. A. Hockhart of Hartford, Conn., to represent the temperance organizations and the Swedish people of this country.

International Congress of Psychiatry, Neurology, Psychology, and Nursing of the Insane.—The second provisional program of this Congress, which is to be held in Amsterdam, September 2 to 7, 1907, has been issued and is printed in Dutch, French, German, and English. Detailed information is given regarding the general arrangements for the Congress, the subjects for discussion, etc. The president is Professor G. Jelgersma of the University of Leyden, and the general secretaries are Drs. G. A. M. von Wayenburg, and J. Van Deventer, Prinsengracht 717, Amsterdam.

Boston University Medical School.—Dr. John P. Sutherland, Dean of the Boston University Medical School, has announced that, beginning next year, the course at the school for the M.D. degree will be increased from four to five years.

Dr. I. Boas of Berlin, editor of the *Archiv für Verdauungskrankheiten* and author of numerous works on gastrointestinal disorders, has been appointed to a professorship in the University of Berlin.

American Academy of Medicine.—At its Atlantic City meeting this organization elected the following officers: *President*, Dr. Thomas E. Davis, Pittsburg; *Vice-Presidents*, Drs. James K. McBride, Pasadena, Cal., F. P. Rogers, Providence, R. I., L. F. McMurtry, Louisville, Ky., A. M. Holmes, Denver; *Secretary and Treasurer*, Dr. Charles McIntyre, Easton, Pa.; *Assistant Secretary*, Dr. A. R. Craig, Philadelphia.

South Dakota Medical Association.—At the twenty-sixth annual meeting of this organization, held in Sioux Falls on May 23, Yankton was selected as the next meeting place. Officers were elected as follows: *President*, Dr. L. C. Mead of Yankton; *Vice-Presidents*, Dr. S. A. Brown, Sioux Falls, and Dr. C. R. Wright of Huron; *Secretary-Treasurer*, Dr. R. D. Alway of Aberdeen.

Upper Cumberland (Tenn.) Medical Association.—At the meeting of this Association, held in Carthage on May 30, officers as follows were elected for the ensuing year: *President*, Dr. Sam Denton of Buffalo Valley; *Vice-President*, Dr. J. Howard King of Chestnut Mound; *Secretary*, Dr. L. D. Cot-

ton of White county. The next meeting will be held at Sparta.

Southern Railway Surgeons' Association.—Officers as follows were elected at the meeting of this organization, held in Washington, D. C., on May 30: *President*, Dr. H. T. A. Lemon of Washington; *Vice-President*, Dr. C. H. Starkel and Dr. T. J. Happel; *Secretary and Treasurer*, Dr. J. U. Ray, reelected. The next meeting will be held at Birmingham, Ala.

Arizona Medical Association.—The officers elected at the sixteenth annual meeting of this organization, held in Bisbee on June 30, are as follows: *President*, Dr. A. R. Hickman, Douglas; *Vice-Presidents*, Drs. A. W. Alcott of Tucson, J. E. Drane, Jr., of Mesa, and L. P. Kendall of Jerome; *Secretary*, John W. Foss of Phoenix; *Treasurer*, E. B. Kitcherside of Globe.

Medical Society of Northern Virginia.—At the meeting of this society held in Alexandria on May 23 officers as follows were elected: *President*, Dr. Tunis C. Quick of Falls Church; *Vice-Presidents*, Dr. G. T. Vaughn of Washington and Dr. F. M. Brooks of Fairfax; *Secretary*, Dr. Avery A. Rittenour of Alexandria.

Arkansas State Medical Society.—These officers were elected at the meeting of this organization held in Little Rock on May 17: *President*, Dr. C. C. Stephenson of Little Rock; *Vice-President*, Dr. H. Fink of Helena, Dr. J. L. Butler of Sheridan, and Dr. C. B. Stevens of Magnolia; *Secretary*, Dr. Morgan Smith of Little Rock; *Treasurer*, Dr. J. W. Scales of Pine Bluff.

West Tennessee Medical Association.—This association, at its meeting held in Jackson on May 17, elected the following as officers: *President*, Dr. H. Hawkins of Jackson; *Vice-President*, Dr. F. D. Smith of Memphis; *Secretary and Treasurer*, Dr. A. I. McSwain of Paris.

Montana State Medical Society.—At the meeting of this society held in Billings on May 16 officers were elected as follows: *President*, Dr. W. W. Taylor of Kalispell; *Vice-President*, Dr. J. C. Shaff of Butte, Dr. R. A. Monohan of Butte, and Dr. G. G. Cogswell of Livingston; *Secretary*, Dr. Grace W. Cahoon of Butte; *Treasurer*, Dr. D. A. Donovan of Butte. Butte was selected as the place for the next annual meeting.

Physicians' Club of Chicago.—At its annual meeting, held May 28, the following officers were elected: *President*, Dr. Daniel R. Brower; *Vice-President*, Dr. Edwin B. Tuteur; *Secretary*, Dr. Wm. T. Belfield; *Directors*, Drs. A. C. Croftan, C. L. Mix, C. E. Paddock, and D. A. K. Steele.

Obituary Notes.—Dr. Felix Formento of New Orleans died on June 2, at the age of seventy years. He was born in New Orleans, but was educated in Italy and was graduated from the University of Turin at the time of the movement for Italian unity. He served as a surgeon in the Sardinian Army and received numerous distinctions from both the Italian and the French Governments. He returned to Louisiana in 1860 and was prominent in organizing the army hospital service in Missouri. He was vice-president of the International Congress of Hygiene at Geneva and was the author of several works on military surgery.

Dr. Robert Augustus Marmion, Medical Director, U.S.N., retired, of Washington, D. C., died of apoplexy on June 8. He was born at Harper's Ferry, Va., in 1844, and entered the navy as assistant surgeon at the age of twenty-four years. From 1894 to 1896 he was a fleet surgeon of the South Atlantic Station. Since his retirement in September, 1906, he had lived in Washington.

Dr. J. H. Hammond of Minneapolis, Minn., was found dead of heart disease on June 1 at the age of sixty years. He had practised in Minneapolis for twenty-five years, but of late had been obliged to give up active work on account of ill health.

Dr. William H. Banks of Kansas City, Mo., died on June 1 after a long illness. He was a graduate of Missouri University in the class of 1891. He had practised in Texas and had served as army surgeon in the Spanish-American war. He was born in Columbia, Mo.

Dr. L. A. Fecteau of Natick, R. I., died on June 2, at the age of fifty years. He was a native of Canada and was a graduate of the New York College of Physicians and Surgeons.

Dr. M. D. Baldridge of Batavia, Ia., died suddenly on June 1 at the age of eighty-two years. He was born in Guernsey county, O., but had lived in Batavia for over fifty years.

Dr. George F. Fuerth of Detroit, Mich., died suddenly of heart disease on June 3 at the age of forty-eight years. He was born in Germany and after receiving his degree from the University of Halle practised for some years in Germany. He came to America in 1893 and since that time had practised in Detroit.

Dr. Alonzo Laurence Stickney of Ashburnham, Mass., died on June 4 of heart disease. He was graduated from Harvard Medical School in the class of 1862 and two years later was made assistant surgeon in the regular army, a position which he held till the close of the Civil War. After practising for a time in Sutton, he removed to Ashburnham in 1871 and had resided there ever since.

Dr. N. K. Whittemore of Elk River, Minn., died on May 31 of nephritis. He was born at Temple, Me., in 1848 and had practised in Elk River thirty-four years. For years he was medical examiner of the Government pension board.

Dr. Valentine Mott Francis, formerly of Newport, died June 7 in West Roxbury, Mass., at the age of seventy-four years. He was born in New York and received his degree at the New York University Medical College in 1859. He practised several years in this city and was a life member of the New York Historical Society. He was connected with the Newport Hospital, and was president of the Newport Medical Society and Newport Historical Society.

Correspondence.

THE MILK SUPPLY OF COPENHAGEN

(From Our Special Correspondent)

Copenhagen, May 21, 1907.

As the question of the milk supply of great cities is now being hotly discussed not only in New York, but in many other parts of the civilized world, it may perhaps be of some interest to your readers to hear a little about the way in which this question is solved in Copenhagen.

The quantity of milk sold in Copenhagen has undergone a very considerable increase during the last half of a century. While in 1840 about 3,000 gallons of milk were sold a day, now more than 40,000 gallons are daily consumed. The daily average a head is estimated at 8/11 pints or about four times the quantity consumed by a Londoner. But this increase has only been possible because, as far back as 1878, the milk trade in Copenhagen was arranged according to the strict demands of hygiene. Perhaps the

most remarkable fact regarding this is that private initiative has proved strong enough to revolutionize the milk supply of a great city like Copenhagen and to place it on the high level it now occupies. The merit of having accomplished this feat undoubtedly appertains to the Köbenhavns Mœlkeforsyning (the Copenhagen Milk Supply Company), founded in 1878 by Mr. G. Busck in company with the late Prof. Panum, Drs. Borch and Engelsted, and other prominent men. The guiding principle of the company has been from the very first "pure milk from healthy cows," and later events have proved how right it was in accepting this rule for its work. By unswerving adherence to this principle it has indirectly forced other similar enterprises, since sprung up, to follow in its wake and has thereby conferred an incalculable benefit on the public.

Thirty years ago the milk supply of Copenhagen was in a deplorable state. The milk was furnished by farmers in the environs of the metropolis, feeding their cows on all sorts of inferior fodder, or by distillers of spirits in the city of Copenhagen itself, who kept cows in order to utilize the residual products of the distillation. If the sanitary state of the cows and the handling of the milk in the country left much to be desired, it will easily be believed that it fared far worse with the milk produced within the walls of Copenhagen, where the cows were never let out into the open air, and where some of them were kept in stables in the second stories of houses in the oldest and most crowded part of the town.

No wonder that the milk was nearly always adulterated and most often tainted and infected. In 1876 of 111 samples of cream only two contained the necessary amount of fat, and 24 had been adulterated by the addition of starch. Of 52 samples of sweet milk only 8 turned out to be what they were sold for.

On this dark background the milk supply of to-day stands out in a very flattering light. But I think that a perusal of the precautions taken by the Köbenhavns Mœlkeforsyning will prove this contention better than many flourishes of rhetoric. All the purveyors to the company engage themselves to feed their cows on forage of only the best quality. All cows used in the production of the so-called "infant's milk" are to be submitted to the tuberculm test at least once a year and must not have shown any reaction. All calves reared by the farmers with a view to milk production are also tested with tuberculin.

Before the return to the stable in the fall the tail, the udder, and the hind quarters of the cows have to be shaved.

Seven veterinary surgeons, appointed and paid by the company, ensure the observance by the farmers of these regulations by visiting the farms fortnightly, and they report once a month to the company on the composition and quantity of the fodder, as on the number and state of health of the cattle. They are also empowered to examine the cows as often as they deem it desirable.

The milking has to be done with the utmost cleanliness. During this operation, therefore, every person of the milking staff must wear a special dress, exclusively reserved for this use; he is provided with water and a towel, so that he can keep his hands clean. The lighting of the stable must be so good as to permit the operator to do his work with the necessary care. Immediately after the milking the milk is strained and cooled down to a temperature of 5° C., usually by means of the Lawrence apparatus. At this temperature it is kept until the transport to the railway station takes place.

The milk is conveyed from the farms to the factory of the company in Copenhagen in milk cans belonging to the company and returned daily to the farmers after having been cleaned and sterilized in Copenhagen. The cans hold, as a rule, eleven gallons. The consigner plumbs the cans sent by him with a seal of lead bearing the name of his farm, so that the contents cannot be tampered with. In the summer the milk vans of the farms must be provided with an awning protecting the cans against the sun during their transport to the railway station, where the milk arrives shortly before the departure of the train. The milk cans are then conveyed to the city in special cold storage vans belonging to the State or to the company. The trains arrive at Copenhagen at ten o'clock in the morning and at the same hour in the evening, carrying about 600 cans with a content of more than 6,000 gallons of milk and cream. The cans are weighed and a sample is taken of the contents of every can. The samples are analyzed and tasted by specially trained women experts. If there is the least thing abnormal about the taste of the milk the contents of the can in question are not sold, but used for the manufacture of butter and cheese. The temperature of the milk is also measured and, if found too elevated, the attention of the farmer concerned is drawn thereto.

After this first examination the milk, cream, etc., is passed through a filter of sterilized sand and gravel, cooled down, and put into cans, which are subsequently sealed by the company. From these cans the milk is later on distributed in the various parts of the town, the cream, however, being sold in stoppered bottles of a liter, half a liter, etc., as is also the so-called "infant's milk," intended for the nourishment of babies. This milk is treated with still greater precautions, the milking, for example, taking place into specially constructed milk pails containing a refrigerating apparatus, whereby the temperature of the milk is already considerably reduced during the milking operation. As experiments have shown, this procedure increases very effectually the period during which the milk keeps sweet and unaltered.

The sale of most of the milk is effectuated from the milk vans of the company circulating throughout all quarters of the town and into some of the suburban districts in the vicinity of Copenhagen. With each van go a driver and from three to five boys. The latter distribute the milk in the houses, fetching and bringing the buyers' vessels, into which the desired quantity is drawn off from the cans. The cream and the infants' milk are sold, as before mentioned, in bottles sealed by the company.

In this way an excellent milk supply is furnished to the population of Copenhagen. Notwithstanding the great care given to the article it has not been necessary to raise the price above what was paid before the company came into existence. A pint of the best quality of cream, warranted to contain twenty-nine per cent. fat, costs fifteen cents, while cream with only fourteen to fifteen per cent. of fat may be had for nine cents a pint. The price of a pint of sweet milk is two and one-half cents.

Only a minimal part of the milk is pasteurized by heating it to 85° C. for twenty minutes. Experiments have shown that milk is undoubtedly deteriorated by heating, the enzymes being destroyed, and that even if pasteurization may do away with certain bacteria, as those of typhoid, scarlet fever, diphtheria, tuberculosis, and lactic acid fermentation the bacteria of putrefaction are able to resist the procedure and multiply rapidly afterwards. Such a nimbus adhered, however, to the name of Pasteur, that some years ago there was a certain amount of uncertainty whether it was not better that all milk offered for sale should be pasteurized. But as far as regards Copenhagen, the contest has now come to a close with an undoubted victory for the non-pasteurization side.

THE MILK SUPPLY OF LONDON.

From an Occasional Correspondent.

LONDON, May 20, 1907.

As in New York, so in London, the question of the milk supply is coming to be a matter of interest not only to medical men and sanitarians, but to the general public as well. For long the fact has been notorious that the conditions governing the milk supply of London are defective in very many respects. A certain number of ardent and strenuous sanitary reformers, among whom were some of the metropolitan health officers, have striven to arouse the inhabitants of London to a sense of the dangers to health involved in a more or less polluted milk supply. Up to quite a recent date such efforts have been in vain. However, within the past few months some of the lay journals of London have taken the matter up, and the importance of pure milk is now generally attracting the attention it deserves.

The *Lancet* during the past year has made somewhat of a feature of the milk question, and especially so far as London is concerned. Some six months ago the manner in which milk was retailed in small provision shops in London was dealt with in a fairly exhaustive way. It was pointed out that 80 per cent. of the shops in which milk was sold were small provision shops, and it was also shown that such shops were, as a rule, dirty and unsanitary, and that the sale of milk therefrom was a distinct menace to the public health, and a fruitful cause of infantile sickness and mortality. Since the publication of these articles the lay journals of London have devoted a considerable portion of their space to a consideration of the milk question, and many schemes have been suggested calculated to ameliorate existing conditions. In the articles above mentioned, the methods of railroad transport are discussed, and many interesting facts in connection with this part of the subject are treated in detail.

The last of this series of articles is of local interest, as in it is made a comparison between the milk supply of

London and that of New York. The dwellers in New York consume per capita far more milk than do the citizens of London. London's daily consumption of milk per capita is about 0.20 pint, while that of New York, according to Dr. G. M. Whitaker, is considerably more than half a pint. Consequently, the quantity of milk conveyed by rail into New York exceeds the amount carried into London by similar means of transport. The mode in which the New York milk is transported by rail is compared with the methods of rail transport which prevail in the London districts, the comparison being greatly in favor of the American methods. For instance, no milk is pasteurized or sterilized before being put on the trains bound for London, nor is any milk conveyed by rail in bottles. Indeed, it appears that the custom of bottling milk is almost unknown in London. Again the vans used by the railroads for conveying milk to New York are, generally speaking, much superior to those used to transport milk by rail to London. Although some of the railroad companies which are large transporters of milk to the British metropolis supply specially built and suitable vans, on the other hand, a large proportion of the milk which is carried into London by rail comes in vans badly ventilated, and in many respects ill-adapted for the purpose, while a not inconsiderable quantity of the London milk is brought in on the guards' vans of passenger trains, in company with a heterogenous mass of material, some of which should not be in close proximity to a product so susceptible to pollution as is milk.

The writer of the *Lancet* article expresses the opinion that what can be done towards insuring a fairly pure milk supply in the State of New York could be done in England. At any rate, it is stated emphatically that milk cans, before they leave the dairy farms from which they are sent, should be locked or sealed, and that the number of special milk trains should be increased. The suggestion is also advanced that refrigerating methods should be brought into practice in England by the railroad companies when conveying milk. Finally, the advice is given that the London County Council should look into the American system of milk stations on the railroads, where milk is received from the farmer of the locality, kept in a proper manner, handled in a proper manner, and placed in a proper manner upon the special trains. It should be flattering to the New Yorker's self esteem that London should wish to take example from this city in regard to modes of milk control. The contributor to the *Lancet* is well acquainted with the conditions governing the milk supply of both New York and London, and he states that the milk supply of New York is better managed in nearly every respect than is that of London.

The British medical and sanitary authorities are, as a rule, opposed to the pasteurization and sterilization of milk, believing that a pure and nourishing milk can be better obtained by paying close attention to the sources of supply, means of transport, and sanitary measures in general than by relying on pasteurization or sterilization. Until such methods have been brought into general use, it would appear to the unprejudiced observer that pasteurization or sterilization, although undoubtedly of the nature of makeshifts, are better than serving milk which is dirty or germ laden. The hopeful feature of the situation is that in both New York and London, and in fact in all large cities of America and of Great Britain, the public conscience is becoming aroused to a keener sense of the menace to life, and to child life in particular, of a polluted milk supply.

OUR LONDON LETTER.

From Our Special Correspondent.

THE ALCOHOLIC STATEMENT—FRACTURES OF ODONTOID PROCESS—HEALED ULCER AFTER GASTROENTEROSTOMY—DURATION OF WIDAL'S REACTION—PRECOCIOUS OBESITY—VIVISECTION, REPORT, AND DEBATE—ITEMS—OBITUARY, SIR JOSEPH FAYRER, DR. GROVES, J.P.

LONDON, May 24, 1907.

THE seed sown by the statement on alcohol, about which I wrote to you last month, continues to produce an abundant crop, but I think the nature of the harvest must be a source of regret. The sixteen signatories, articles, correspondence, and advertisements in the newspapers, of course, were to be expected as the first fruits. Now follow on circulars of all shapes, containing assertions of varying degrees of credibility as to the views of the medical faculty, backed up by facsimiles of a page of the *Lancet* and similar reproductions, all of course intended to impress the recipients with the value of alcohol, whether as wines, beers, or spirits. I hope the sixteen gentlemen who signed the joint statement get even a larger number of these circulars than have encumbered my letter box, that they may be aware of the extent to which their names are being advertised by "the trade" as the leaders of medical opinion. They need not then have to visit taverns, where their statement is exposed, to convince themselves of the use to which it is being put and to open their eyes to what they must have been blind not to see when they signed their testimonial. They are "all—all honorable men," and the wonder is that the perspicacity with which it is natural to credit them did not save them from committing themselves to such a document. If a few general practitioners had done so what would have been said? It is now generally admitted that a person "in the interests of trade," not a doctor, originated the scheme, and was successful in obtaining the sixteen signatures. The exact manner of his procedure is not worth inquiring into.

Mr. E. M. Corner has devoted great attention to fractures of the odontoid process of the axis, and examined the specimens in all the museums of these islands. From his study of these and the records of all the histories obtainable of fatal and non-fatal cases he has contributed a paper to the Royal Medico-Chirurgical Society. He says there is no reason why a patient who has sustained such a fracture should not recover without any spinal symptoms; in fact, with nothing more than a painful, stiff neck. In such a case there would seem to be more danger from overlooking the fracture than from the injury itself. That was the happy side of the clinical picture; the other was instant death if the injury were overlooked. In fact, these fractures fell into line with what he has shown to be the case in other fractures of the upper cervical spine, viz.: that the patients may suffer only a painful stiff neck. He, therefore, concluded that all injuries of the neck should be skiagraphed and examined by a skilled radiographer, for it is very easy for an unskilled observer to overlook the injury. The skiagraph should be taken through the open mouth.

Mr. Warrington Howard remarked on the importance of recognizing the possible consequences of such an injury, for a patient might fracture his odontoid process and, feeling no more discomfort than a few days' stiffness of the neck, might go about his ordinary work for months and then die suddenly. Two such cases had occurred. He also referred to a case of extensive disease of the odontoid process without any symptoms except wryneck. The patient was a child and recovered, but tuberculous meningitis came on, and at the post mortem the process was represented by a mere spicule of bone. The moral was to have a skiagraph taken, and preferably through the mouth.

Dr. A. J. Whiting remarked on the contrast between these cases, whether there was instant death or practical immunity of the spine, at any rate for a time, and cases of fracture—dislocation of the lower cervical spine, which usually produced complete paralysis of all four limbs and of the sphincters, though life of a sort continued for months, so that the patients with the upper injury seemed better off. Probably the transverse ligament of the atlas protected the upper vital part of the cord. The absence of symptoms was no reason why sudden death should not supervene at any time.

At the Clinical Society, on Friday, Mr. Sherren gave an account of a case of gastroenterostomy for chronic ulcer, in which healing was verified at the post mortem twenty-eight months after operation, the patient having at that date become melancholic and cut his throat. The anterior operation with no loop was done, the posterior being impracticable on account of adhesions. There was a large ulcer on the lesser curvature. At the post mortem the operation opening admitted two fingers and the pylorus was patent. Microscopical examination showed the healing was complete. Mr. Sherren commented on the good results of gastroenterostomy even when the ulcer was distant from the pylorus, so that excision was not the operation of choice even in such a case.

Mr. Clutton, president, asked if Mayo's method of fixing the jejunum so as to make it lie from left to right had been adopted. He had used it for the past eighteen months. Mr. Sherren replied in the negative; he had tried the plan in some cases, but had given it up.

Drs. H. French and G. Louisson read a paper on the time that Widal's reaction persists after typhoid. They had traced 135 patients who, while in hospital, had given the reaction—the standard being clumping within half an hour in a dilution of 1 in 200. The test was repeated after the illness at periods from two months to ten years. They obtained in 7.5 per cent. complete reaction, in 22.5 per cent. incomplete, and in 70 per cent. none. The interval after the illness made little difference, and it almost seemed as if when cases persisted they did so indefinitely—several lasted eight years. The president said he had found the bacilli in some complications three years after the fever,

and Dr. French replied that he had not examined for bacilluria. Perhaps the persistence of bacilli and agglutinative power were correlated.

A paper on precocious obesity and hirsuties with hypernephroma, by Drs. Guthrie and Emery, described the case of a boy at four and three-fourth years, thirty-six inches high, weighing over four stone. After death, from pulmonary tuberculosis, the hypernephroma was found on the left side. The second case was a girl of three and a half years, thirty inches high, weighing thirty-seven pounds. In both cases the pulse was intermittent and the intelligence good. Other cases were mentioned by several speakers; some with great muscular development (the informal Hercules type), others only obesity and hirsuties. Hyperphroma was not always present.

The Vivisection Commission has issued a second report containing the evidence taken in February and March. Among the witnesses examined were Mr. Power, C.B., Chief Medical Officer of the local Government Board; Professor Cushing, F.R.S., Sir Douglas Powell, Bart., President R.C.P., and Dr. F. Taylor. These represented sane medical opinion. In opposition, Miss Kenealy and Mr. Graham offered the usual prejudices of the antis. On Tuesday the antis achieved a sort of success by having induced Professor Halliburton to condescend to engage in a public debate with one of their lecturers. Notices of the matter were, of course, secured in the newspapers the next day, and those who think guinea-pigs, rats, and other creatures ought not to be sacrificed in the interests of humanity have started a few more "horrors." The ladies who assembled to support their champion showed what they were by shouting "brute!" when the name of Lord Lister was mentioned. Such ignorance and prejudice will scarcely be enlightened by the facts put forward by Dr. Halliburton or any amount of scientific reasoning.

Cases of cerebrospinal meningitis continue to occur in various localities. One was reported last week in Nottingham, which had not previously been invaded. The origin of the infection has not been traced. Manchester, Wrexham and Pilsby report cases, and eighteen deaths were registered in Scotland during the week.

Dr. E. C. Seaton, M.O.H. for Surrey, in his annual report considers the causation of typhoid in the country in 1895-1906, and concludes that polluted and infected foods are more frequently the cause than water supply. He is doubtful whether 10 per cent. of the cases can be due to water infection.

The Edalji case has at length been decided. Acting on the recommendation of the committee he appointed to consider all the circumstances, the Home Secretary has recommended His Majesty to grant a free pardon, as the committee considered the prisoner had contributed by his own foolish letters toward his conviction. The Home Secretary decides that it is not a case for compensation.

Sir Joseph Fayrer, Bart., K.C.S.I., etc., died on Tuesday, full of years and full of honors. He had been ailing for some time, but his indisposition took a grave turn ten days ago and he passed away, in his eighty-third year. He began medical study in the Bermuda Naval Hospital and continued in various schools, British and Continental. In 1847 he took M.R.C.S.; the Fellowship in 1878; in the meantime having taken the Edinburgh M.D. and Fellowship and then elected F.R.C.P. Lond. At the age of 23 he was assistant surgeon on H.M. ship the *Victory*, but two years later he transferred from the naval to the army service, and after a year in that to H.E.I.S. His Indian career thus begun in 1850 and continued to 1874, when he returned to England as Surgeon-General and was made President of the Indian Medical Board. From this time he had a position as a leading consultant in London until 1904, when he retired to Falmouth, where he died. He filled, as it were, three careers, viz.: military surgeon, university professor in Calcutta and administrator and consultant in London. As a military surgeon he saw field service in 1847 as a volunteer in the hospitals during the sieges of Rome and Palermo, three years later in Burma and the capture of Rangoon. He was next appointed to Lucknow, and was senior medical officer there during the siege. Later on he was at Cawnpore. For his services in the mutiny he was promoted and received the thanks of the Governor-General in Council. In 1858 he came home on sick leave, and on returning to India was appointed professor of surgery at the University of Calcutta, of which he afterward became president of the medical faculty and served on the senate and in various other positions in the university school and the hospitals. He accompanied the Duke of Edinburgh during his tour, and later went to India once more with the King, then Prince of Wales. He had been appointed Honorary Physician to the late Queen Victoria, and the King, on his ascension to the throne, made him Physician Extraordinary. His scientific work had secured him the Fellowship of the Royal Society and that of many other medical and scientific organizations, the presidency of several being offered him. Edinburgh and St. Andrew's universities conferred their honorary LL.D. His son Joseph, who succeeds to the Baronetcy, is Lieutenant-Colonel in the R.A.M.C. He leaves three other sons and a daughter. His writings were numerous on many departments of Indian medicine, surgery, toxicology, and climates. His "Thanatophobia of India" appeared in 1881, and must be known to you, as must many of his contributions to tropical diseases. In 1897 he wrote the life of "Sir Ronald Martin," and in 1900 "Recollections of My Life."

Dr. Joseph Groves, J.P., Medical Officer of Health for the Isle of Wight, Rural District, died on Tuesday, in his sixty-eighth year. He was a Kings College student and graduated at the London University, B.A., 1859; M.B., 1867. He also took the L.R.C.P. the next year. In the 1866 epidemic of cholera he acted as M.O.H. in the Second District. For twenty years he had held his office in the Isle of Wight. He wrote an account of that district as a health resort, and also a work on the "Treatment of Insanity." He had been President of the Society of Medical Officers of Health.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

DISAPPEARANCE OF CHOLERA—SEWERS AS BREEDING PLACES FOR MOSQUITOS—TYPHOID FEVER—BERIBERI—RELAXATION OF QUARANTINE RESTRICTIONS—PERSONAL.

MANILA, April 15, 1907.

A CAREFUL review of the available data on hand at the present time would seem to indicate that cholera has entirely disappeared from the Philippine Islands. A few scattered cases are being reported from northern Samar, the province of Capiz, and the province of Occidental Negros. The total number of cases and deaths, however, does not amount to more than approximately five cases per week. The Bureau of Health has made repeated efforts to obtain specimens for laboratory investigations from such cases, but generally only one case occurs in a locality, and the places are so remote that before a person competent to make a microscopical examination can arrive on the scene, the person is either dead or has recovered. From the fewness of the cases and the entire lack of any spread of the disease, it would seem that the diagnoses of cholera are extremely problematical, especially in view of the fact that the various forms of poisonings of the ptomaine order, caused by eating decomposed fish and others foods in which virulent poisons are frequently encountered, are so common, it would seem that such cases are not cholera, but are due to the poisons mentioned above.

The extensive excavations which are being made at the present time in the city of Manila for the purpose of installing a new sewer system have thrown considerable light upon the failures of the campaigns conducted by the Bureau of Health in the past against mosquitos. At certain seasons of the year, notably in the dry season, it has been practically impossible to free even such a well paved section of the city as the walled city from mosquitos. The conclusion was almost reached that unless the walled city could be freed from mosquitos with comparatively small outlay, that it would be practically useless to attempt a general mosquito eradicating plan in the islands. Owing to the failure of the repeated efforts of the Bureau of Health, the question of mosquito extermination outside of Manila has not received much attention during the past year. It seems now that this matter is satisfactorily explained by the slow velocity of the water in the storm sewers in the walled city. In the rainy season, contrary to expectations, the walled city is almost entirely free from mosquitos. This is explained by the fact that large quantities of water pass through the sewers in this time of the year, and the velocity of the current is such that mosquitos are unable to breed; whereas, in the dry season, no water entering the sewer, the current becomes more and more sluggish, until finally the flow ceases altogether and only a series of pools remain, which are due to the inequality of the levels of the the drain. Such pools offer excellent breeding grounds for mosquitos; in fact, large numbers of wigglers have been found in the sewers. Many of the present storm sewers will be relaid with better levels, and it is probable that some relief may be expected in the future. The new sewer plans, however, do not contemplate any extensive changes in the storm water sewers, the new system being only for house drainage.

Typhoid fever seems to be obtaining a firmer foothold in the Philippines than has heretofore been the case. As the changes which ordinarily accompany an introduction of increased civilization are being more and more introduced in these islands, it is becoming more apparent that this disease is constantly affecting more persons. At the present time the construction of the new railroads in the islands is responsible for the gradual introduction of typhoid in many places at which it has not been encountered heretofore. Fortunately, so far, the disease has apparently been due to direct importation, it having occurred almost entirely among Americans and Japanese who have only recently come to the country, and either arrive in the incubation period or have ingested infected foods obtained in the countries from which these new arrivals come. At the present time, at the railroad hospital at Cebú, there are three cases of typhoid, and about twenty-five cases have occurred in Manila during the past month. It seems probable that the reasons why typhoid has not spread more heretofore in the Philippines are not so much because of the tropical climate, but because the ordinary vehicles by which the disease spreads have not been present. For instance, it is only a few years since milk of local production has been used in the islands; there were practically no general water distributing systems or reservoirs; in the absence of sewer systems it was practically impossible to infect places in which oysters and other shellfish grow; and the comparative absence of flies during the greater portion of the year are all explanations as to why there has not been a more general spread of the disease heretofore.

Beriberi, which a few years ago seemed to defy all efforts toward its eradication among persons connected with the light house service, and more particularly among employees who are engaged at isolated houses, seems now to be thoroughly eradicated. The measures taken consisted in adding more meat to the ration issued, and insisting upon making of rigid rules with regard to employees eating with knives, forks, and spoons instead of with their fingers. Which of these two measures is responsible for the disappearance of the disease is not actually known, but from the favorable experience at the Culion Leper Colony, where a serious outbreak occurred, and which was not arrested until an increased proportion of meat was added to the diet, would seem to indicate that in spite of the assertions of laboratory workers that the cause is not to be found in the diet, that this form of treatment is an important element in its eradication.

Owing to the very favorable condition of public health in the islands, the quarantine restrictions are to be still further reduced. Hereafter all vessels engaged in inter-island trade will not be required to obtain bills of health, beginning May 1, 1907. If the present favorable conditions with regard to public health continue, it is understood that still further restrictions will be removed in the future.

There has been no case of plague reported in the Philippines since April, 1906.

Dr. George D. Fairbanks, who has been connected with the Bureau of Health since 1903, and who, during the past two years has been house surgeon at the Civil Hospital, has resigned his position and will return to his former home in Texas.

Progress of Medical Science.

New York Medical Journal, June 1, 1907

Eyestrain in School Children.—W. S. Cornell has made a study of this subject as concerns school children in Philadelphia. In 1,156 children he found normal vision in 66 per cent. The test consisted simply in distance vision with the Sneller types with the best natural light obtainable. Of the 34 per cent. of defectives about 6 per cent. had only one-half normal vision or less. About 70 per cent. of the defectives were not wearing glasses. This state of affairs is due, he thinks, first, to the medical profession who ignore the fact that the vast majority of reflex headaches in children are due to eyestrain, and who ignore the round-shouldered delicate children, making no systematic effort to find out the cause of their condition; second, to the teaching profession whose knowledge of anatomy and physiology is unpractical. They spend much time in telling the children about the effects of alcohol on the stomach and liver and almost no time at all in looking out for departures from normal of the needful sense-functions, and third, to the parents who assume an attitude of indifference and resentment. Cornell finds that girls suffer more than boys from eyestrain and that there is a direct relation between poor vision and scholarship.

Pyocyaneous Ulcer of the Cornea.—P. Fridenberg reports the case of a girl of sixteen years who had been staying at the seashore and who, after an automobile ride, complained of irritation and some pain in the right eye. An ulcer appeared the next day, which, in spite of all treatment, completely destroyed the cornea. Scrapings from the cornea and the contents of the conjunctival sac revealed a pure culture of the *Bacillus pyocyaneus*. The interesting features of the case are first the lack of any determinable injury. Pyocyaneous infection is generally traumatic in origin, the injury having been inflicted with a soiled weapon or with dirt. One would hardly expect to find the *Bacillus pyocyaneus* far removed from crowded habitations, out doors at the seashore. The bacillus was found in pure culture, and the matter from both ulcer and conjunctival sac was otherwise sterile. In spite of this, there was nothing characteristic in the local conditions. The ulcerated area was a dirty gray. There was no green discoloration whatever which might have led us to suspect the nature of the pathogenic organism. The course of the ulceration was rapid and malignant. There was no perforation; the cornea became entirely shrunken and opaque and then gave way to intraocular pressure. After the development of the ulcer there was no pain. The patient did not feel the cauterization with pure tincture of iodine, ordinarily quite painful, and had little or no discomfort, even from the application of the actual cautery.

Morphological Diagnosis of Pathogenic Protozoa.—J. Ewing notes that the great point of disagreement among zoologists is not so much with reference to the existence of a certain protozoon, but with reference to the right of certain intracellular bodies to be included in the cycle and the relations of one set of forms to another. This matter has come up especially in the search for protozoa in cancer, rabies, and the exanthemata. The mere recognition of protozoa may be an easy matter, but the identification of cellular degenerative products is most difficult. Ewing's object is to urge that serious dangers are inherent in the mere morphological diagnosis of protozoa in diseased human tissues, and he declares that the collateral evidence must be favorable before new and very peculiar protozoa can be established as the cause of disease. The great danger surrounding the morphological diagnosis of protozoa in human tissues lies in the fact that in many diseases, some of bacterial origin, intracellular processes give rise to structures closely resembling protozoa. This fact is then presented by the author with reference to variola, scarlatina, measles, rabies, glanders, and cancer. He says that collateral evidence is almost conclusive against the protozoan origin of malignant neoplasms since no parasitic invasion can explain the autonomy and organoid character of many tumors and there is no parallel protozoan disease anywhere in the animal or vegetable kingdom. The present state of our knowledge points to the conclusion that the virus of variola and rabies and possibly of measles is intimately connected with the tissue proteids which form the bulk of the specific cell inclusions of these diseases, but is itself of a nature not yet understood and not yet paralleled among known protozoa.

Journal of the American Medical Association, June 8, 1907.

Prostatitis.—E. G. Ballenger bases his paper largely on the facts observed or confirmed by the study of over one hundred prostates. More than half of these were chronically inflamed and nearly one-third of them were normal. He devotes special attention to the chronic inflammations, in nearly 80 per cent. of which the patients gave a history of a previous gonorrhea. In one of his patients were found large numbers of colon-like bacillus in the prostatic secretion, but no gonococci. The average age of the patients was 30, the ages varying between 19 and 50 years. Ballenger's experience leads him to believe that in the majority of patients chronic prostatitis and seminal vesiculitis are insidious, the patient being unaware of the fact that his prostate is involved. He concludes his article as follows: "The prostate gland is without doubt the cause of the majority of obscure urinary and sexual symptoms, and should always be examined where there is any uncertainty as to their origin. Among the factors that tend to perpetuate a chronic or recurrent gonorrhea a nidus of infection or irritation in the prostate is the most frequent cause. It is in this variety of prostatic inflammation that the largest number of errors are made in the diagnosis. Palpation, pus and proteid are the three things to rely on in reaching a conclusion as to the condition of the prostate. By palpation through the rectum the gland, if diseased, may be found enlarged, nodular, irregular, boggy, or apparently normal. Pus in the secretion expressed from the meatus or found in the urine or fluid voided after massage, when

the urethra and bladder are excluded as possible sources, is positive proof that the prostate is inflamed. Proteid in the fluid passed after massage is equally as reliable as pus in the diagnosis of prostatitis.

The Diagnosis of Pyelonephritis.—E. Beer publishes the histories of two cases which seem to point to a new diagnostic sign of the involvement of the kidney parenchyma. In the first case the patient discharged methylene blue stained pus in the urine at intervals up to two and three-fourths years after the last administration of the drug. The second patient had pyelonephritis (verified by nephrotomy), and had recurrent discharges of methylene blue stained pus over a month after the last administration of the drug. He is of the opinion that the pigment is fixed in the pus in great part, if not wholly, in the leuco form, and that its presence in the abscesses is the result of the excretion of the renal epithelial cells. He produced a pyelonephritis in a dog and then for several days administered methylene blue. The kidney was removed two weeks later and, after treatment with oxidizing agents, showed multiple bluish-gray pus foci throughout its substance. He summarizes his conclusions derived from the facts so far as follows: 1. There is no differential diagnostic sign between simple pyelitis and pyelonephritis. 2. Pyuria from the upper urinary tract may be due to either of these conditions. 3. By the use of the above described methylene blue test it would seem that a differential diagnosis may be made. 4. Methylene blue is deposited in the parenchymatous abscesses and may be stored in these for years. 5. A late discharge of methylene blue, bound to the pus, is indicative of the rupture of such parenchymatous abscesses into the pelvis of the kidney and is consequently diagnostic of pyelonephritis.

Meningococcus Septicemia.—C. E. Simon reports a case of meningococcus infection in which the organism was found in the blood, the eighth on record and the first in which it could be demonstrated directly in the blood smear taken from the ear. There was a very high grade of leucocytosis—50,000 as a conservative estimate, and an estimated ratio of 7,380,000 per cubic centimeter of blood. A noteworthy feature was that the large mononuclears were engaged in phagocytosis almost as much as the polynuclears, and their increase, both actual and relative, was especially worthy of note. In his former differential counts in meningococcus meningitis cases there was always a marked polynucleosis with low mononuclear values. The previously published cases in which the meningococcus has been found in the blood are reviewed, and Simon hints that this is possibly explained by the rarity of blood examinations that have probably been made, and advises, since negative findings in the meningeal fluid are not unusual, that the blood be also examined in all doubtful cases. Culture methods with bouillon, blood serum, hydrocele agar, and blood agar should be employed. He hardly thinks his own method with blood smears as likely to be successful.

The Lancet, May 25, 1907.

Hypopharyngoscopy.—P. T. Hald enumerates the various divisions of the pharynx and points to the matter of inspecting its laryngeal portion and especially that portion behind the lamina of the cricoid cartilage. Various methods of passing instruments into this section have been in vogue for a long time, but all have their disadvantages and even dangers. The author has therefore been led to follow the plan devised by von Eicken of Freiburg. The patient's fauces, root of the tongue, and larynx are cocainized, he sits in a high chair while the examiner kneels before him. Then a stout laryngeal probe is introduced through the rima into the subglotic space and the larynx is pulled forward and upward, the proximal straight part of the probe resting against the upper teeth, so that it acts as a lever. In the mirror it may then be observed that the larynx is drawn from one and a half to two centimeters away from the posterior pharyngeal wall, the two pyriform recesses joining in a common cavity. Often a facetting of the lamina of the cricoid is visible through the mucosa, laterally to a median prominence. Occasionally it is observed how part of the mucosa loosely extended over the lamina of the cricoid cartilage and its muscles becomes drawn out to a fold stretching backwards when the larynx is lifted away from the posterior pharyngeal wall; when the pull becomes stronger the fold disengages itself from the posterior wall of the pharynx and sinks back to a level with the rest of the mucosa on the lamina of the cricoid. Occasionally the author has been able to see the gullet open up during respiration and has been able to inspect its upper portion.

Two Cases of Pulmonary Regurgitation.—Detailed clinical histories of the cases with post-mortem findings are given by D. B. Lees and V. Z. Cope. Case one was one of infective endocarditis affecting only the pulmonary valves and occurring in a single woman of twenty-four years. Case two was that of a man of thirty-nine years with an aortic aneurysm which ruptured into the pulmonary artery and caused regurgitation. The authors make an analytical study of ninety-nine recorded cases. In fourteen of these the incompetency was due to an aortic aneurysm rupturing into the pulmonary artery and causing the valves to adhere to the walls of the artery. The lesion is said not to be very uncommon. The diagnosis was made difficult by the accompanying aortic regurgitation. The presence of an aneurysm was regarded as certain, but the extraordinary nature of the sounds, both as to intensity and continuity, made those who saw the case confident that there was something in addition to aortic incompetence and this lesion. The suggestion was discussed as to whether the aneurysm had broken through into the pulmonary artery, but no certain conclusion was arrived at on this point. During life the pulmonary incompetence was not differentiated from the accompanying aortic regurgitation. In this case also there was a distinct history of a sudden muscular overexertion. The patient was a heavy smoker, but the authors are not prepared to say how much of a factor this habit was in this special case. They note that infective endocarditis of the pulmonary valve is most frequently of gonorrheal origin, though in their own case (case one) this fact could not be demonstrated.

Acute and Chronic Appendicular Pain: Medical and Surgical Treatment.—A general consideration of this subject is made by Saint-René Bonnet. He gives the histories of (1) a typical case of chronic appendicitis without mucomembranous enterocolitis cured by medical treatment alone, (2) a case of mucomembranous colitis in the course of which painful secondary reflexes arising from the appendix quite disabled the patient and called for surgical intervention, and (3) a case of chronic mucomembranous enterocolitis in the course of which acute appendicular pain, due to a supervening cause—a large appendicular calculus—necessitated operation, which was successful. The author calls attention to the following causes which have induced medical men to restrict surgical treatment: (1) in the course of operations, the appendix has often been found to be quite normal or only slightly involved. It seems, therefore, quite difficult to consider it the cause of the trouble which had necessitated the operation. (2) Sometimes when the appendix, whether healthy or not, has been removed, chronic pain persists just as before; even fresh attacks similar to that of relapsing appendicitis occurs. (3) In spite of the general tendency to resort to surgical treatment, there are many cases where the symptoms seem to point to a fatal termination, but in which, however, recovery is obtained without surgical interference. (4) These strictly medical cures assume greater importance when the results of operating during the acute period of the affection, with all the risks it entails become better known. These facts at first puzzled both physicians and surgeons, but most of them were explained when careful studies of the morbid syndrome, now so frequently met with and which is called mucomembranous enterocolitis, were made, the intestinal symptoms of which may be thus tabulated. The author states that in well-characterized mucomembranous enterocolitis we find chronic constipation with or without occasional attacks of diarrhea; diarrhea, which may become chronic, and is observed in the place of chronic constipation more than is generally supposed; spasmodic contractions of the large bowel which alternate or coexist with dilatation of one or more of its portions; persistent pain which becomes intense during the acute periods of the affection; passage of mucus and casts with occasional intestinal hemorrhages, and in some cases abundant evacuations of intestinal gravel. He adds that there are two important signs which must always be kept in mind, for they are practically never absent. Firstly, when paroxysms of mucomembranous enterocolitis are localized or predominate in the right iliac fossa at, and around, McBurney's point, they present symptoms which may resemble exactly those of an acute attack of appendicitis, and when there are no acute paroxysms of the disease there may be persistent pain which simulates that of chronic appendicitis. As in true appendicitis, the pain, whether acute or chronic, is of a shooting, stabbing, or colicky character, or is replaced by a more or less marked sensitiveness in the right iliac region. This pain is increased by movement. Secondly, experience teaches that when in the course of supposed acute appendicitis or of chronic appendicular pain, mucous casts are passed in the stools the physician is bound to feel entirely reassured as to the nature of the trouble, and is enabled to give a good prognosis.

British Medical Journal, May 25, 1907.

Sudden Death at the Climacteric.—E. Pratt reports the case of a woman of forty-five years to whom he was hastily summoned, but who was found dead on his arrival. Inquiry developed the fact that inside of two hours she had "felt queer," vomited, was faint, and one hour or so later the hands suddenly clenched, the face grew dusky, nails were discolored, she felt very cold, became unconscious, gave three blowing expirations, and then seemed as if dead. For the previous year she had suffered from occasional severe headache; for the last six months she had been subject to "fainting turns," with frequent retching, such attacks lasting half an hour to an hour, when she would be all right again; the attacks always occurred early in the morning. The frequent flushes and cold sweats of the climacteric were experienced, and irregular catamenia, of late every two weeks or so, not much loss, but extending over a longer period than normally. The last menstrual period was a week previous to the fatal attack. She was a healthy, cheerful, bright, and happy woman. She had borne seven children, five now living. Her father died suddenly at the age of sixty. The autopsy revealed nothing, all organs and structures being normal, with no signs of internal hemorrhage or of poisoning. The author notes that attacks similar to those just mentioned are common enough at the climacteric, but he believes that such an attack originating in the genitalia might so act reflexly that the balance would turn toward death instead of loss and recovery. He gave, at the inquest, as the cause of death "asthenic syncope," and has been unable to find any record of an exactly similar case.

Tubercle and Erysipelas.—C. B. Whitehead reports the case of a three-year-old child with enlargement of the neck glands. The group chiefly affected was the posterior cervical and there was no difficulty in diagnosing an ordinary tuberculous adenitis. There was no improvement after a month's medicinal treatment, together with the application of a liniment containing potassium iodide; in fact, one of the glands near the surface seemed to be softening rapidly, so that he decided to remove them. The operation, however, had to be postponed, as the child suddenly developed an attack of facial erysipelas, which started just over the most prominent part of the glandular swelling; possibly the micrococcus gained entrance here through some abrasion caused by the rubbing. The erysipelas pursued a favorable course; it spread all over the face, the only bad symptom being albuminuria, which did not last long. The interesting point was that during the attack the enlarged glands, which formed a very prominent tumor, entirely disappeared.

Unnoticed Lateral Curvature.—W. J. Somerville says that he has been surprised to find how seldom deformities of the back are recognized by the family physician unless his attention is called to the condition by the patient's mother. Frequently, he says, he is consulted by a mother in regard to some faulty attitude on the part of her daughter or son, on account of "one shoulder drooping," "both shoulder blades prominent," "one hip sticking out," etc. On examination a lateral curvature of the spine is easily discovered. Too frequently the deformity is so marked that a cure is impossible, the bodies of the vertebræ having become altered in shape. Had such a child been properly treated, say at eight or nine years of age, when the slight deformity was due to simple muscular weakness, the gross and permanent deformity might have been avoided. Again, he is occasionally told by mothers that when the doctor had been spoken to on the subject his reply was that the child would "grow out of it." Whoever, he asks, saw a child "grow out" of a lateral curvature without careful and appropriate treatment? As an alternative a poroplastic jacket is frequently suggested. But this, by freeing the spinal muscles from responsibility and movement, simply encourages the deformity to become more marked. He would, therefore, venture to urge the profession to be on the lookout for "a drooping shoulder," chiefly the right, and when this is observed, to ask permission of the mother to expose and examine the child's back. In nine cases out of ten it will be found that a lateral curvature exists. Suitable medical gymnastics under medical supervision, and not merely under the care of an unqualified man or woman, will, as a rule, cure early cases, or will, at any rate, either lessen the deformity or deprive it of its more obvious and conspicuous proportions.

The Microorganism Isolated from Acute Rheumatism.—This question is reviewed by E. W. A. Walker, who dwells particularly on the relation of this particular streptococcus to the other members of the streptococcus group. His own studies refer particularly to a group of fifteen rheumatic cases from ten of which a constant streptococcus was obtained in pure culture. In two cases the original cultures were contaminated with *Staphylococcus albus* from the skin and in the other three cases, which were post-mortem specimens, with a motile bacillus judged to be the *Bacterium coli*, but this fact was not worked out in detail. In eight of the cases the organism was isolated during life, while in the remaining seven it was found in the heart's blood post mortem. Experiments on animals, details of which are given, produced the morbid lesions of rheumatism. The differences in culture, behavior, etc., from other streptococci are given, and it is worthy of note that while this special germ produced invariably fever and acute arthritis, and occasionally in addition peri- or endocarditis, or both, and in large doses a fatal result, it never produced pyemia or pyemic abscesses as is frequently the case with ordinary streptococci. Summarizing then his own results and those of other observers, he notes that this organism has been isolated in pure culture from subjects of the disease, both during life and on post-mortem examination, by a succession of observers on a relatively large number of occasions; that it has been seen microscopically in rheumatic lesions—in the synovial membrane of joints in the cardiac valves, and in the meninges in cases of acute rheumatic chorea; and that it was both seen in a rheumatic nodule, and cultivated from it in pure culture by Paine and Poynton. On injection into animals it produces morbid lesions similar to those of acute rheumatism. It has the appearances and general cultural characters of a streptococcus. But it produces in considerable amount an acid, formic acid, which is not known to be produced in like amount by streptococci from any other source. And this appears to afford a specific distinction. Walker notes some objections to the acceptance of the causal theory of this particular organism. It has not been found by all observers. It has been suggested that the organism was either a contamination or a terminal or agonal infection or a secondary infection, but against the latter theory is the fact that the organism has been isolated during life. It has been further suggested that the organism was the occasion of a secondary infection superposed on the rheumatism. This view, says the author, is conditioned on one's conception of what true rheumatism consists in. In general, he regards the case in favor of the organism as not yet absolutely proven.

Berliner klinische Wochenschrift, May 20, 1907.

Oxygen Baths.—Franze and Pohlmann report the results obtained by the use of oxygen baths prepared according to the method suggested by Sarason. To prepare such a bath 300 g. of sodium biborate is dumped into the tub containing the water at the desired temperature. A small quantity of borate of manganese, as catalyzing agent, is then sprinkled over the surface of the water. The formation of oxygen begins in from one to three minutes and lasts for about a quarter of an hour. Shortly after entering the tub the surface of the bather is covered with extremely small bubbles of oxygen, and black flakes of manganese peroxide are precipitated and settle on the skin, but these are readily wiped off. The authors used the baths for six patients, who received thirty-five treatments. Two of the patients were in normal health, three suffered from heart lesions of various sorts, and one suffered from neurasthenia. In all cases there was a reduction of blood pressure and of the pulse rate. Four additional baths were given to two patients suffering from arteriosclerosis, but were not well borne, the already high blood pressure was much elevated, and dyspnea, palpitation, and subjective discomfort compelled abandonment of the treatment. The authors consider that the oxygen bath is not a suitable substitute for the carbon dioxide bath, but that it is likely to be of value in the treatment of neurasthenic patients, in certain forms of heart disease accompanied by irritability, and in painful neuritic affections. It should be used with care, however, if arteriosclerosis exists.

Presence of Spirochæta Pallida in Physiological Secretions of Persons Affected with Hereditary Syphilis.—A. Pasini demonstrated the presence of *Spirochæta pallida* in the epithelium and lumen of the alveoli of the lungs, the bronchi, the convoluted tubules of the kidneys, and the sweat glands in two babies subject to hereditary syphilis, but showing no manifestation of it at the time of death. He believes that *Spirochæta pallida* has the power of penetrating the epithelia of various organs during life by means of active movements. The cells penetrated then undergo degeneration. The author concludes that the sputum, urine, and sweat of the hereditary syphilitic may contain the spirochetes, even when the organs present no manifestations of the disease. It seems logical to deduce from these facts that the secretions of these organs are contagious.—*La Riforma Medica*

Book Reviews.

Diagnose und Therapie der Anämien. Nach funktionellen Gesichtspunkten auf Grundlage qualitativer Blutuntersuchung. Besonders für Ärzte und Studierende. Von Dr. Joseph Arneth, Privatdozent an der Kgl. Universität Würzburg. Drei lithographische Tafeln mit über 210 Einzelblutzellen (in Farben), 12 anderweitige Tafeln mit Blutbildern. Würzburg: A. Stuber's Verlag (Curt Kabitzsch), 1907.

The author of this monograph on the diagnosis and treatment of anemia enjoys a considerable reputation in Germany for his discoveries in the field of hematology. He has developed a complicated method of classifying the polymorphonuclear cells of the blood according to the number and arrangement of the nuclei, and has also published the first case of leukanemia. Such qualifications, and the clinical opportunities offered under von Leube at Würzburg, would lead one to expect a thorough piece of work. The volume is, indeed, excellent, although it is certainly not for the student, but for the specialist. The title is also somewhat misleading, as not only the anemias, but the leukemias as well, are included in the discussion. The only criticism to be offered is that the tendency is shown to discuss obscure and unimportant points to the exclusion of a clear, full perspective of each disease type; so that while the expert hematologist might read the volume to advantage, the beginner could not always obtain a clear picture of the blood disease from the description. The second part of the volume, on the treatment of anemia and leukemia, is very interesting in many respects, especially as a full discussion is given of the results of the treatment of leukemia by the *x*-ray. The drawbacks and dangers of such treatment are clearly presented and emphasis is laid upon the disappointing phases of this form of therapy, in which the results are not permanent. A series of excellent colored plates of various blood cells is appended to the text.

A Compend on Bacteriology, Including Animal Parasites. By Robert L. Pitfield, M.D., Pathologist to the Germantown Hospital; Pathologist to the Hospital for Lung Diseases, Chestnut Hill; Pathologist to the Widener Memorial School; Late Demonstrator of Bacteriology at the Medico-Chirurgical College, Philadelphia. With four plates and eighty other illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

This compend is similar to others in this well known series. The essentials of the subject are here presented in an accessible form, and there are chapters on infection and immunity. The book will be of service to medical students preparing for examination.

Diseases of the Nose and Throat. By J. Bruce Ferguson, M.D., Instructor in Diseases of the Nose and Throat in the Post-Graduate Medical School and Hospital, New York. Series edited by Victor Cox Pedersen, A.M., M.D. Philadelphia and New York: Lea Brothers & Co.

This epitome gives clearly and concisely the diagnosis and treatment of the various diseases of the nose and throat. It is, throughout, practical; and is intended for medical students, both undergraduate and postgraduate. The only criticism we have to make is on the language of several of the prescriptions; there is room for improvement here, particularly as the book is written for students.

Manuel Pratique de Massage et de Gymnastique Médicale Suédoise. Par J. E. Marfort, ex-Professeur de Massage et de Gymnastique Médicale et Orthopédique à l'Institut de l'Empereur Nicolas I er. Troisième Édition. Avec 111 figures intercalées dans le texte. Paris: Vigot Frères, 1907.

This new edition differs so much from the former ones that it is practically a new work. It has been recast, much enlarged, and contains more than twice as many illustrations. In its present form it is a fairly complete manual of the subject and will compare favorably with many more pretentious works.

Der Tripper. Laienverständlich dargestellt. Von Dr. Orlowski, Spezialarzt in Berlin. Würzburg: Curt Kabitzsch, 1907.

Die Syphilis. Laienverständlich dargestellt. Von Dr. Orlowski, Specialarzt in Berlin. Würzburg: Curt Kabitzsch, 1907.

These two pamphlets, about forty octavo pages each, present all that the layman needs to know of the two venereal diseases. Patients afflicted with these troubles ask many questions during their visits at the office. The busy doctor has no time to answer all of these, yet he would like to gratify the intelligent patient's natural curiosity. This is the evident purpose of the pamphlets. They possess a high educational value and may serve as a pattern for similar tracts in English.

On Tabes Dorsalis. The Lumleian Lectures Delivered before the Royal College of Physicians, London, March, 1906. By David Ferrier, M.D., LL.D., F.R.S., Fellow of the College, Professor of Neuropathology in King's College, etc. New York: William Wood & Company, 1906.

In these three lectures Ferrier covers the entire ground of tabes dorsalis from the viewpoint of etiology and of anatomical and physiological pathology, the latter including a study of the symptoms from the scientific viewpoint. The lectures are illustrated by a number of drawings and diagrams, and a bibliography which will prove of great help to the student is appended. The subject is treated in the lucid, systematic style of thoroughly prepared didactic lectures and the book makes excellent reading for those who like a thorough yet not a cumbersome treatment of such a complex theme as our modern knowledge of tabes.

A Study of the Human Blood-vessels in Health and Disease. A supplement to "The Origin of Disease." By Arthur V. Meigs, M.D., Physician to the Pennsylvania Hospital. With 103 original illustrations. Philadelphia and London: J. B. Lippincott Company.

In his book, "The Origin of Disease," the author considers the anatomy and pathology of the blood-vessels in a very incomplete and very brief manner. The present monograph is the outcome of the studies which Dr. Meigs has pursued since the appearance of his earlier book, and contains a considerable number of illustrations beautifully printed on special paper from stones, after pencil drawings which are distinguished for their delicacy of touch and their clearness of minute detail. The work is not a systematic text book on the diseases of blood-vessels, but rather a collection of the author's specimens illustrated and described, and arranged in as orderly a manner as possible. The introductory chapters deal with the minute anatomy of arteries, veins, and capillaries, and the genesis of new blood-vessels. Then follow chapters on the pathology, general and special, of the blood-vessels. The third and last group of chapters deals with the diseases of vessels in various organs and tissues of the body.

The diseases of the blood-vessels are so intimately connected with organic disease in general, with tuberculosis, syphilis, and "old age" in particular, that their study, however tedious and however minute it may be, is of the utmost value. It is to be regretted, perhaps, that Dr. Meigs has not condensed his material into more easily digestible form. The book abounds in valuable facts, and the illustrations are very elaborate, but there is a certain prolixity of style which makes the book difficult to read through. Dr. Meigs deserves credit, however, for his original work, and his book undoubtedly contributes a great deal to our knowledge of the blood-vessels.

L'Ataxie Tabétique. Les Origines, son Traitement par la Rééducation des Mouvements. Par le Dr. H. S. Frenkel, Directeur de l'Établissement pour la rééducation motrice à Heiden (Suisse), etc. Traduit de l'Allemand par le Dr. von Biervliet (de Bruxelles). Préface de M. le Professeur Raymond. Avec 132 figures dans le texte. Paris: Felix Alcan, 1907.

This is a French translation of Dr. Frenkel's book on the treatment of tabes by systematized motor exercises. The work is divided into two parts; the introductory chapters deal with the historical data, the types of locomotor ataxia, the etiology, the diagnosis, and the theoretical basis of the treatment. The second part deals with the technique of the reeducation treatment of Frenkel. Here the practitioner will find a well-illustrated detailed description of the various exercises, and the manner of applying them in tabetic patients. These exercises are not difficult to learn, and require but simple apparatus. The book is therefore of much practical value to those who are willing to devote their time to the systematic treatment of locomotor ataxia.

Beiträge zur Diagnostik und Therapie der Geschwülste im Bereich des zentralen Nervensystems. Von Prof. Dr. H. Oppenheim. Mit 20 Abbildungen im Text und 6 Tafeln. Berlin: Verlag von S. Karger, 1907.

This book is a special treatise based on the writer's personal observations in this field and includes only those cases which were susceptible to surgical treatment. The author of the book has had innumerable opportunities to study this class of diseases during his association with v. Bergmann, Sonnenburg, and F. Krause, and his work is essentially a personal record. There are a number of excellent plates appended to the text, both in colors and half tone.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-eighth Annual Session, Held at Atlantic City, June 3, 4, 5, 6, and 7, 1907.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 968.*)

HOUSE OF DELEGATES.

Thursday, June 6—Fourth Day.

Report of Reference Committee on Amendments to Constitution and By-Laws.—Dr. GEORGE W. GUTHRIE, chairman, read this report, which recommended an amendment to section 4, chapter 10 of the by-laws by striking out all of the section after the words "five members" and substituting the words, "to be appointed by the President on the first day of each annual session." On motion the report was adopted.

Report of the Reference Committee on Section Work.—This committee reported with reference to the Senn medal that, as it was a surgical matter and the committee was unable to get access to individuals who read essays, it should be referred to the Executive Committee of the Section on Surgery, and the committee so recommended. On motion the report was so referred. The committee to which was referred the resolution of Dr. Richard Cabot of Boston as to the eradication of rabies, recommended acquiescence in the resolution; that it be transmitted to the Committee on Medical Legislation, and that a resolution be adopted leaving the control of the disease to the Bureau of Animal Industry of the Department of Agriculture at Washington; that the committee act in harmony with that bureau; and that public instruction relative to the disease be left in the hands of the Board of Public Instruction. The report was adopted.

Report of the Committee on Scientific Exhibit.—Dr. F. B. WYNN, chairman, read the report. He recalled the fact that the first scientific exhibit was at the Atlantic City meeting of the Association seven years ago. The scientific exhibit had proved of great practical utility. Its aim was the objective demonstration of the work accomplished in the different departments of the Association, as well as of progress the world over. The committee recommended that, in recognition of conspicuous service, neatly engraved certificates of award might be given, say, to the three laboratories or institutions presenting the best exhibits, and to encourage original investigation that a gold medal be awarded for the best exhibit of original research. It especially recommended that for the ensuing year a gold medal be awarded to the best tuberculosis exhibit, the exhibit to be compact, and designed to educate the public. On motion the report was adopted.

Report of Reference Committee on Reports of Officers.—Dr. P. M. JONES of California, the Secretary, read this report, stating that it was unanimous. As to medical education, the committee indorsed the opposition to that course of certain physicians in organizing or conducting incompetent medical schools. The committee commended the work of the Council on Pharmacy and Chemistry, and strongly recommended that the members of the Association confine their prescriptions to articles contained in the U. S. Pharmacopœia, the National Formulary, or such as had been approved by the Council on Pharmacy and Chemistry. The committee believed that a minimum fee of $5 for life insurance examinations was just and fair, and deprecated the organized effort of certain companies to compel the acceptance of a lesser fee. The committee agreed with the view that present conditions would eventually be amicably settled, and concurred in the recommendation that the committee be discharged. It recommended that the various reference committees be appointed two months in advance of the annual meeting, and that the reports referred to these committees early enough for consideration. This recommendation caused considerable discussion, and finally, on motion of Dr. Hall, this part of the report was changed to read: "That at least two weeks before the annual meeting of the Association printed reports be sent to every member of the House of Delegates, and that reference committees be appointed on the first day." The report commended the manner in which the Board of Trustees had conducted the affairs of the Association. The committee believed that the statement of audit was sufficiently definite and comprehensive, and that to make public further the more intimate business details would be unwise and poor business policy. It considered the compilation and publication of the American Medical Directory an undertaking of the greatest value to the Association and to the entire medical profession, and considered the financial status of this portion of the Association's work eminently satisfactory. At this point a long discussion arose as to the statement of audit, several gentlemen speaking in favor of a more detailed report. Dr. Harris, on the part of the Board of Trustees, gave at length the reasons for not making a report in more detail. The question had been studied very carefully, and the method adopted was the one in use in most of the large business concerns of the country. Dr. Simmons also spoke in explanation of the methods adopted by the Association for carrying on its business affairs. On motion of Dr. McMurtry of Louisville a vote of confidence was tendered Dr. Simmons, and he was praised for his triple services as Secretary, Editor, and General Manager. The committee recommended that Dr. McCormack continue his work, and that the Board of Trustees appropriate $600 for that purpose. It earnestly recommended that every effort be made to stimulate interest and activity in county society work. The committee recommended that the report on branch associations be referred to the State associations by the General Secretary, with a request for an expression of their views, to be presented at the next annual meeting. The committee offered a resolution most earnestly requesting all medical journals to refuse to aid in promoting the sale of preparations which had not been approved by the Council by refusing advertising space to such preparations, and requesting the moral and financial support of the members for those medical journals, whether privately owned or controlled by medical organizations, which disregarded commercialism and stood firm for honesty and right dealing, thus sustaining the Council in its great work for the medical profession. Finally, the committee moved the adoption of a vote of thanks to the officers of the Association for their valuable and efficient services. On motion the report as a whole was adopted.

Report of Reference Committee on Medical Education.—Dr. LUND, the Chairman, read this report. The committee specifically indorsed the compilation of tables showing the standing of medical schools. While the House of Delegates still adhered to the requirements of a high school course of four years before entrance into a medical college, it thought that as soon as possible the requirement should include a knowledge of physics, chemistry, and biology. The committee recommended that night schools should not be in good standing before the Association. The licensing boards of the States should have charge of the preliminary requirements instead of that being determined by the schools themselves. The committee was in favor of the rapid extension of reciprocity in medical licensure. The report closed by complimenting the Council on Medical Education, and recommending a vote of thanks for its work. On motion, the report was adopted. A resolution was offered relative

to the high schools in the South, where there were only three or four high schools with a course of over three years. The object of the resolution was to endeavor to induce the high schools in the South to raise their course to four years. The resolution was adopted.

A resolution was adopted providing that the journal of the Association be sent free to all medical libraries in the Medical Library Association, the names of the libraries to be submitted to the Secretary of the Medical Library Association.

Application was made by the Southern Medical Association for recognition by the American Medical Association as a branch association. The report was referred to the appropriate committee.

The Committee on the Davis Memorial asked that the request for an appropriation of $5,000 be referred to the Board of Trustees. On motion, the report was so referred.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Herbert L. Burrell of Boston; *First Vice-President*, Dr. Edwin Walker of Evansville, Ind.; *Second Vice-President*, Hon. Hiram R. Burton, M.C., of Delaware; *Third Vice-President*, Dr. George W. Crile of Cleveland, O.; *Fourth Vice-President*, Dr. W. Blair Stewart of Atlantic City, N. J.; *General Secretary*, Dr. George H. Simmons of Chicago; *Treasurer*, Dr. Frank Billings of Chicago. The three *Trustees* whose term expired this year, namely, Drs. T. J. Happel of Tennessee, W. W. Grant of Colorado, and Philip Marvel of New Jersey, were reelected.

A resolution was offered and adopted providing that recognition be given to the branch associations applying for the same, subject to the adoption of a uniform constitution and by-laws, to be prepared by the Committee on Organization of this Association.

It was decided to hold the next annual meeting in Chicago, Ill.

Dr. Happel stated that the request for an appropriation of $5,000 for the Davis Memorial had been referred to the Board of Trustees without a recommendation by the House of Delegates. The Trustees did not wish to assume the responsibility, and he wished some action taken by the House. After much discussion it was decided to postpone the matter until next year.

After a resolution thanking the President for the impartial and honest way in which he had presided over the deliberations of the body, the House of Delegates adjourned.

SECTION ON SURGERY AND ANATOMY.

Wednesday, June 5—Second Day.

Physiology of Exophthalmic Goiter.—Dr. S. B. Beebe of New York read this paper. He said that the title of it should rather have been "Physiology of the Thyroid Gland in Its Relation to Exophthalmic Goiter." He said that recent work had definitely shown the thyroid to belong to the so-called vital organs. There was very little actual scientific knowledge of the gland. He then spoke of the recent positive proof that had been developed of the essential differences between the thyroid and the parathyroid—myxedema developing after removal of the first and tetany after removal of the second. He said that in his experimental work with Dr. Rogers he had been able, by the employment of beef parathyroid nucleoproteid suitably administered to save animals from tetany even after they had gone into profound convulsions one, two, and even three times, but that death could never be averted for more than three weeks. That this was due to the toxic condition of the blood was shown by the fact that heavy feeding of meat would cause convulsions earlier after parathyroidectomy than in animals in normal condition. He spoke of the detoxication theory and mentioned that thyroid feeding stimulated metabolic activity. During some stages of the disease it was unquestionable that large quantities of nitrogen were necessary to maintain normal body weight.

Pathology of Exophthalmic Goiter.—Dr. W. G. MacCallum of Baltimore read this paper. He said that as yet there was no unanimity of opinion as to the degree of change which took place in the thyroid. It was unquestioned, however, that many of the changes found had not the characteristics of primary changes. Neither was it yet determined whether the well known disturbances in metabolism were the cause or the effect of the disease in the thyroid or in the central nervous system. Classifying the gross changes he enumerated them as follows: Enlargement of the gland not always great. Dilatation of veins usually marked and very characteristic. Interior of tumor not hyperemic. Loss of elasticity. Color an opaque gray. The amount of colloid varied, but it was characteristically diminished in amount, its place being taken by a fine network of fibrous tissue. The acini were lined with characteristic high cylindrical epithelium instead of the flat form of normal cell. Mitotic figures were frequent. Adenomata occurring in these glands in conjunction with the exophthalmic lesion were not uncommon. They were advantageous and had nothing special to do with the disease. The thymus was usually considerably enlarged. In sixteen cases the parathyroids had been examined and found normal. In the two or three cases examined the sympathetic nervous system had been found normal. This was also true of the central nervous system. Thyroid, lymphoid, and thymus changes were the only ones constantly observed.

Diagnosis of Exophthalmic Goiter.—Dr. L. F. Barker of Baltimore read this paper. He said that some observers had gone so far as to deny the existence of struma, but careful study had always shown it to be present. As a rule he said the swelling was not large, particularly in the early stages of the disease. The isthmus of the gland was generally broad and thick and the pyramidal lobe was increased. In acute cases the tumor was often softer than the normal gland. There was a characteristic granulation of the surface. Most important of all were the vascular characteristics. Pulsation was in many cases visible, and by the palpable expansion and the bruit invaluable assistance could be obtained in making the diagnosis. Tachycardia was the most constant symptom; the heart always running above 90 and sometimes approaching 200. Under the latter conditions the patients frequently complained of subjective feelings of cardiac distress. The exophthalmos was the most striking symptom. It was absent in its true form in about one-third of the cases. A differential diagnosis of the character of the exophthalmos was to be arrived at by the use of the exophthalmometer. If present the true form was bilateral and continuous. Tremors were so invariably present that some observers had considered them the fourth sign. They were characterized by a rather constant vibration of eight to ten per second. These tremors were not confined solely to the extremities, but extended frequently to the muscles of the trunk. The digestive apparatus often was involved—diarrhea and vomiting being quite characteristic occurrences in advanced stages of the disease. Dyspnea was a late symptom and generally of cardiac origin. The genitourinary system presented no constant findings. The psychic phenomena were marked and often the very first to be observed. They might be so marked as to necessitate the regulation of the patient under detention. He recited the eleven signs which, besides exophthalmos, might not infrequently be seen in the eyes. In closing he said it should not be forgotten that all pulsating strumata were not Basedowean.

Medical Treatment of Exophthalmic Goiter.—Dr. R.

B. Preble of Chicago read this paper. He said that treatment must be directed to the correction of neuroses and of individual symptoms and to the improvement of thyroid metabolism. Rest should be physical and mental; it should be general and it should be complete. The diet was of particular importance and should be suited to the particular case. Certain advantages could be gained by various changes in climatic conditions, some doing well in mountains, some at the sea coast. All forms of electrical and hydrotherapeutical treatment undoubtedly acted only by suggestion, and it must not be forgotten that these people of all others were most liable to suggestion. Of drugs, opium was the most valuable, although the most dangerous. All gland extracts were probably valueless and thyroid extract was unquestionably harmless. Cytotoxic preparations were still under trial. In conclusion he said it was far better to operate too early than too late.

Surgical Treatment of Exophthalmic Goiter.—Dr. Albert Kocher of Berne, Switzerland, read this paper. He spoke from the experience derived by himself and his father in a series of 3,460 cases of operation for goiter. Of these, 315 were for Graves' disease. He stated that their results to date had been so satisfactory that there seemed no need of changing the method. He referred in passing to the operation of sympathectomy and stated that it was useless. In the last 91 operations there had not been a single death and before this the mortality was but 3½ per cent. This he said would be lower. Decreased mortality was due to a wider recognition of the necessity of prudence in handling the tissues. Prior to operation a careful study should be made of the strength of the heart with a special reference to determining whether the existing enlargement were of a compensatory or dilatational type. The blood pressure determined by the Riva-Rocci instrument was of very great importance. If it was low it was necessary to study the effect of exercise upon the patient. They should always be prepared most carefully for operations even if such were to consist solely in the ligation of one vessel. A second thing studied was the degree of intoxication. Another important point and one most recently developed was the examination of the blood. In his last fifty-eight cases there had been a marked increase of lymphocytes and a diminution of polymorphonuclears. The leucocyte count itself was normal, the increase of lymphocytes being proportional to the degree of disease. Nothing was known as yet of the cause of this lymphocytosis. It was different from that which accompanied pus formation. It explained the danger of the very slightest infection in these cases. In answer to the question, does the operation cure, he said that the symptoms were often increased after operation. This was due mainly to hemorrhage and to gland injury. Eighty-three per cent. had been cured, some of these as long as seventeen years without recurrence. The heart and the eyes took longest to recover. As to technic he said that more than two arteries should never be ligated at once. Never more than one-half the gland should be removed except for special reasons. The surgeons and the physicians must work together in order to obtain the best results.

Dr. W. S. Halsted of Baltimore said that in future he believed much good would be derived from the serum of Beebe and Rogers. It would some day make a most acceptable substitute for the surgical work, which, at best, was crude and maiming. As to the danger of postoperative tetany, he said that during the past two or three years it had become relatively frequent owing to the increased number of glands resected. The pathology of tetany had been made comprehensible by the discovery of the parathyroids. Each gland—there were usually four—was separate and had a separate blood supply; and it might well be said that their protected position was indicative of their extraordinary value to the individual. The speaker believed that these glands could be seen at operation. Less often were they removed bodily than was their circulation interfered with. Certain observations recently made at the Johns Hopkins Laboratory seemed to contraindicate the stripping of the posterior capsule as advised by Charles Mayo. Ligation of the thyroid even might cut off the tiny blood supply of these minute but valuable glands. As to the possibilities of successful parathyroid transplantation he said that we were still in doubt. So far as their observation had gone, the transplanted organs had been absorbed with but certain exceptions. These occurred when the organ had been placed on or near the surface of the spleen rather than in its substance.

Dr. Frank Billings of Chicago asked how any logical and satisfactory treatment of the disease could possibly be formulated in our present lack of knowledge of the disorder. One thing known about it was that in certain places it was endemic. He said that the medical results obtained by specific individual treatment were sometimes good, but that surgical therapy must in most cases be employed. He cited the history of a woman who had apparently recovered after eight months' rest in bed.

Dr. William Mayo of Rochester said that what he had to say would be spoken for his brother. He paid high tribute to the value of Kocher's hyperthyroidism theory. It had given to the surgical world a working pathological basis. Three types might be recognized clinically: The vascular goiter, the solid goiter, and those cases in which hyperthyroidism developed late. There was a pseudohypertrophic type. This called for the removal of the tumor, not the thyroid. As to the operative relief obtained, it depended upon the removal of sufficient glandular tissue and was characterized by a long continued convalescence. Their operative mortality in 170 cases had been nine, but four of these had occurred in the first sixteen cases, there having been but one in the last seventy-five cases. The lesion was surgically curable if operation was not undertaken too late.

Osteoplastic Operations.—Prof. E. Küster of Marburg, Germany, read this paper. He detailed the history of osteoplastic methods from the time of origin in Germany until the present day. He said that preeminently the conditions of success in all bone work were absolute asepsis and a contact of the bone fragment with other bones. He showed numerous specimens illustrative of his work and the instruments which he devised for its execution.

The Technique of Appendectomy.—Dr. John A. Wyeth of New York read this paper. He paid tribute to the men whose courage and resource had given the operation to the world. He lamented the fact that there were still so great a diversity in the technique and urged that the operation be put on a better defined basis. He advised the perpendicular incision with separation of the rectus. The length of incision through the peritoneum should average four inches. The primary incision of peritoneum one inch, to be enlarged if necessary. The particular point which he brought forward with much emphasis was the necessity of ligating the appendix itself with strong silk. He would disinfect the stump with carbolic acid and alcohol. He objected very strenuously to the employment of the purse-string suture or any form of suture of the intestinal wall. This was because the blood supply of the appendix in a large number of cases came not through the mesentery, but crossing through the wall of the cecum passed directly into the appendix itself. He gave a long list of recorded cases in which there had been serious hemorrhage, the result of the use of the purse-string suture.

Dr. Dawbarn of New York said that the cause of postoperative hemorrhage was to be found in the failure of the operators to apply the technique of the purse-string suture properly. He advised the use of linen thread and

stated that if after an operation for gangrenous appendicitis a fecal fistula developed it was the operator's fault. Like Kraske's treatment for erysipelas, he interrupted lymphatic continuity and provoked leucocytosis by the introduction of a double suture line.

Dr. Emory Marvel of Atlantic City said that he considered the small incision to be the best in the male, whereas the long perpendicular incision found best use in the female. He did not agree with Dr. Wyeth in the necessity for tying off the appendix.

Dr. C. von Zwalenburg of Riverside, Cal., said that the blood supply of the appendix was often anomalous. He recited a most interesting description of a series of experiments which he had made upon the effect of dilatation in the dog's appendix. At thirty millimeters pressure there was a decided slowing in the circulation; at sixty there was partial stasis; at one hundred this was complete.

The Operation of Gastrojejunostromy and the Physiological Results.—Dr. H. J. Paterson of London, England, spoke of the great importance of further knowledge on this important subject. The amount of bile which regurgitated into the stomach after this operation had been much exaggerated, for it probably did not represent more than five or six per cent. of the gastric contents. Obviously, if bile were present pancreatic juice must also be present. A diminution of gastric acidity was the first effect of the operation. This was not due to the presence of alkaline fluids which had entered the stomach from the duodenum. The average diminution was thirty-five per cent. This was obviously too great to be entirely a chemical reaction. There was also a diminution of chlorides. This was due to diminished secretion. Some acid undoubtedly was squeezed out of the stoma. This led to an earlier secretion of pancreatic fluid. There might also be a reduced secretion of secretin. As to the effect on gastric digestion, he believed that a diminution of the chlorides was not an indication of diminished digestion and as proof cited the examination of feces. The effect on the gastric motility was not so great as to make it of pathologic import. Before operation, if impaired by stenosis movement, it increased postoperatively. If unimpaired, it may be increased or diminished, but always within physiological limits. As to the question of drainage he said that the size of the opening probably determined a certain amount of drainage. If it were not drainage which caused the obvious improvement in many of these patients, what was it? If only drainage, why not use stomach tube? Hyperacidity was always diminished not because of drainage he believed, but owing to a diminution of the chlorides. Metabolism was not affected. Whether the food passed through the stoma or not, he considered still to be an open question and of academic interest only.

Dr. J. T. Gilbride of Philadelphia said that the operation was now on a physiologic basis and expressed the thanks of the section for the manner in which it had been presented.

Dr. W. B. Cannon of Boston said that he was particularly interested in the question of whether or not this was a drainage operation. According to his results, which were obtained by fluoroscopic observation, the pressure at the pylorus was three or four times greater than at the stoma; this was due to peristaltic waves, which not only compressed the food, but liquefied it as it pressed against the pylorus. He referred to the corroborative findings which had been reported from the Surgical Research Laboratory of Columbia University.

Dr. J. W. Draper Maury reviewed the work referred to by Dr. Cannon and stated that if dogs were fed a string to which a bag of shot had been tied, when gastroenterostomy was performed, positive observation could be made as to the function of the pylorus and the stoma. This could also be done by observing the weight in dogs after low gastroileostomy.

Vaccine Therapy of Surgical Infections Controlled by the Opsonic Index, with Reports of Results.—Dr. L. L. McArthur of Chicago said this subject was of particular interest to surgeons because of the fact that the ordinary infections they met with were the particular ones destroyed by phagocytosis. If the phagocytic capacity could be increased and if at the same time vaccines could be employed to raise the systemic index, the result ought to be promising. In general he summed up as follows: The opsonic index of Wright offered valuable assistance in the diagnosis of the nature of many obscure infections. That it was at present the most accurate method of controlling the dosage of vaccine therapy, but might later be replaced by a simpler technique. That sufficiently gratifying results had been obtained to encourage others to use vaccine therapy in conjunction with the recognized treatment of the given ailment and in particular in conjunction with Bier's treatment.

The Pelvic Articulations, with Especial Reference to the Differentiations Between Lesions of These Articulations and Other Surgical Conditions.—Dr. J. E. Goldthwait of Boston read this paper. He said that the pelvic bones were held together by ligaments and that the articulations were true joints; they had, because of their lack of cupping and because of their oblique position and the irregular manner in which weight was applied to them, a singular liability to strains and to disease; he said that this was particularly true of the sacroiliac joint. The pain in this region was produced by a slipping of the two bones. An important point made was that the backache so characteristic after prolonged operations could be entirely relieved by proper support during the operation to the lumbar spine.

Foreign Bodies Lost in the Peritoneal Cavity.—Dr. Archibald Maclaren of St. Paul, Minn., said that the five-yard sponge and long hemostatic forceps were the most important factors in preventing this serious accident. He cited a series of cases in which all manner of materials had been left within the abdomen and urged a continuance of the vigilance which was being universally practised.

Local Anesthesia in General Surgery.—Dr. James F. Mitchell of Washington, D. C., said that the chief reason for the employment of a general anesthetic in more than one-half the average run of major operations in hospitals was the time element; local anesthesia was slow, success could be obtained only by great patience and by a thorough knowledge of the varying sensibility of the tissues. He recited a long series of operations which he had performed under local anesthesia and urged its more general employment.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Wednesday, June 5—Second Day.

Early Postoperative Intestinal Obstruction.—Dr. C. C. Frederics of Buffalo read this paper. He said postoperative ileus was one of the serious sequelæ following abdominal operation. Intestinal obstruction following abdominal operations of all kinds was quite frequent. He divided postoperative obstructions for convenience into early and late, the early including those occurring previous to the patient's discharge from the hospital, that is, within about two or three weeks. In the earlier cases it was often difficult to make the diagnosis, for failure of the bowels to move, the flatulence, temperature, and many things called for great care in making a diagnosis. The passing of gas, or of some feces, should not lull into a feeling of safety, for careful observation would show no real improvement in the patient's condition, no decrease of distention or vomiting, no improvement in pulse or general condition. There were three well-recognized forms of intraperitoneal lesions which accounted for these con-

ditions, viz., septic peritonitis, mechanical obstruction by adhesions or bands, and organic spasm of the bowel. Many of the symptoms of obstruction and septic peritonitis were the same and the differentiation was of vital importance to the patient and the surgeon. In mechanical ileus the peristalsis was accompanied with griping pain coming on in paroxysms. Many cases had been reported by different observers in which tonic spasm of the bowel had caused occlusion and on operating or at autopsy no other cause for obstruction was found. The surgeon often had to shoulder the responsibility of an exploratory incision. The vomiting of obstruction had been called reversed peristalsis, but this explanation for the profuse vomiting was an incorrect assumption.

Dr. Frederics said that every operation should be done with the object not only of relieving the patient of his ailments, but of protecting him against postoperative sequelæ of every kind. In most cases adhesions of some form existing prior to operation or produced by the pathological process present, or as a result of the operation, were the cause, and to prevent these as much as possible was the work of the surgeon. In operating the intestines should be handled as little as possible; large flat gauze sponges or towels should be used to isolate the intestines, and these would irritate less if wrung out of warm sterile salt solution before use. One should avoid unnecessary tearing of the peritoneum, the spreading of pus, and if possible aspiration. Denuded points of peritoneum, especially the stump of broad ligaments, tumors, etc., should be covered. In all pelvic operations in women drainage could best be done through the vagina, the cigarette drain filling all demands. If necessary the omentum should be stitched where the operator wanted it to remain, but drainage should be avoided when possible. Where old adhesions existed between the bowels it was a question whether it was best to break them up and thus make opportunity for new and probably worse adhesions. It was the consensus of opinion among surgeons that too early or too strenuous efforts to move the bowels should not be made, for the whole nervous apparatus had received a shock at operation. Rest was indicated and only the lower bowel should be stimulated to pass gas for the relief and comfort of the patient. Some would forbid morphine on account of the after effects, but if the operator had to suffer the pains himself he would probably give the patient relief. These patients should have an anodyne, and codeine phosphate, 1 to 1 1-2 grains, hypodermically, would quiet the pain and cause no nausea. This was in line with withholding cathartics that the patient might get in shape for her organs to begin function again. If a cathartic did not give good results it might be concluded that it was harmful. Atropine, eserine, and physostigmine in large doses had not done what was hoped for them. Enemata might be used as less harmful. Change of the patient's position was advisable. In these cases early operation was the watchword. The largest mortality was within three or four days. In some cases the patient was killed by the lethal dose of the toxins locked up in the bowels, and when the obstruction was relieved this accumulation was released, to be absorbed with fatal results. It might be well to bring a knuckle of the gut into the wound, incise, clean out, use lavage into both afferent and efferent loops. How and how much was to be done depended on each case and must be determined by the operator. There was little doubt that in the future when the patint was *in extremis* the operation would be to do an enterostomy at the most prominent point of distention or to one side of the original incision.

Prevention and Treatment of Postoperative Intestinal Obstruction.—Dr. Daniel H. Craig presented this paper. After referring to his previous articles on the subject and reviewing the action of eserine upon the intestines, Dr. Craig described the anatomy of the intestinal walls and the nerve plexes that were involved in the action of the drug. Postoperative paralysis was probably due to the dual influence; inhibition from stimulation of the splanchnic fibers and exhaustion from overstimulation, and hence fatigue of the gangha in Aurbach's and Meisner's plexes. To regulate peristalsis it was necessary to stimulate spinal reflexes acting through the splanchnics and restore the energy to the intestinal nerve ending and muscles. To meet this condition eserine salicylate was found fitted and a continued use of it with study of its action had borne out the assumption that its action in intestinal obstruction was very valuable. As the cases classed here were the recent ones, the factors to be considered as causative of postoperative obstruction were reduced to paresis, volvulus, thrombosis of the intestinal vessels, and adhesions in connection with kinks and slight local infection. Then the diagnosis of postoperative intestinal obstruction within the first few days resolved itself practically into the differentiation between mechanical obstruction, paresis, septic peritonitis, and shock. Dr. Craig said that for six years it had been his custom to give the patient a hypodermic injection of atropine sulphate preceding the anesthetic, and upon the operating table, as soon as it could be determined that it was not contraindicated, from two to five minutes after the opening of the abdominal cavity, he gave an injection of eserine salicylate in fresh solution. Constant employment of this method had made him more enthusiastic in its employment than ever. Two arguments had been presented against it, one that fatal intestinal paresis was too uncommon to necessitate its prophylaxis in every case by this procedure. While in a measure that was true, the fact remained that such cases did arise and moreover the means used to prevent the condition also added to the comfort of the patient. The other objection was that the prevention of adhesions interfered with nature's process of preservation by walling off by adhesions. We might say that these adhesions were pathological and not protective. The eserine prevented enterospasm or overcame it when existing by producing the peristaltic wave. The eserine also prevented meteorism and thus added much to the comfort of the patient. Even when eserine was not used as a prophylactic it was often used to cure postoperative intestinal obstruction by setting up peristalsis, thus straightening out the kinks and the obstruction. As to the dosage, Dr. Craig said he used 1-40 gr. on the operating table, but meteorism and abdominal distention could be produced by too large or too frequent doses of the drug. The keynote of success in the after-treatment of cases in which prophylactic doses had been used was to let the patient alone, for cathartics and enemata were unnecessary.

Successful Treatment of Acute Postoperative Ileus by Incision and Drainage of the Intestine.—Dr. Francis D. Donohue presented this paper. He said some paralysis of peristaltic activity usually followed surgical interference in the abdominal cavity. The milder forms were readily overcome by the usual methods, but those that did not yield presented a most dangerous complication. Peristaltic inertia often caused "kinking" and serious conditions might result. The symptoms developed early and in twenty-four to thirty-six hours might be well marked. Persistent vomiting, changing from bilious to stercoraceous, should cause anxiety. With this came abdominal distention not relieved by enemata and the vomiting was not controlled by gastric lavage. The treatment by eserine and physiological doses of atropine might occasionally prove useful, but when a case had reached a critical stage mechanical treatment offered the best chance for recovery. The value of enterostomy in postoperative procedure was yet to be fully appreciated. It afforded a means for escape of gas and feces, it afforded an opportunity by the injec-

tion of a solution of magnesium sulphate to provoke peristalsis at considerable distance from the point where the tube was placed, and by it stimulating fluids and food might be introduced. In all cases preliminary to drainage by the tube all loops of markedly distended intestine should be incised, the liquid contents and gas emptied out, and the opening closed by continuous intestinal suture. The resulting fecal fistula might be closed or left to nature. Irrespective of where the distended loops occurred, a permanent tube should be left in the cecum for drainage and for other treatment.

Dr. NOBLE of Philadelphia said he was pleased with the optimism of Dr. Donohue, but his experience was such that he devoted every energy to preventing obstruction. He took pains at the operation and did not operate in acute conditions. He did the same thing in appendicitis where it was possible. Often the patient was put on the table too quickly without the surgeon taking enough time to study the case. Years ago he lost patients who died from septic peritonitis. He found in one case that the stomach occupied nearly the whole abdomen, and since then he had relied much on the stomach tube. As far as the treatment of postoperative intestinal obstruction was concerned, nearly every *real* case ended fatally.

Dr. MONTGOMERY of Philadelphia said the important point was the scarring of as little surface as possible for adhesions, and he did not permit the patient to remain in one position. When there were symptoms of obstruction he used lavage and enemata, and sometimes operation had to be resorted to. He had a patient now that was adverse to an operation, but when enemata and lavage failed he opened the abdomen and found a twist in the intestine. He favored washing out the intestine and leaving it open for lavage.

Dr. TABOR JOHNSTON said an important point was the preparing for the original operation by thorough study of the patient's condition, for often the patient was hurried into the hospital and operated upon the next morning and thus prophylactic measures were neglected. The fate of the patient was virtually settled when she was taken from the table. By doing work carefully and leaving out no detail there would be little need for secondary operation.

Dr. STONE said he thought it was seldom necessary to reopen a patient's abdomen, and when she was put to bed her fate was virtually settled. The reader of the paper did not mention enemata of alum water. Dr Stone said he would use eserine. He called the condition where the intestine was paralyzed to an extent of about six feet and vomiting took place, "reversed peristalsis." He thought that peristalsis was a wave going along the intestine and not so much the side movements. He believed in making the incision large enough to do the work well.

Dr. GORDON of Portland, Me., said he believed in making haste slowly. He had few cases of intestinal obstruction, but cases with lots of germs inside, and he liked to go after them. He was a believer in the use of eserine, but he thought operators were a little hasty in many of the cases. Even if there were exciting conditions the patient would likely come around all right. In many cases he used a high enema of quinine sulphate or sometimes a low enema with a bulb syringe. He used 20 to 30 grains in two ounces of water. If the patient vomited, he used the stomach pump, for one could thus work at each end of the canal at the same time. He believed in letting the patient drink all the water desired.

Dr. GOLDSPOON of Chicago said he believed in preventing the trouble and gave a large dose of castor oil before operation, as much as ten ounces, and large enemas. The patient was allowed liquid diet to within eight hours of operation and plenty of water all the time. He gave strychnine twelve hours before the operation, and if the heart was feeble two minims of camphorated oil. It had been shown that to expose the intestine to the air was injurious and in operating he did not want to see an intestine any more than a snake. He used wet cloths to protect the intestines, dipped in a bicarbonate solution. The covering of denuded surface was all-important, but he did not fix by the omentum.

Dr. DEAVER of Philadelphia said the discussion sounded like one on wind colic rather than obstruction. When operating, he believed in quick work. Get in quick and get out quick. Many of the patients had accumulation of gas and in ordinary practice he did not see many cases of postoperative intestinal obstruction. The cases he saw were after bad septic conditions, as in appendicitis. He never got obstruction in chronic appendicitis, but in the acute cases seven in ten patients recover and three die.

Dr. FRY of Washington said he had a case after cesarean section in which he gave eserine and the bowels moved, but the condition recurred and the patient died. He believed in the use of the stomach pump, but he also gave alum enemas.

Dr. CARSONS of Troy asked why one should handle the intestines and said it was because the patient was not under full anesthesia. If the patient was in profound anesthesia the bowels would drop down out of the way and there would not be the sudden spasms that come by contraction. The bowels shoud be let alone for forty-eight hours. Once in a while he had cases of obstruction in the pelvis and by manipulation got the loop out and the patient recovered. Sometimes sepsis gave the symptom of obstruction, and this might produce the gastric symptoms on account of toxin absorption. Atropine aided in some cases and he believed eserine was beneficial.

Dr. BONAFIELD said he had unbounded faith in eserine. In one case the house physician gave 1-30 of a grain to a woman weighing about eighty-five pounds and things looked bad for a time, but she came out of it all right. He thought peritonitis was confused with obstruction.

Dr. BANDLER of New York said that he did not always get the desired results with eserine, but in most cases it was an aid.

Dr. FISHER of Philadelphia said he was confident that 50 per cent. of the cases were due to conditions of the stomach and he found that 1-8 grain of morphine was useful at times. Interfering to move the bowels too soon often made trouble; in case of distention of the stomach he used the stomach pump.

Dr. FREDERICS said he did not mean to go into the question of antiseptics, distention of the stomach, etc., but he did contend that when postoperative obstruction of the bowel occurred it was necessary to act promptly, for if one waited the patient would die.

Dr. CRAIG said he did not wish anyone to think that he would use eserine in mechanical obstruction. In driving a horse the question was, which was the best—a whip or oats. Eserine was the oats and milk of magnesia was the whip. One should not be in a hurry to make the bowels move if the patient was doing well.

SECTION ON DISEASES OF CHILDREN.

Wednesday, June 5—Second Day.

The Greatest Menace to Whole Milk in City Supplies.—Dr. ALEXANDER MCALLISTER of Camden, N. J., read this paper. The cry of the day was for whole milk, whereas in the past it had been for pure milk. Pure milk might be far removed from whole milk. Whole milk, on the other hand, was always pure milk—milk whose integrity was untouched by age, science, or knavery. Legislation and eternal vigilance had gone far to give our cities pure milk. The former menaces to pure milk had become largely matters of history in consequence of improvement in trans-

portation, the employment of ice, inspection, etc., but a new danger had arisen in the wholesale pasteurization of milk. This was to be very much deprecated.

Certified Milk and the General Milk Supply of Louisville.—Dr. Henry Enos Tuley of Louisville, Ky., detailed in this paper the work accomplished in Louisville within the last ten years along the line of bettering conditions in the dairies and improving the milk supply. Political influences had hampered the work of putting an end to distillery-fed dairies, which had been the most serious menace to the health of the community, particularly the children. The bacterial content of milk from swill-fed cows was enormous, as could readily be imagined from the condition of filth in which such cows were kept. The swill caused a persistent diarrhea and the cows fairly reeked in their own foul liquid discharges. The result was appalling. At present, however, as an outcome of persistent effort on the part of those who had undertaken the work, not a gallon of swill was used, the dairies were kept under proper condition, and the milk supply vastly improved. Inspection was not yet perfected, however. The sale of milk from tuberculous cows could, with proper laws properly enforced, be entirely stopped. He outlined the scope of the work of milk commissions, and made a plea for certified milk—for pure milk, rather than impure milk pasteurized.

Dr. Alfred Friedlander of Cincinnati, O., said that the chief difficulties encountered in Cincinnati resulted from the fact that the majority of cows were slop-fed, and the distillery interests had been powerful enough to check any move to put a stop to this practice. It had been accomplished, however, and the commission now certified two grades of milk, viz., the certified milk, and the inspected milk. The requirements for these were just the same except as to bacterial content. Certificates were now given to dairymen who wished to deliver milk in cans to the hospitals under the requirements of inspected milk.

Dr. Thomas S. Southworth of New York City called attention to the three classes of individuals who advocated the pasteurization of the entire milk supply of New York City. These were: (1) Those who conscientiously believed that pasteurized milk was even more of a life-saver than modified milk; (2) those dealers who were planning to put out pasteurized milk in large amounts, and who therefore wished to create a large demand; and (3) the manufacturers of pasteurizing apparatus.

Dr. C. K. Johnson of Burlington, Vt., was of the opinion that a large, perhaps the largest, part of the trouble with the milk supply rested with the small corner grocery or creamery, where the cans were allowed to stand open much of the time. He thought much could be accomplished by cooperating with the dairymen and stimulating them by joint meetings and in other ways to take an interest in the matter of furnishing pure milk.

Dr. Walter G. Murphy of Hartford, Conn., cited two cases of tuberculosis in cows that were giving milk up to the time of their slaughter. In one autopsy revealed a tuberculous abscess, containing half a pint of pus, immediately attached to a milk duct.

The paper was further discussed by Dr. Louis C Ager of Brooklyn, N. Y.; Dr. S. McC. Hamill of Philadelphia, Pa.; Dr. C. W. Brown of Elmira, N. Y.; Dr. C. G. Kerley of New York City, and others, and the discussion was closed by Dr. McAllister and Dr. Tuley.

The Disadvantages of Low Proteids in Infant Feeding.—Dr. Alfred Hand, Jr., of Philadelphia, Pa., who read this paper, said the term "low proteid" was used by him to mean any percentage below 1.8 per cent., or half of that present in the whole cow's milk. When low percentages were given for a prolonged period there was risk of various conditions developing, such as constipation, failure to gain in weight properly, irregular sleep, colic, indigestion, and increased susceptibility to various infections. In avoiding the dangers of overfeeding there seemed to be a tendency to go to the other extreme and to feed infants on too weak a mixture. The aim should be not to overtax the digestive powers, but at the same time not to leave too wide a margin of unused power.

Dr. Thomas S. Southworth of New York City thought the normal child at the end of the first six months should be given a higher percentage of proteids than the two per cent. mentioned by Dr. Hand.

Dr. John Lovett Morse of Boston, Mass., did not believe that a baby of a given age should have a given amount of proteid in its food. It was true that it must have a certain amount of proteid, but this should depend upon its weight and not upon its age. It must have two grams per kilo in order to thrive.

Dr. G. R. Pisek of New York City emphasized the importance of the proper examination of the stools as an index to digestive power of the child.

Dr. Hand closed the discussion.

The Importance of the Early Recognition and Treatment of Rachitis.—Dr. Thomas S. Southworth of New York City presented this paper. It had been claimed by some that all bottle-fed infants are rachitic. This did not apply to those whose food is properly controlled, or whose digestion is good. Rachitis developed because of parental blindness in many instances, the parents failing to recognize peculiarities in the child which needed special attention. Many times, too, physicians failed to recognize the early symptoms of the disease. Rachitic deformities were often far advanced before medical aid is sought, and the early signs were often unrecognized and untreated. Evidences of rachitis might easily be overlooked upon superficial examination. There was great variation in the incidence of the symptoms. While rachitis might undoubtedly begin before the fifth month, yet in his experience this was exceptionally the case. The grouping of the symptoms was also subject to great variation. Rachitis was of very frequent occurrence among infants. Acute rachitis was a menace to infancy, and rachitic deformities a menace to the adult. Prophylaxis should therefore be strongly urged. Racial predisposition had been noted, negroes and the poor children of foreign parents seeming particularly susceptible to the condition. The dietetic treatment in the first and second years was of great importance. The use of cod-liver oil and phosphorus, singly or together, was advocated. Phosphorus was of great value in cutting short the acute and progressive symptoms of the disease.

Dr. A. W. Fairbanks of Boston, Mass., asked Dr. Southworth whether he attributed the inability of rachitic children to walk to weakness of the musculature of the ligaments, or of the bones. He also asked whether organic phosphorus had any advantage over inorganic phosphorus.

Dr. John Lovett Morse of Boston, Mass., agreed with Dr. Southworth as to the frequency of rachitis. In an investigation at the Infants' Hospital in Boston it had been found that 80 per cent. of the infants showed bony signs of the disease, and he believed that such signs could be found in 50 per cent. in private practice. The only pathognomic signs were to be found in the bony skeleton. Improper hygienic surroundings played as important a rôle as did food. He believed that bony tenderness to which Dr. Southworth referred was due to scurvy and not to rachitis. He took issue with the reader of the paper concerning the value of phosphorus in these cases. It was of prime importance to keep such infants out of doors and to feed them properly.

Dr. Isaac A. Abt of Chicago did not concur in the view that rachitis is due to an excess of fat, but rather inclined to the belief that it was due to a general toxemia, a chemical poisoning produced as the result of faulty met-

abolism. Rachitis might be congenital, particularly in the case of colored and Italian children. Heredity probably played some part, certain infants having a rachitic tendency. They do not inherit the disease itself. He agreed with Dr. Southworth as to treatment, except that he did not begin sufficiently early to give something more than milk. Some rachitic children at the end of eight or nine months might be given any of the animal broths with vegetables boiled in it. Heubner advocated this with undoubted success.

Dr. C. G. Kerley of New York City believed rachitis to be a disease of malnutrition. Malnutrition, with bony changes predominant, was always found in rachitic children. Hygienic conditions certainly played an important part, and while fresh air and proper hygienic surroundings were of more importance in these children than in others, yet the question practically resolved itself into the child's ability to take care of its food. It was not uncommon to see rachitis in children who were ideally cared for in every way; in such children, however, faulty nutrition was a factor. He thought infection could be ruled out in rachitis. Granting that it is a nutritional disorder, the treatment should be instituted accordingly. Codliver oil was beneficial, but he had failed to see any good results from the use of phosphorus.

Dr. S. McC. Hamill of Philadelphia, Pa., said that his experience was somewhat at variance with that of other speakers concerning the matter of the relationship of these manifestations to the nutrition of the child. He had seen children brought up under the most ideal hygienic surroundings, whose health was perfect, develop rachitic manifestations. He emphasized the importance of fresh air both night and day.

Dr. R. B. Gilbert of Louisville, Ky., considered rickets due to a deficiency in lime salts and thought the treatment should be in accordance with this factor. He did not advocate the use of phosphorus, but phosphate of lime would bring about an improvement.

Dr. Southworth, in closing the discussion, said the various structures—muscles, ligaments, and bones—as well as the nervous system, were involved. He used the official oil of phosphorus and insisted that its administration would cut short, as he had said, the acute symptom. He considered dietitic measures more important than hygienic. The tenderness mentioned might be scorbutic, as suggested—that was still a mooted question.

The New Era in Pediatrics; Its Causes and Scientific Foundations.—Dr. G. R. Pisek of New York City called attention in this paper to the fact that a revolution is taking place in pediatrics. Men of broad training had gone beyond clinical observations and had tried to establish the principles that cover these clinical facts. The training and education of the younger physicians in the modern medical college made them capable of working along scientific lines, and these facts were modifying practice and teaching. The utilization of the sciences allied to medicine had tended to remove medicine from the realms of empiricism. The newer chemistry of milk had upset the older theories concerning milk. The general laws of animal nutrition had been found to apply to infants and the broad principles of nutrition established by vast numbers of experiments on animals could be used as a basis for teaching. The fundamental laws of animal life, adaptation to environment, inherent protective ability, and immunity, were assuming greater value and had a direct bearing upon the field of pediatrics.

The Relation of Pathological Conditions of the Nasopharynx to the Dental Arch.—Dr. E. A. Bogue of New York City presented this communication. The etiology of narrow dental arches and adenoids was apparently identical, both arising from stoppage of the nose and inflammation of the mucous surfaces. The withdrawal of the infant's tongue from the roof of the mouth, in order to breathe, was the main cause of narrow dental arches. Nasal stenosis was a concomitant of mouth breathing. The treatment should consist of the expansion of the dental arch and ablation of hypertrophied lymphoids. When taken at about the sixth year and understandingly treated, the results would be: Proper articulation of all the teeth with each other, giving as perfect masticatory surfaces as possible; power of correct enunciation and vocal resonance; ample nasal passages and apparent enlargement up to the normal of all the bones and sinuses of the face.

Dr. H. L. Lowenburg of Philadelphia and others discussed the paper.

Adenoids in Infancy.—Dr. John Lovett Morse of Boston, Mass., said, in this paper, that the general impression among rhinologists was that adenoids in young children should not be removed, as they will surely recur and necessitate a second operation. He did not agree with this. Adenoids were very common among infants and should be removed without delay. The symptomatology of adenoids in infants was characteristic, but different from that in childhood. They produced marked disturbance of nutrition, rickets and deformities of the chest. They were the most important cause of recurrent "colds in the head" and chronic "snuffles." They often caused an irritating cough without physical signs, and were frequently accompanied by attacks of catarrhal laryngitis and spasmodic croup. Restlessness and sleeplessness were often explained by the presence of adenoids. Otitis media in infants was almost invariably caused by adenoids. Various illustrative cases were cited.

Dr. G. L. Richards of Fall River, Mass., called attention to the low position of the open end of the Eustachian tube in young infants and to the fact that a very small amount of adenoid tissue would cause trouble, leading ultimately to otitis media and further to mastoditis.

Dr. T. W. Kilmer of New York City and others continued the discussion, which was closed by Dr. Morse.

Prophylaxis in Cerebrospinal Meningitis.—Dr. A. Seibert of New York City read this paper, in which he advocated the disinfection of the nasopharynx in all persons coming in contact with meningitis patients by means of a 50 per cent. resorcin-alcohol solution, applied with absorbent cotton. He was not satisfied with his results until a bacteriological report on the efficiency of the method had been made. He presented a chart giving the finding of this bacteriological investigation. Recent epidemics had shown that this disease is transmitted by persons harboring the meningococcus in the catarrhal mucosa of the nasopharynx.

Dr. F. S. Churchill of Chicago, Dr. Alfred Hand, Jr., of Philadelphia; Dr. A. W. Fairbanks of Boston; Dr. Louis C. Ager of Brooklyn, N. Y., and others engaged in the further discussion, which was closed by Dr. Seibert.

Empyema in Children.—Dr. Melvin M. Franklin of Philadelphia emphasized, in this paper, the importance of early diagnosis. Exploratory puncture aided in this. He recommended incision in children under six years of age; in older cases resection was to be recommended. The frequency of the nonrecognition was a cause of death otherwise ascribed to pneumonia. He emphasized the value of the aspiration syringe as a positive aid in diagnosis, and of immediate surgical intervention.

Dr. W. C. Hallopeter of Philadelphia called attention to the importance of having the transverse colon empty when making an examination of a case of suspected empyema. It was of the utmost importance that effusion be recognized early.

Dr. H. L. Lowenburg of Philadelphia spoke of the unsatisfactory results of physical examination in these cases. Signs in the chest were not always positive. In large effusions very little was gotten from percussion. The reso-

nance which was obtained posteriorly and high up, close to the vertebral column, was important, and flatness in one axilla was almost pathognomonic. Palpation gave little information. Auscultation gave the best results. A case which would recover as a result of simple puncture would get well anyhow.

Dr. A. C. Cotton of Chicago recalled a number of cases in which he had reason to believe that a cure had resulted from lumbar puncture. The statement that the presence of pus always pointed to surgical interference did not always hold true. When the aspirating needle showed pneumococcus pus, pure culture, one need not be in a hurry to operate; if it showed streptococcic pus, operation was required at once. He still believed that it was not advantageous to admit air into the pleural cavity.

Dr. A. H. Wentworth of Boston, Mass., advocated immediate surgical treatment in the event of empyema, regardless of the nature of the bacteria found.

Dr. G. R. Pisek of New York City suggested that if empyema were always regarded as an abscess no one would hesitate to advise operation. If thorough drainage be instituted convalescence was very rapid.

Dr. A. Seibert of New York City recalled two cases of infants in whom he had resected a rib with satisfactory results.

The discussion was continued by Dr. A. W. Fairbanks of Boston, Mass; Dr. Thomas D. Parke of Birmingham, Ala., and others, and closed by Dr. Franklin.

Urinary Infection in Children.—Dr. Isaac A. Abt of Chicago read this paper. He called attention to the relative frequeny of cystitis and pyelitis in young children. The colon bacillus was the organism most frequently found, though the germs of typhoid fever, tuberculosis, and gonorrhea, and the pyogenic micrococci might produce the disease. Infants who were suffering from persistent temperature for a succession of days should in every case have the benefit of a urinary analysis, both chemical and microscopic. The symptoms of the disease, the findings of urinary examination, the differentiation of cystitis and pyelitis, the complications, prognosis, and treatment were detailed in the paper.

Dr. Cotton, Dr. Graham, Dr. Morse and others discussed the paper, and Dr. Abt closed the discussion.

SECTION ON PRACTICE OF MEDICINE.

Wednesday, June 5—Second Day.

Dr. Thomas D. Coleman, Augusta, Ga., Chairman.

The Abdominal Symptoms of Thoracic Disease.—Dr. Allen A. Jones of Buffalo read this paper. He said that acute pleuritis was sometimes accompanied by pain referred to the hypochondriac region of the affected side, and a peculiarity of the pain was its constancy. It was not merely felt upon deep breathing, nor more severely upon inspiration, as was so commonly the case with pleuritic pain. The abdominal pain that was present in some cases of lobar pneumonia was striking in its deceptive characteristics. Not only might the pain of lobar pneumonia be felt in the epigastrium or hypochondrium, but in rare instances it might be present in the inguinal region. If in the right inguinal region the disease might resemble appendicitis so closely as to render the diagnosis difficult. Among the more acute diseases of the lungs or pleura that brought out the point in his paper, none showed better than empyema. This might give rise to symptoms of an acute inflammatory or suppurative condition of a part below the diaphragm. The explanation of the transference of pain to the abdomen in thoracic disease was clear when they recalled the anatomy of the six lower intercostal nerves. Abdominal tympanites constituted one of the annoying symptoms of the disease. A light ice-bag over the epigastrium might impart tone to the abdominal sympathetics. In regard to abdominal symptoms in cardiac disease, one of the most common was epigastric pain resulting from myocardial disease. It was frequently seen in angina pectoris. The patient complained of flatus. It was to be noted that the stomach symptoms did not yield to digestants, but under the effects of iodides and nitroglycerin. Doubtless aortitis was the fundamental fault in not a few patients, as the pain caused by thoracic aortitis might be felt in the epigastrium. An important factor existed also in the dilated and over-distended superior mesenteric vein.

Dr. C. F. Hoover of Cleveland said that this subject was an interesting one, and, in looking over the literature in the Surgeon-General's library, he found mention of reflex pain in thoracic disease made by a Frenchman as far back as 1858. In considering these cases he thought that the phrenic nerve was involved, and that there were three points of tenderness which were of great importance in differentiating between intrathoracic and intraabdominal disease, (a) along the phrenic trunk, between the two heads of the sternoclavicular muscle, (b) just above and external to the umbilicus, (c) the left intercostal space external to the border of the erector spinal muscle.

Dr. Stengel of Philadelphia spoke of a case of pneumonia being operated upon for appendicitis. He said that pain in the abdomen was more frequently seen in children. Extreme tympanites occurred more frequently in pneumonia with diaphragmatic pleurisy. In these cases probably the splanchnic nerves were involved, as they passed through the diaphragm.

Dr. Alexander Lambert of New York said that the paper of Dr. Jones was a timely one, and he referred to cases mistaken for appendicitis. He said that when the pain was due to pleurisy or pneumonia there was an appreciable time between inspiration and expiration when the rectus muscle relaxed. When it was not relaxed it was difficult to distinguish between pleuritic or other involvement.

Dr. W. S. Thayer of Baltimore referred to a very nervous patient, who sent for his physician at any time, day or night. He complained of excruciating pain in the chest at the third intercostal space. Morphine was given several times during the night. The pain was very indefinite. The patient said he was going to die. In a few days the patient went into a state of collapse. There was a marked leucocytosis of 20,000 and the patient gave a clinical picture of a perforative peritonitis. Dr. Halsted operated and found the colon enormously distended with gas. Two days later the patient died. The autopsy showed a large thoracic dissecting aneurysm.

Dr. Neilson of Milwaukee referred to a lady whose symptoms were similar to those described by Dr. Thayer. She complained of pain over the sternum and stomach. Several diagnoses had been made. He called it aortitis, and three weeks later the patient was in a comatose condition and hemiplegic.

Cardiac and Vascular Accompaniments of Diabetes Mellitus.—Dr. Arthur R. Elliott of Chicago presented this paper. He considered his clinical observations treating particularly of the blood pressure. In many of the cases the condition of the heart was normal. Out of twenty five cases of diabetes, in 17 per cent. (average) the heart was enlarged. In a few cases renal changes, hyaline degeneration, and chronic nephritis were present. The myocardial changes were mostly fatty, together with brown atrophy. The state of the circulation was a very important one. One hundred and fifty observations were made on this series of cases; thirteen were males, twelve females, and of all ages. The average blood pressure was 127 mm. The age was the most important factor in influencing the type of diabetes. It was less severe and progressive in the stout and elderly than in the young. Weight exerted a

marked influence in determining the blood pressure. Acid intoxication (diaceturia) was observed in nine cases. Albuminuria associated with diabetes, when due to chronic nephritis or renal sclerosis, showed increased pressure values, although toxic albuminuria exerted no such influence. There was nothing to show that the myocardial and vascular degenerations of the chronic types of diabetes were essential to that disease. There was no such thing as the "diabetic heart." Such complications were only factors in increased arterial sclerosis. Obesity and gout generally preceded cardiovascular degeneration.

Dr. H. S. Stark of New York said that the efforts to establish a relationship between cardiac and muscular disease to diabetes had failed. He believed that diabetes was not a pathological disease *per se*, but that it was an overactivity of an organ which produced not only renal, but circulatory disturbances.

Dr. Heinrich Stern of New York City said that he had studied diabetes for a number of years, and that he had never found any great blood pressure. As to acetone, like cardiac and vascular condition, all were found in the course of the disease, and were not its causes.

Dr. Elliott closed the discussion.

The Venous Pulse and Some of Its Applications.—Dr. L. G. Grosh of Toledo and Dr. Arthur R. Cushny of London, England, presented this communication. They spoke of the research work of Mackenzie and of the importance of considering cardiac activity from the standpoint of its physiological properties of rhythmicity, excitability, contractibility, conductivity, and tonicity. In a number of experiments the venous pulse taken before and after opening the thorax was found unchanged. In the jugular tracing, as a rule, a series of elevations separated by deep depressions were seen. One of the waves corresponded to the auricular contraction. Tracings from the jugular veins of dogs, as compared with tracings procured from the pulsations in the neck of man, were shown. Vagus stimulation arrested the auricular contraction completely, while the ventricle was aroused to contraction by a series of shocks. This was of interest because of the action of drugs on the auricles or ventricles. It was thought that much attention might be directed to the form of the auricular wave in the jugular pulse, that much information as to the state of the heart might be derived from this source, as had occurred from the study of its time relations.

Dr. George Dock of Ann Arbor said that it was only a few years ago that the heart was looked on simply as a contracting muscle. In the last eight years much had been written about Stokes-Adams disease. The heart was certainly a complicated organ, and the fibers of His played an important part in irregular cardiac cases. Much of this advance had been due to experimental physiological investigation.

Dr. Hirschfelder of Baltimore spoke of the interrupted "sea- wave" and of the different interpretations of it. Whenever the tricuspid valve opened there was a fall in the curve. Tricuspid insufficiency meant cardiac breakdown. The nature and origin of this irregularity was important. If it could be proven that it originated in the ventricle then digitalis could be used.

Dr. George Norris of Philadelphia spoke of the necessity of studying heart diseases by recent methods and of the need of the cardiosphygmograph.

Dr. Grosh closed the discussion. He spoke of the importance in measuring the auricular activity and of *Pulsus irregulosis* in "heart block." In conditions like general sepsis there was a marked irregular ventricular contraction.

The Tone of the Respiratory Center in Tabes Dorsalis.—Dr. C. F. Hoover of Cleveland presented this paper. He spoke of apnea and its relation to the preataxic period of tabes dorsalis and reported three cases, all exhibiting unquestionable signs of tabes, which developed apnea. Two patients had each two attacks of apnea, which followed in every instance a hypodermic injection of a small dose of morphine. In these cases there was a vasomotor relaxation of both the arteries and veins, but there was an apparent disproportion between the suspended respiration and the cyanosis. He was unable to find any reference to cases of apnea with tabes dorsalis in the library of the Surgeon-General. A fourth case with chronic aortitis, diffuse arterial sclerosis, and chronic nephritis had attacks of apnea whenever he fell asleep, and was then awakened with air hunger and hyperapnea. Sometimes the apnea lasted for several seconds before respiration became automatic.

Dr. A. A. Jones of Buffalo said that in speaking of respiratory failure in tabes he had seen a case of a middle-aged man who was addicted to the use of morphine. He drank whiskey and smoked. Suddenly he had an attack of apnea which lasted two hours. Camphor and strychnine were given and he recovered. In a day or two he had another attack, not breathing for three minutes. He responded to active stimulation.

Dr. Hoover, in closing, said that tabes dorsalis had been overlooked in these cases of apnea. He suggested in treating these cases that the patients should be inverted as one resuscitates the new-born child. Recently he had tried this treatment in a case of tachycardia. The pulse was 244 per minute, and with this treatment, together with deep inspirations, pulse rate was reduced one-half.

Physiological and Clinical Observations upon the Alimentary Canal by Means of the Roentgen Rays.—Dr. G. E. Pfahler of Philadelphia read this paper, and concluded as follows: (1) The roentgenoscopic and the roentgenographic method of examination each had its advantages. Roentgenoscopically, they studied the motion of the viscera, while roentgenographically they recorded the finer details. (2) The roentgenoscopic method was a dangerous procedure to the operator unless he was properly protected, and even then the amount of exposure should be reduced to the minimum. (3) The bismuth-kefir mixture (bismuth subnitrate 1 ounce, and kefir 1 pint) was the best medium to render the alimentary canal opaque, because it was easily digested, held the bismuth in suspension almost perfectly, and because it tended to counterbalance the constipating effect of the bismuth. (4) The Roentgen examination would demonstrate obstructive disease anywhere along the alimentary canal, and much information as to the character of these obstructions could be obtained. (5) The esophagus could best be studied by oblique illumination. Peristaltic movement could be seen carrying the food downward. Solids were likely to lodge for a short time at the level of the arch of the aorta, but passed quickly through the cardiac orifice. A swallow of liquid, on the other hand, lodged in the lower third of the esophagus for a period of about seven seconds before all of it passed into the stomach. It was probably detained at this point by the sphincteric action of the cardiac orifice which only allowed the liquid to pass in slowly. The capsule dropped through probably before the sphincter had had a chance to act. (6) The Roentgen method of examination was probably most useful in the study of the stomach. By this means the size, form, position, its motility, its mobility, and the effects of massage, respiratory movements, abdominal contractions, peristaltic action, and the effects of food could best be studied. (7) The normal stomach was slightly oblique in the standing posture. Approximately, its upper two-thirds was vertical, and its lower third was nearly horizontal. Essentially the pylorus must be on a level with the lower pole. Its lower pole was usually an inch above the umbilicus. The stomach was normally a very movable organ, as was shown by the fact that about two-thirds of it crosses the median line when the patient lies upon the right side, as was demonstrated by one of my roentgenographs. When distended with food, the pylorus was carried downward

and to the right. (8) The respiratory movements caused the upper pole to move to the extent of the movements of the diaphragm. The lower pole moved from one-half to one inch between forced inspiration and forced expiration. With deep inspiration the fundus was increased in diameter and the pylorus moved to the right. (9) The contraction of the abdominal muscles would cause the stomach to rise from one to five or six inches, depending upon their strength and the degree of ptosis; however, in extreme gastroptosis the stomach might lie below the elevating force of these contractions, as he had observed in one case. (10) These abdominal contractions might be used to mix the food in the stomach. If a person ate an ordinary meal and then took an ounce of bismuth it could be thoroughly mixed with the food in a minute or two, and then studied by the rays. (11) These abdominal contractions seemed to stimulate the peristaltic movements. Therefore, they assisted in emptying the stomach by raising it so that it served as a reservoir, by removing the obstruction which was caused by the kink in the duodenum, and by stimulating the peristaltic movements. (12) These contractions caused not only the stomach to rise, but the entire abdominal viscera. The lower portion of the chest expanded and the diaphragm rose. (13) The reverse conditions developed when the abdominal wall was relaxed. In other words, the tendency in a normal person to splanchnoptosis might be seen when these walls were relaxed. (14) Therefore he believed, first, that the abdominal wall was the main support of the abdominal viscera; second, that the elongated chest might be secondary to the descent of the viscera, and third, that the most important element in the treatment of the gastroptosis and the phthisical chest was the strengthening and toning of the abdominal wall and the correction of posture. (15) In severe grades of gastroptosis, the portion of the stomach that rested below the level of the pylorus served as a retention sack, but the point of actual obstruction to the passage of the food was a kink formed in the duodenum about one inch from the pylorus, where it was firmly attached to the spinal column. The food lying between this kink and the pylorus was usually separated from the food in the stomach by a sharp line. This would serve as a differential point between this form of obstruction and that caused by carcinoma. (16) The Roentgen rays were of value in collecting additional information in the diagnosis of carcinoma of the stomach, but should not be depended upon to make an absolute diagnosis. (17) When a supporting bandage was applied in the treatment of gastroptosis there should if possible be a Roentgen examination to determine whether it was properly applied and whether it was serving its purpose. (18) A moderate gastroptosis might be present and not produce symptoms as long as the motility of the stomach was good. If, however, the motility of the stomach be disturbed by some intercurrent cause, then symptoms would be produced.

Dr. Steele of Philadelphia spoke of the morbid physiology of the stomach and of the great clinical aid the *x*-ray had been, particularly in gastroptosis. It was of great usefulness in those minor cases of atony and insufficiency of the stomach. Formerly it was thought that all stomach diseases were due to faulty secretion. At present one had no reliable method of determining the motor condition. The normal gastric activity and mixing of foods, together with opening of the pylorus, were now studied. Functional disturbances did not belong to gastroptosis, for they were also acquired. There seemed to be some ground for holding that these cases might be of congenital origin. There were certain cases that showed gastroptosis by the *x*-rays without giving rise to any symptoms, and others had very marked symptoms. The best form of treatment was that which improved the general nervous condition.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 10, 1907.

First Vice-President, Dr. Wendell C. Phillips, in the Chair.

Sins of Omission and Sins of Commission in Gynecology.—Dr. G. H. Balleray read this paper. He said that those who engaged in the practice of gynecology had a great number of sins to answer for; the sins of omission were credited to the general practitioner, and the sins of commission to the specialist. The sins of omission began in the lying-in room, and many of the diseases that the child-bearing woman suffered from were due to the negligence of the medical attendant during the two or three weeks immediately following delivery. Lesions of the genital tract were overlooked, the vagina was not douched, and the patient was allowed to leave the bed about the ninth day and at once assumed the upright position and generally returned to her usual occupation, besides enclosing her chest and abdomen with a corset. As a result the vaginal outlet, owing to possibly a nonunion of a perineal wound, was large; the vagina had not undergone involution; the uterus was large and heavy, and the cervix lacerated. When on her feet the uterus sagged down, and the uterine ligaments, having not yet recovered their tonicity, offered but little resistance to its descent. In addition the tight corset and the constipated condition brought about complete procidentia of the uterus. If flexion was produced, it induced venous stasis and interfered with the process of involution, led to catarrhal endometritis, salpingitis, and chronic invalidism. The medical attendant had done nothing to obviate this deplorable condition. Had he repaired the lacerations of perineum and vagina, kept the woman in the recumbent posture for about four weeks, having during this time administered three large and hot vaginal douches daily, the patient might have assumed the erect posture and engaged in her ordinary occupations without detriment. Dr. Balleray believed that all of the recent lacerations of the cervix, or nearly all, would heal spontaneously, if the patient retained the recumbent posture for a month and the vagina was kept thoroughly clean. Primary suturing of a lacerated perineum had proved a very successful operation and it should be practised in nearly every case. Some authors had stated that in all primiparæ the cervix was more or less lacerated; if this statement was true he thought it to be a sad commentary on their obstetric skill, or the degeneration of tissue, resulting from civilization. After the patient was up and about, she should wear the weight of her skirts suspended from the shoulders. No corset should be worn. The period immediately following delivery was not the one in which the women should practise calisthenics. He could not too strongly insist upon the fact that in the treatment of recent lacerations, the results of labor, rest, and cleanliness were of the greatest importance. Cancer of the cervix, which constituted fully 90 per cent. of all forms of cancer of the uterus, never occurred except in those cases in which some form of traumatism had been applied to the cervix. He did not believe that there was a well authenticated case of cancer of the truly virginal cervix on record. Neglected lacerations of the cervix were responsible for the occurrence of cancer of that portion of the uterus. The physician should examine every woman he had attended in labor to ascertain if she was suffering from any lesion of the genital canal. It was only necessary for the profession to be imbued with the necessity of such an examination in order to make it popular. One of the greatest difficulties in carrying out this in private practice was the ill-conceived *amour propre* of the attending physician who was apt to feel that the revelation that a lesion of the genitals existed would be regarded by

the patient and her friends as evidence of lack of *savoir faire* on his part. When the operative gynecologist was consulted in cases of this kind, he should explain to the patients that the lesions of the genital tract sometimes occurred in childbirth even under the most skilful treatment. As a factor in the causation of pelvic disease in women, gonorrheal infection occupied a prominent position and at least 40 per cent. of all women suffering from diseases peculiar to their sex owed their invalidism to the baneful influence of the gonococcus. That nearly all such women could be promptly cured in the early stages of the disease, if properly treated, did not admit of a doubt. If the time ever came when the family physician would take the trouble to examine into the nature of every case of purulent discharge, and would resort promptly to efficient means of treatment, they would then meet with very few of those cases of destructive inflammatory lesions of the female pelvic organs. It was to be hoped that the time would soon come when the family physician would familiarize himself with the means of diagnosis in the incipient cases of cancer. Dr. Balleray said that the sins of commission were the sins of the operative gynecologist. At times he was thoroughly honest in his conviction that he was doing right, but in many cases mutilating operations were performed which were unjustifiable, and had absolutely no *raison d'être* except in the love of *éclat,* and the undying fondness which some men cherished for operative gynecology.

Dr. Edward A. Ayers said that what he would have to say would be limited to obstetrical errors. Obstetrical work had in many instances been simply an annex to gynecological work, and being a poor paying field had not been even fairly mastered by its followers in the general class of practitioners. He was inclined to think that the average results obtained in obstetrical work were lower than in any other branch of medicine or surgery. The most effective service a physician could render a pregnant woman lay in a thorough antepartum diagnosis. Given an abnormality which might be expected to vary the physiological rule, foreknowledge of its existence would enable the obstetrician to minimize its evil effect. Second-class skill would get better results applied in advance than first-class skill applied in emergency. The chief dangers that might develop in pregnant patients were from placenta prævia, eclampsia, malpositions, pelvic insufficiency, and infection. In placenta previa a good prognosis was greatly favored by full preparation for either vaginal or cesarean delivery. Location of the placenta during pregnancy was usually impossible when normally implanted, but central cases would generally cause sufficient enlargment of the os and lower segment softening, with possible direct palpation of the placenta at the internal os, to afford a diagnosis after the seventh month. In practice most cases were unfortunately announced by hemorrhage. Eclampsia threatened by signs well known in urine and nervous system in over 90 per cent. of cases, and in the majority of cases these symptoms could be expelled or delivery induced. The fetus had no established attitude but would gradually take the most comfortable position, that of least pressure and constraint, and ordinarily this was with back forward to fit the maternal lumbar curve and head down which was less neck flexing than the reverse. Whatever position they might find at the seventh month, if they found the pelvic inlet too small to allow head and cervix descent later they should anticipate a shoulder, transverse, or breech presentation. If they found a sagging abdominal wall and uterus with long transverse and short axial diameters, a face, shoulder, or transverse presentation should be anticipated. This sagging, if not correctable during pregnancy by corset support, should lead us to prompt attendance at labor and adjustment of the presentation. Pelvic insufficiency which occurred in about 13 per cent. of all cases required skill in diagnosis. Anyone could recognize a two and one-half-inch conjugata vera after a few examinations of pregnant women, but it required experience to foretell successful forceps delivery in borderland pelvic insufficiency. A full preliminary diagnosis that would give the expert more than a peep into the future removed most dangers of infection. There were many other important details worthy of mention, but those just cited covered most of the field of our "sins of omission" in obstetrics. A study of vital statistics impressed one with the thought that a peculiarly vitalized responsibility was fast falling on obstetrical service. This was due to our declining birth rate, which if it were not for immigration would be on a par with that of France. The decline in the number of children per family was not due to obstetrical shortcomings, and could not be removed by preaching against reproductive restriction, but it lay within the power of the obstetrician to reduce fetal and early infant mortality. With a still-birth mortality of 6 or 7 per cent. added to an infant mortality of 10 per cent. during the first month and 15 per cent. additional by the end of the first year, or one reproductive failure to two successes, one could readily see how large an impress could be made on declining birth rates by improving obstetrical work. As to the "sins of commission," he said that an obstetrical meddler might be defined as one who assisted nature at the wrong time. To give ergot at any time, or to rupture the membranes without knowing how or when labor should be terminated; to institute artificial dilation of the cervix for reasons of impatience, or misinterpretation of preliminary for strenuous contractions; to apply forceps traction with greater regard for securing fetal advance than for cervical endurance; to make any greater compression of the fetal head with forceps blades than blade slipping problems required; to needlessly use forceps; to allow a womb and its voluntary reinforcements to decide speed rates when fetal heads are coming around the curve; to keep the knees flexed against the abdomen when the head crowns the perineum; to try to preserve perineal integrity without seeing the parts; not to know that a uterus is exhausted and to allow it to bleed first and each time make compression afterwards; to postpone perineal stitching when it could be done at the time; to douch an aseptic vagina; to keep a postpartum patient on her back when uterine circulation is stagnant, or to sit her up when it will increase lochial flow; to allow quiescent breasts to fill up and cake; to omit treating nipples as open wounds; to curette a clean uterus, or not to curette away placental remnants; to allow a milk-full mother to avoid suckling her child without protest are a few things that to omit is to fall short of our opportunities for good. Judgment, art, diagnosis, but the greatest of these is diagnosis, early, accurate, and full.

Dr. William M. Polk said that proof was to be had that the doctor was in error when he stated that cancer of the virginal cervix had never occurred. There were other causative factors than trauma of the cervix. Then the statement that the patient should remain in bed one month after delivery was not exactly correct; here the personal equation came in; each case should be treated on its individual merits. All should agree with Dr. Ayers that an antepartum diagnosis was very important. The systematic scraping of the interior of the uterus recently pregnant was a villainous procedure.

Dr. Edwin B. Cragin believed it would be better to speak of the sins of omission in obstetrics and the sins of commission in gynecology. In looking over the work at the Sloan Maternity they had been led to get the patients up a little early rather than to keep them in bed beyond the normal time of nine or ten days, for the reason they found that retroversions were extremely common. If they sent these patients out in two weeks, which was their rule, many would go with retroversions

if most of the time was spent in bed. At present all sat up in bed as early as the fifth day, and were out of bed on the ninth day, and it was observed that posterior displacements of the uterus were less common than when they remained in bed longer. With regard to healing of the cervix, he believed it was better if the patient was allowed to get up so that the parturient canal would drain and keep clean; this was better than the use of douches with their possible risk of infection. As Dr. Polk had stated, each case must be decided upon its merits. With regard to repair of lacerations of the cervix, Dr. Cragin said he was afraid to teach students to make repairs of these immediately after labor. If it was an operative case, with assistants, full anesthesia, with a good light, repair of these cases immediately after labor should be done if the tear was extensive. But without proper assistants, with poor light, to expos ethat cervix to see if it was lacerated, and then to repair it, was, he thought, accompanied by danger and students should not be taught to do it. One of the greatest sins in gynecology had to deal with the repair of a little bit of a laceration of the cervix. If a woman had a little nick in her cervix, with the squamous epithelium covering it nicely, with no subinvolution of the uterus, with no increase in menstruation or cervical catarrh, Dr. Cragin's practice was to leave it alone. These women did better without having their cervical canals narrowed and drainage interfered with.

Dr. J. Riddle Goffe said he did not fancy the title of Dr. Balleray's paper because he had not brought out the sins of omission of the gynecologist, but the sins of commission of the obstetrician. The importance of involution of the uterus should not only be emphasized, but the involution of the ligaments, which were in truth prolongations of uterine tissue, should also be emphasized. These ligaments hypertrophied as the uterus hypertrophied, and involuted as the uterus involuted. Dr. Goffe did not believe that, when the abdomen was opened for any purpose, the healthy or normal appendix should be removed. No tissue or organ that did not offend should be removed. The removal of a normal appendix was an added danger. He wished to call a halt in this practice of removing healthy appendages.

Dr. Brooks H. Wells said that if the labor was managed with ordinary skill and care as to the maintenance of asepsis, if the attendant refrained from unnecessary vaginal examinations or manipulations of the cervix and kept the external parts clean during the puerperium by instructing the nurse as to the manner and intervals of washing and the frequency with which the vulvar pads were to be changed, he would not often have fetid lochia or sepsis, and the average patient he believed would be better off without the vaginal douche. Tears of the perineum and vagina should be looked for at the end of labor, and sutured if found, except when the parts were so contused and edematous that operation seemed to be out of the question. Tears of the cervix did not require immediate suture unless so deep as to cause persistent hemorrhage. When the patient had suffered deep perineal tears she should be kept off her feet until the laceration was healed; otherwise she was better if allowed to sit up in bed or on a commode during defecation and micturition, as this posture effectually freed the vagina from clots and lochia. Where retroversion and prolapse was found after labor Dr. Wells did not believe the attendant should be often blamed for it, or that it was caused by too tight a binder or too early rising from bed. In the great majority of the cases the displacement was present before. The causes of deep laceration of the cervix he divided into two groups, the traumatic or instrumental or manual delivery and chronic endometritis, or more properly, metritis. The tear in a healthy cervix from external force would often heal, especially when favored by asepsis and rest; the tear from chronic disease was not apt to heal. Gonorrhea when limited to the vulva and vagina, if rigorously attacked, could be promptly cured, but such limitations were rarely met with. The statement made by Dr. Balleray that "neglected laceration of the cervix was responsible for the occurrence of cancer of that portion of the uterus," and that "where there is no traumatism there is no cancer," was true to only a very limited extent. He had personally seen three cases of cancer in undoubtedly nulliparous cervices; two of the women were virgins and the third had only had sexual intercourse for a short time. Cervical injuries should not be overestimated in their influence in the causation of cancer.

Dr. Louis J. Ladinski believed that if a lacerated cervix had not healed within one week it would not heal at all whether the patient was in bed or not. Therefore, he could not agree with Dr. Balleray that keeping the patient in bed for weeks would favor the healing of a torn cervix, nor did he agree that vaginal douches would tend to promote union; repeated douching, on the contrary, would only interfere with the adaptation of the lacerated surfaces of the cervix. With regard to immediate trachelorrhapy, this should not be attempted unless under the most favorable conditions as regarded asepsis, equipment, and assistants. It was different, however, with lacerations of the perineum if the work was done by those who had sufficient experience in this line of work. Dr. Ladinski said that if lacerations of the cervix was a factor in the production of carcinoma of the cervix even to a slight degree, he would certainly have seen a much larger number of cases than he had. Of the few cases seen by him, two were observed in positively nulliparous women, one of which was seen with him by the late Dr. Mundé. With the exception of the slight tears mentioned by Dr. Cragin he was in favor of repairing every cervix that was lacerated, hypertrophied, or everted. With regard to gonorrheal infection, he said that frequently without any external evidences they found that not only the endometrium was the seat of infection, but the tubes, and even the peritoneal cavity had also been involved. He related a case that showed that the gonococci might infect the tubes, and the pus leak into the peritoneal cavity producing a general peritonitis, without any external signs whatever. He closed his discussion by stating that it required no emphasis on his part to say that there was absolutely no justification in removing uteri containing a little nodule, or a little fibroid, or an absolutely or nearly normal ovary.

Dr. Robert T. Morris believed that an unnecessary death rate would follow the removal of normal appendices. When they opened the lumen of a normal appendix, they opened a direct spigot of infection for the peritoneum, at a time when the peritoneum was not prepared for self-protection. When there was a real infection of the appendix, be it ever so slight, a protective leucocytosis was called out rapidly, and then they could do a great deal with the appendix safely. With regard to primary trachelorrhaphy, if one closed a tear in the cervix immediately after delivery, and included a little nidus of infection in the depths of the wound, he placed it out of the current of protection from the lochia; this lochia was the patient's protection, loaded as it was with nucleins and other elements prepared by nature. With regard to repairing old scars of the cervix, he asked what had become of Emmet's sign. If they pressed the finger or probe against a cervix scar, and there followed an immediate reflex to the lumbar plexuses, or if local pain was complained of, then there was good presumptive evidence that the scar was a persistent source of disturbance, and that it had entrapped nerve filaments, and required surgical repair.

Dr. Charles L. Dana said that a large per cent. of backward children, imbeciles and idiots was the result of some defect in the condition of the mother during the parturient process; therefore, it became necessary not

only to examine the urine, measure the pelvic diameters, etc., but they should see if there was anything in the life of the parent that might influence the condition of the child. An interesting point to him was that the bilateral arm palsies, epileptics, cerebral hemorrhages, hemiplegias, defective mental development, etc., were, in many cases, due to conditions which might be relieved by surgical interference. When a child was born and had general convulsions on the second, third, fourth, or fifth day, the cause was probably meningeal hemorrhage, and Cushing advised opening the skull, and washing the hemorrhage out, claiming that this would bring the child to its normal condition. In regard to the work of the gynecologist, Dr. Dana said that he remembered the time when all sought him with the hope that he could relieve the women of their neuroses or psychoses: they were choked with attention.

Finally the neurologists had to take the defensive, and assumed the attitude of open hostility against the gynecologists. They were operating upon uteri, curetting, sewing up tears, etc., but they were not curing the nervous manifestations. To-day the attitude had been changed. He had often asked neurotic patients what had been the result of operations, and he had come to the conclusion that, in a large proportion of the cases of so-called psychoneuroses, operations for the relief of subinvolution, tears, the removal of scars, did not really do any good, but often did harm. In the psychoneuroses group of patients, those with obsessions, operations were generally unsafe; they might cure them of back or pelvic pains, but they got up something else. In the hypochrondiacal group of patients, operation might relieve the local condition, but not the psychic condition. In the simple neurasthenic group of cases, where the patients were made ill by irritations in the pelvis, operations were extremely helpful.

Dr. Edward A. Ayers said that everywhere, throughout the world, the cases of epilepsy averaged one to six per thousand. The statistics of the English lying-in institutions showed that where the mothers, during the pregnant state, were accustomed to overindulgence in alcohol, the per cent. of epileptics was from 40 to 50 per thousand among the infants born. It was also shown that, when the mother was intoxicated, the fetus *in utero* might absorb seven-eighths of an ounce of alcohol. This evidence showed that certain forms of nervous maladies had a direct relationship to the condition of the mother.

Dr. George H. Balleray said that after abortions or miscarriages there could be no objection to passing the finger, or the hand if necessary, into the uterus to remove secundines. The curette he believed was not justified, and should be condemned in the hands of the general practitioner. In regard to cancer of the cervix, he said he had never seen a case in a virgin uterus. When the abdomen was opened for pelvic conditions and the appendix was normal, he thought it meddlesome surgery to attempt its removal. He believed in keeping the patients with extensive laceration of the cervix, of the perineum, or of the vagina, but especially in the former, in bed. He employed douches in these cases, because, as in general surgery, wounds would not heal unless kept clean. With regard to the gonorrheal cases, the women should be kept as quiet as possible and the vagina should be thoroughly cleansed. Sulphuric acid 1-30, or bichloride 1-4000 should be given, not less than two gallons, and as hot as 110° F. If this treatment was carried out every day, with the woman kept in the recumbent posture, one could get control of the disease in two weeks. The tendency was for gonorrhea to travel up: therefore, the treatment should be early and pursued energetically.

Locomotor Ataxia. A New Theory as to Its Cause.—Dr. L. N. Denslow presented this communication. (See page 985.)

Medical Items.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended June 7, 1907:

STERILIZED HORSE SERUM IN SURGERY.

BY RAYMOND PETIT, M.D.,

PARIS.

LATE ADJUNCT CHIEF OF CLINIC TO THE FACULTY OF PARIS.

WHEN isotonic saline solution is injected into the peritoneal cavity there is produced an afflux of a considerable number of polynuclear white blood cells to the spot, and the natural resistance of the serous membrane to any infection is markedly increased. Such is the experimental fact that has been brought to light by the experiments of Issaeff. This author found that in a peritoneum prepared by the injection of isotonic salt solution he could inoculate several lethal doses of the cholera vibrio without there being any bad results, while uninjected animals succumbed to a single dose in twenty-four hours.

At the request of M. Metchnikoff, I have repeated these experiments with various chemotactic substances and with several species of pathogenic microbes. It has been found after several attempts that boiled horse serum is the substance which is of the most use for inducing polynucleosis. Many other substances may be used to produce polynucleosis by chemotaxis, such as physiological salt solution, peptonized bouillon, aleurone, nucleinic acid, and various normal sera; but they do not produce the desired afflux of leucocytes to the same degree nor with identical effects. Aleurone, for example, draws a large number of polynuclear leucocytes, but hungry for grains of aleurone, they gorge themselves and have not the same appetite for phagocytosis with reference to microbes.

The normal sera have seemed to produce the greatest polynucleosis which may be utilized for phagocytosis, and that of the horse is the best, since it is less toxic than that of the cow, and can be made almost entirely inoffensive by heating it in a water bath for two hours, for three consecutive days, at a temperature of 90° C., to destroy the alexin without altering the natural sensibilization.

After having thus produced a polynucleosis in the peritoneum of animals, it has been found possible to inoculate with impunity into the serous membranes a number of lethal doses of cultures of cholera vibrios, typhoid bacilli, *Bacterium coli*, *Staphylococcus pyogenes*, etc.

The results of these experiments led to the attempt to use this method in the treatment of infections in man. The results obtained have been excellent, and since 1900 sterilized horse serum has been employed in suitable cases in private practice, as well as in the Hospital for the Treatment of Industrial Accidents. I have become convinced that we can cure by phagocytosis and that the afflux of polynuclears by means of sterilized horse serum takes place not only in the peritoneum, but in all the serous cavities, in the mucous membranes, and in wounds of all regions. More than a hundred cases can be cited, some of which have already been published, in the *Revue de Gynécologie et de Chirurgie Abdominale*, by Pozzi (July and August, 1906), and in the Bulletin de la Société d'Obstétrique de Paris (February 19, 1906).

The cases treated may be summarized as follows:

1. *Abdominal Surgery.*—The sterilized horse serum has been used as a prophylactic measure in operations of a non-septic character, and as a curative measure in cases characterized by infection. Cases in which it was used as a curative measure include appendicitis with abscess, operated on in the active stage, general peritonitis, and suppurative salpingitis with pelvic peritonitis, and suppurating cholecystitis with pericholecystitis. In all these operations we have made the usual interventions, with the usual aseptic precautions. In all cases of acute appendicitis the appendix has been removed at one sitting. After the operation drainage has been employed and the serous cavity has been lightly packed with gauze impregnated with sterilized horse serum; horse serum has also been poured into the peritoneal cavity through the drainage tube. The dose usually employed was 30 cubic centimeters. On the following day the same dose was repeated, through the drain. Under these conditions the temperature was slightly elevated at first, and then fell to about normal. The character of the pus was at once changed; instead of a serous fluid, a creamy, thick pus appeared, the "laudable pus" of the ancients. The pus before the operation examined under the microscope contained but few elements of defense (leucocytes and polynuclears), with a considerable number of free microbes; after the use of the serum innumerable phagocytes were found gorged with microbes, and few free microbes. Suppuration diminished rapidly, and the case entered at once upon a phase of active granulation, continuing until cicatrization was complete. A case of acute appendicitis with large prerenal and subhepatic abscesses was cured completely in three weeks, with a good cicatrix.

Under the head of prophylaxis the serum was made use of in two ways. In the course of operations for ovarian cysts, epithelioma of the ovaries, abdominal hysterectomy for cancer, and extrauterine pregnancy, ruptured or unruptured, when a fault in the asepsis was feared, or after a prolonged operation with adhesions, the serum was poured into the peritoneal cavity in doses of 30 cubic centimeters. Drainage was instituted and gauze saturated with the serum was left in place, or immediate suture of the entire incision was made. In all the cases thus treated there were no bad results.

In cases of gastroenterostomy or enteroanastomosis a different procedure was employed. The evening before the operation there was injected into the peritoneum 30 cubic centimeters of the serum, a puncture being made with a special trochar, constructed

by Galante, which protects the abdominal organs from injury. Injections made in this manner have never caused any trouble, and the procedure allows an operation on a peritoneum that is protected by a reinforced resistance due to the presence of the polynuclears.

2. *Gynecology.*—Most of the cases under this category are puerperal infections, post-partum or post-abortum, very characteristic, accompanied by high temperature and even the presence of thick false membranes over the cervix, vaginal walls, and vulva. The procedure is as follows: It is first ascertained that the uterus is empty, by removal of placental debris with the curette or of membranes with forceps; the uterus is then cleansed by means of two or three hundred grams of physiological salt solution and swabbing the interior of the uterus and the vagina with a piece of heavy, sterilized gauze on forceps. A piece of sterile gauze is impregnated with the serum and in the center of the folded strip is placed, as if in a pocket, one to three grams of serum evaporated in a vacuum. This pocket is introduced to the fundus of the uterus, placed transversely from one horn to the other, and the remainder of the strip is packed into the uterine and vaginal cavity without making any pressure. This packing is left in for twenty-four hours and renewed daily for three to eight days thereafter. The strips when drawn out are sticky, having taken up a liquid which is thick and gray, like a solution of rubber, of a strong and peculiar odor, extremely rich in polynuclear leucocytes in full phagocytic action.

The temperature after being somewhat elevated for a few hours falls after the first packing. At the same time the false membranes and eschars come away, the wounds granulate actively, and the general condition rapidly improves.

3. *Purulent Pleurisy.*—Two exceptionally grave cases of purulent pleurisy have been treated, one in an infant (staphylococci and streptococci), the other in an adult (staphylococci, streptococci, and anaërobic bacteria) with pulmonary gangrene. In both cases, after resection of ribs with drainage, there was poured into the pleura thirty cubic centimeters of serum each day for several days. Both patients were rapidly cured, and the pus presented the same transformations as have been noted above.

4. *Various Phlegmonous Infections.*—In this group are included severe submaxillary phlegmon, diffuse phlegmons of the limbs and trunk, anthrax, furuncles, tendinous phlegmons, erysipelatous phlegmon, edematous gangrene, septic injuries of the fingers, etc. In all these cases multiple incisions and drainage were made use of: then the serum was poured into the drains and the wounds tamponed with gauze soaked in serum, after powdering them with serum dried into powder. Rapid healing with excellent cicatrices was the result.

5. *Burns.*—Several cases of burns have been treated, those produced by fire as well as by chemical agents (vitriol). In these cases moist compresses were employed of aseptic gauze soaked in serum. Burns of the second degree, dressed after evacuating the serum from the blisters, were cured in one week. In burns of the third and fourth degree with eschars the latter became detached in three or four days and left behind a pink, granulating surface. In one case there were burns of the third and fourth degree on both legs and one arm. At the same time dressings were employed of phenic acid on one leg, horse serum on the other, and sterilized water on the arm. The eschars treated with horse serum separated first; one week later those treated with sterilized water separated, while those on the leg, treated with phenic acid, persisted several days longer. The same rapid separation of the tenacious eschars which form after acid burns was observed. A case of eschars after a trophoneurosis should be added to these cases, which was as happily modified by the treatment as the others.

6. *Repair of Wounds by Second Intention.*—It has been observed that abscesses, granulating wounds, atonic wounds, such as old varicose ulcers, etc., are rapidly modified under moist compresses of horse serum. After the second dressing the wound becomes rosy, and an active granulation invades it; it bleeds easily, and soon begins the formation of new skin.

It is not well to apply this dressing more than once, and if it is continued there is soon produced an arrest of the process of skin formation. A very rapid formation of skin is obtained by using for compresses a solution of bicarbonate of sodium, 1-100. The best of results have been obtained by the use of semi-moist compresses, that is, by employing moist compresses without covering them with impermeable silk tissue.

To sum up, there have been obtained with sterilized horse serum, healing and cicatrization, both excellent and rapid, in severe cases and even in desperate diseases, after failure with the ordinary methods of treatment. These results have caused the systematic trial of this treatment, based on chemotactic and phagocytic properties, as well in hospital as in private practice; and for the last two years the statistics have left nothing to be desired to convince one of the value of the treatment.

The use of sterilized horse serum is but a means to realize a new method, a means that has been made use of because it presented the best vehicle for the use of phagocytosis by formation of polynuclears, a vehicle most favorable to the life of the cells of the organism. As soon as a better method has been arrived at that method should at once be substituted.

What is desired is rather to establish this new method of treatment, based on the discoveries of Metchnikoff, laboratory experiments, and clinical cases, than to exploit the value of sterilized horse serum. This method of surgical treatment of infections is concerned above all with the organism affected; it seeks above all to utilize the resources of the organism itself, to increase to a maximum its natural means of defense, and place the tissues in a condition of offense under the best and most favorable conditions for repair. Differing entirely from antisepsis and asepsis, which always retain their indications, this method seeks not to destroy the microbes in a wound by the aid of chemical agents and caustics, which alter the vitality of the cells; it no longer contents itself with placing a boundary to the approach of the germs; on the contrary it seeks to aid the organism to make its own defense and repair. Aseptic in its application, since the horse serum is sterile and is used on sterilized gauze, this method has for its object to create antisepsis by phagocytosis and to favor the life of the cells by cicatrization.

Ophthalmia Neonatorum.—J. Clifton Edgar advises the preparation of the vagina in all suspected cases by the use of a douche of a mild alkaline solution, followed by one of a 1 to 5,000 bichloride of mercury solution. In addition to this Credé's treatment of the eyes should be carried out, namely: Wash off each eye with a separate boric acid wipe; into each eye instill two drops of a 2 per cent. solution of silver nitrate; in about thirty seconds wash out the excess with saline solution.—*Colorado Medical Journal.*

PYREXIA IN TUBERCULOSIS.*

WHAT IT TELLS US AND HOW IT MAY BE CONTROLLED.

By HENRY P. LOOMIS, M.D.,

NEW YORK.

We have in the thermometer a most important aid in the diagnosis of certain obscure cases of tuberculosis, as well as the greatest help in estimating the character and activity of tubercular processes when once established. It is especially the day temperature by which this indication is given.

The thermometer tells us when our cases are arrested or cured. It aids us in many of our plans of treatment; without it tuberculosis would be a much more difficult disease to handle than it is. It is as a plea for its more general and systematic use that I venture to bring to your attention certain facts in reference to the temperature in pulmonary tuberculosis. One who watches phthisis in hospitals and sanatoriums quickly learns how important the daily temperature curve is, how its variations are to be interpreted, and how it modifies treatment. The practitioner who sees the case only in his office or possibly once a day at the patient's home, and then without a continued temperature record, is at a great disadvantage. Often if the temperature is taken it is found to be normal, and the patient is allowed to go about, although during most of the rest of the twenty-four hours the temperature may range above 102°.

All persons with phthisis can be taught to take their temperature regularly and keep accurate records of the same. This is a plan I have long adopted with patients who are seen only at stated intervals. I have found it of great help—it enables them under directions to regulate their exercise and often change the time of taking the medicine. It may be argued that neurotic individuals would be unfavorably affected by this constant knowledge of the amount of fever they have. I have found this the case only in a very small number of individuals—after the reason of this temperature taking has been explained. If it is not advisable for the patient to take his temperature, some member of the family can do it, if the patient is not sick enough to have a trained nurse. Since I have adopted this plan I have been surprised at the amount of temperature certain cases were running who were going about, often attending to their business, and whom I supposed had no elevation of temperature to amount to anything.

I believe the temperature should be taken at least every four hours from the time of awakening to going to bed, to give us a temperature curve of value. Dr. Brehmer insists that a two-hourly temperature curve is much better. While it is advisable to take the temperature per rectum when it is convenient, this I do not think is absolutely necessary if care is used in taking mouth temperature. I have compared the two curves in a large number of cases, temperature being taken both by the mouth and rectum, and the variation is always constant and usually one-half degree. The fever in phthisis is no doubt dependent upon two causes, one the absorption of the proteins of the tubercle bacilli, the other the absorption of the toxins from the secondary bacteria (mixed infection).

The range of temperature during the progess of active pulmonary tuberculosis is one of the most important indications we have of the specific morbid process. By means of the temperature range we can in some instances suspect tuberculosis and make a tentative diagnosis long before physical signs and symptoms are sufficient to justify such a diagnosis. By the temperature alone almost any case can be diagnosed within three weeks from its onset, for by that time other causes for the rise in temperature, such as typhoid fever, scarlet fever, pus formation, etc., can be excluded. Although the temperature affords a very accurate measure of the activity of pulmonary tuberculosis, it does not follow that when fever is absent we are to conclude that the patient is free from the disease. It does enable us, however, to interpret the physical signs which are present.

Again the range of temperature during the progress of tuberculosis is one of the most important indications which we have of the activity or subsidence of the specific morbid process. It is sometimes a more precise indication of the amount of tuberculosis than either the symptoms or physical signs. In the presence of an active disease the temperature rarely touches or even reaches the normal line. Fluctuations take place in every twenty-four hours, but the lowest temperature recorded is febrile. The higher the day temperature the more active generally is the process and the more unfavorable the prognosis. So long as there is an active temperature range it may safely be assumed that a deposit of tubercles is taking place, even though the physical signs remain for a time unaltered. I might make two exceptions to the above statement.

1. It must be remembered that a large amount of tuberculous deposit, such as is seen in so-called fibroid phthisis, may be present in the lungs without causing any rise of temperature, but this proves that the morbid process is quiescent and localized, and that no systemic poisoning is taking place. In these cases tubercle bacilli may be found in the sputum even in large numbers; but a normal temperature is by no means the rule in fibroid, for there is generally a slight rise reaching to 100° or 101° F., continuing for a time, and then the temperature may become normal for a time only to rise again for a varying period. This alteration may endure for years, slowly undermining the health. In other cases of disease of this type the disease progresses so slowly and the deposit at any one time is so slight that it is insufficient to elevate the temperature to any extent. Towards the close of life in certain chronic cases the temperature not uncommonly becomes normal and so continues until death. These people die from irreparably broken down health or serious secondary disease rather than from the active tuberculosis disease. Although the course of the temperature is a rough indication of the course of the disease, it must be remembered that other factors are at work in the production of pyrexia in addition to the actual tuberculous process.

2. It must not be forgotten that personal idiosyncrasies may affect tempertaure. It is a well known fact that febrile reaction set up by similar agencies varies greatly in different individuals. Some have an unusually high temperature from trivial causes, while others are only slightly affected. These form an exceptional class of cases and in them the temperature chart may be equivocal, and hence must not be too closely regarded if other symptoms point to different conclusions, such as wasting, night sweats, anorexia, diarrhea, etc.

*Read at a meeting of the Section on General Medicine of the New York Academy of Medicine, March 19, 1907.

Although the temperature affords a very precise measure of the activity of a tuberculosis, still, in forming a prognosis, we must be careful not to overestimate it, for other circumstances must be taken into consideration. In many cases, although the temperature is high, the disease after a time declines and the patient recovers. In forming a prognosis in cases with elevation of temperature we must be governed by the effect of absolute rest and treatment. If in spite of this the temperature continues high, the prognosis is bad. If the appetite and power of assimilation, in spite of the temperature, remain good, the prognosis is good. These cases often gain in weight in spite of more or less fever, but usually a temperature precludes a gain in weight in spite of the appetite.

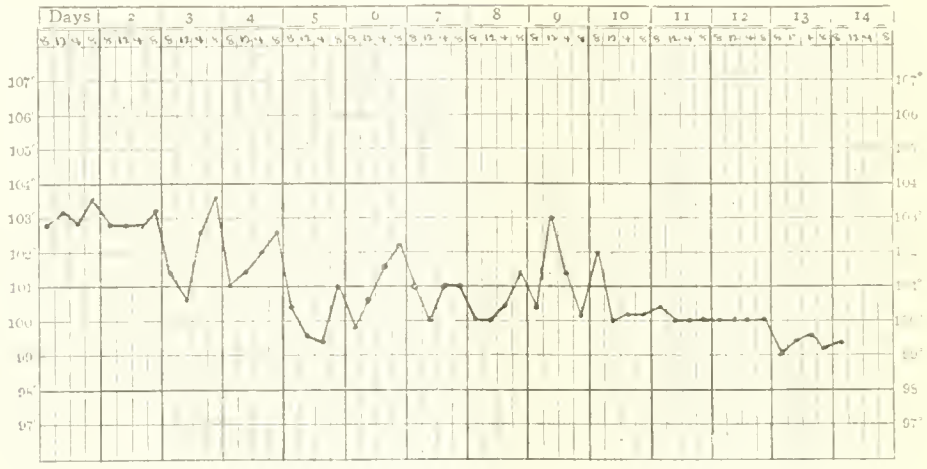

CHART 1.—Showing the effects of the drug when administered continuously; the dimethylamido-pyrazolon was given every four hours, beginning on the second day.

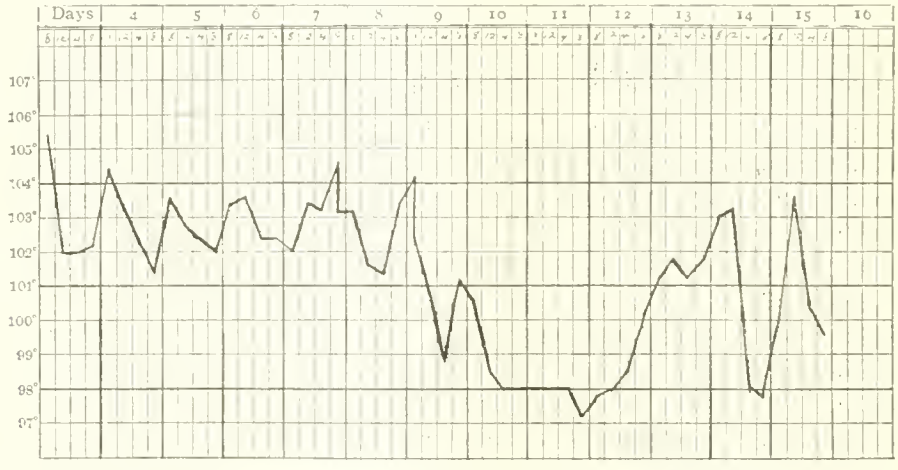

CHART 2.—Showing the effects of the drug administered for three days, the dimethylamido-pyrazolon was given every four hours on the seventh, eighth, and ninth days only.

The thermometer is a very important aid in estimating the seriousness of a pulmonary hemorrhage; if accompanied by high temperature it indicates that when the hemorrhage stops the evidence of marked destructive changes will be recognized at an apex by physical examination. Hemorrhages with but little or no fever, even if severe, are of little importance unless the case is one of fibroid phthisis.

The diagnostic value of the temperature range in a case of phthisis, during active stages of the disease, may be roughly summed up as follows:

1. If the daily temperature is high and never touches the normal, and especially when accompanied by a rise of two or three degrees at night, the case is probably one of acute localized miliary deposit, or possibly of acute general pulmonary tuberculosis.

2. If the daily temperature is irregular, sometimes normal, and at other times ranges between 100° F. and 101° F., and associated with an evening rise, it may be inferred that a slow and inactive deposit of tubercle is taking place. A general gain in weight and general improvement would be observed as long as the evening temperature remains below 101.5° F.

3. If the temperature during most of the day remains about normal and the evening rise does not exceed 101° F., one may infer that the tuberculous process has advanced very slowly if at all.

4. If the day temperature remains always normal and the evening rise does not exceed 99.5° F., one may infer that the tuberculous process is quiescent.

Treatment of Pyrexia.—In the treatment of pyrexia in pulmonary tuberculosis it should be borne in mind that a patient does not suffer or show the

constitutional disturbances at all compared with patients suffering from other active diseases, such as those with pneumonia or typhoid fever. This applies even to those cases of phthisis with a maximum temperature fully as high as that of other fever patients, and at the same time it must be remembered that a reduction of fever in phthisis cases does not offer the same amount of relief as it does in other cases—notably typhoid fever. In fact, cold sponges, which are so effective in every acute disease, are very apt to be followed by chilly feelings which may persist for a long time and render the patient very uncomfortable. It is also well to remember that the maximum temperature seen in phthisis is apt to be much less prolonged than it is in other fever cases, but at the same time it should be kept in mind that many of the symptoms seen in cases of phthisis can be referred directly to the effects of the fever, such as anorexia, loss of weight, and night sweats. While the cold sponges are not ordinarily advisable as a means of reducing temperature in phthisis, still the sponging of the surfaces night and morning in lukewarm water to which an equal quantity of alcohol has been added should be followed in almost every case of fever, as it is not only exceedingly grateful to the patient, but will modify or control to a certain extent not only the temperature, but many of the other symptoms, especially the night sweats. It is only in those cases of phthisis with a persistently high temperature that the fever should be directly treated, and in most other cases the various measures adopted to improve the person's health will in time have a controlling effect upon a moderate fever. In cases of phthisis in which the temperature range is distinctly an unfavorable element, the fever should be treated in the following manner:

We should bear in mind the fact that the patient should be treated exactly as if he was suffering from an acute inflammatory disease, such as lobar pneumonia. The patient should be kept absolutely still in bed and should use the bed pan and the urinal. The reason for this is that "the fever in itself denotes loss of bodily substance; if to this is added further loss through movements, the loss is as a rule too great to be covered by nutritive processes which are depressed by fever—the result is a waste of body substance and increased absorption not only of fat and albumen, but also of the proteins which set up more fever. It is above all important to break this vicious circle." This can only be accomplished by *rest* in bed. It has been found in sanatoriums that fever can be much more readily controlled where arrangements can be made so that the bed can be wheeled out upon the piazza. The patient lies in the open air and is always completely protected from the rays of the sun. My experience has proven that the direct sun rays have in the majority of cases of phthisis, even in those in whom the disease is quiescent, a tendency to elevate the temperature. A modification of this plan can be adopted in private houses by bringing the bed close to an open window in suitable weather and thoroughly protecting the patient from draught. A tuberculous patient with a high temperature should be kept not only physically, but mentally quiet. Visits from friends and long conversations should be prohibited. The diet should be the same as in acute pneumonia. The patient should be fed on what is known as "soft diet" every two or three hours in a small quantity. The diet should consist of milk modified by lime water or vichy water, or better, peptonized. Beef tea to which has been added a small quantity of one of the meat extracts can be given. Soups, such as chicken or mutton broth, are suitable in these cases. Stimulants should be given at regular intervals, but in small quantities. Four teaspoonfuls of whiskey to a glass of milk makes a good combination. In ordinary cases four ounces of whiskey or brandy may be given daily. Dr. Brehmer considers wine much more advisable for this class of cases and is in the habit of giving Hungarian wine, or a stronger wine (8-12 per cent. alcohol) about three wine-glasses a day. Many patients who do not take whiskey readily can find a substitute in a good wine, such as port, sherry, or Madeira. No objection can be made to the use of tea or coffee in moderation, especially the early morning cup. If the digestive organs are in exceedingly good condition an ordinary diet with three meals daily may sometimes be given even with high fever. Forgetfulness of the fact that high temperature in tuberculous cases should be treated exactly as in cases suffering from an acute or infectious disease is the reason more than any other why so unsatisfactory results are obtained and why the temperature is looked upon as a part of the disease and necessarily uncontrollable. It is my experience that most antipyretics do more harm than good in cases of phthisis; and while an elevation of temperature can often be controlled by large doses of antipyrin, antifebrin, or phenacetin, the effects are only temporary and at the expense of the patient's vitality and general comfort. When the temperature of tuberculous patients cannot be modified or to a certain extent controlled by the indirect methods which I have suggested, the use of quinine and codeine, given in combination, is sometimes attended with the most gratifying results. Five grains of quinine in a capsule with a one-quarter grain of codeine ordered every four hours is continued until the patient has taken a drachm of quinine. When an effect has been produced upon the temperature range the quinine is reduced to every six hours and later three times a day. The only other drug I am in the habit of using is dimethyl-amido pyrazolon (pyramidon). Professor Kobert, who has tested this drug in a large number of cases of tuberculosis, reports that he has never seen any depression or unpleasant effects follow its use. In his report he compared its effects in a number of cases with quinine, euquinine, antipyrin, antifebrin, and the salicylates, and found it superior to any of them. At the sanatorium at Liberty it is extensively used to control tuberculous temperatures. In fact it is practically the only drug now used. When it is effective the disappearance of the fever is gradual and the subsequent rise in temperature as its effects pass off is slow. The abatement of the fever of consumption in the early morning is often accompanied by violent sweats. In order to control these sweats, which are not only very unpleasant, but also distinctly harmful, I am in the habit of using one of the salts instead of the drug itself—namely, the acid camphorate. Whether the salt or the drug itself is used the dose which I have found most effective is ten grains every four hours. The drug occurs as a tasteless white powder very soluble in water. As I have said, you will find the effects of this drug on temperature to be gradual, and three or four days must elapse before marked effect is noted. Then the temperature in cases in which it is effective will be noted to be gradually coming down.

It is now a generally accepted fact that most of

the fever proceeds from the absorption of the septic by-products, generally of the ordinary septic microbes. We have two means at hand which are claimed by some to diminish the septic changes which usually occur in the diseased area: (1) The inhalation of various volatile drugs; (2) the use of antistreptococcus serum.

Of the former I often make use, and it seems to me with extremely satisfactory effects upon temperature in some cases. The patient can wear an oronasal respirator at times during the day and often it is possible to wear it at night. I have found that a mixture of equal parts of creosote, alcohol, and chloroform, ten drops on the sponge of the inhaler, gives the best result.

There are a number of antistreptococcus sera on the market and when they are prepared by well known houses are reliable. I have made repeated trials of them in a number of cases of mixed infection with fever, but never have I been able to satisfy myself that they have any controlling effect upon the temperature. I cannot recommend them.

The freer the elimination of the purulent material from the diseased area the less likelihood there is of septic infection and fever. Therefore to bring about this we rather encourage expectoration and do not stop the cough by cough mixtures unless it becomes very troublesome at night; the morning cough should be especially encouraged, as that serves to get rid of the secretion which has accumulated during the night. This can often be encouraged and made much easier for the patient by giving early in the morning a glass of hot scalded milk to which seltzer water has been added.

An important practical point to decide is often presented to the physician, namely, shall a febrile patient undertake a change of climate? I do not know in certain cases of tuberculosis a more difficult problem to decide. So much depends upon the decision. We would naturally say that cases of active temperature should not be moved. Still, I have seen, as you all have, patients with tuberculosis that have run high temperatures for weeks which have resisted all treatment show a marked improvement with a quick reduction of their temperature upon change of climate. These are the exceptions, however. My rule has been in the ordinary febrile cases, after the temperature has been below 100° for three days, to allow the patient to get up at first for an hour or so a day, then longer. As soon as the patient is able to go about the house without having a temperature of over 101° at any time within the twenty-four hours to say that a change of climate can with safety be made if it is deemed advisable from a general consideration of the cases. I believe patients running a higher temperature should not be sent away unless the physical and local conditions both warrant the change, and then only when the case is put directly under the care of a physician where the patient is going.

I would summarize the treatment of pyrexia as rest, mental and physical, in the open air if possible; liquid nourishment and alcohol in a form most agreeable to the patient; tepid spongings with alcohol and water, equal parts, and if these means fail, pyramidon or quinine and codeine.

58 East Thirty-fourth Street

Obstetric Pads.—M. V. MacDonald says that a good grade of cotton waste, at seven or eight cents a pound, such as is used by engineers for cleaning purposes, can be made absorbent by boiling in a soda solution, and makes an excellent foundation for obstetrical delivery pads.—*Nurses' Journal of the Pacific Coast.*

THE PROBLEM OF INFANT FEEDING.

By O. HEUBNER, M.D.,

BERLIN.

PRIVY MEDICAL COUNCILLOR; PROFESSOR OF PEDIATRICS AT THE UNIVERSITY OF BERLIN; DIRECTOR OF THE UNIVERSITY CLINIC FOR CHILDREN'S DISEASES IN THE CHARITÉ HOSPITAL.

As a text for the following remarks I will relate the histories of two children recently examined in my clinic at the Charité. These two little patients, twins, were one month old. Both showed inferior bodily development. The elder but weaker child, the boy, was artificially nourished from birth. He received at first 60 to 100 grams of milk six times a day, and afterward a smaller amount every two hours; but he did not thrive on this quantity. The child's weight at birth was 3,150 grams, and at one month of age 2,550 grams. He had had disturbances of nutrition from the very beginning. The stools became greenish, and vomiting occurred. Calomel caused improvement in the stools, but the vomiting continued. That is the typical pathological history of a large number of children artificially nourished from birth; it has been the usual case in our clinic for a decade and a half, and it is probably the customary experience in general practice. Since he was received into the clinic the child has been given the breast.

The child was poorly nourished, its entire body being generally lean and unpadded, and the face bore the expression of suffering. It was, so to speak, a child whose own condition made it sad. One may say as a general rule that so long as children do not feel well they take no interest in their surroundings. When they cry they show deep wrinkles about the nose and mouth. This child may afford me an opportunity to discuss the question of feeding during the first days and weeks of life.

It is just at this period that the nourishment of children is of the greatest importance for their entire future. One-third of all the children who die in the first year of life succumb during the first month. It may safely be said that the artificial nourishment of children is attended with much greater difficulties during the first fortnight or month than later on, and that disturbances of nutrition are much more frequent and severe during this period.

Scarcely were the first days passed in the life of this little one before the various troubles began, in spite of careful attention in the clinic. The child's mother was unable to nurse it, because she was at first afflicted with parametritis and afterward showed signs of renal disease. The kidney affection in itself is no contraindication to nursing, for the loss of albumin is not so great but that it can be compensated for; and if the mother had only been able to nurse the child during the first four weeks a great deal would have been gained.

What, now, are the measures to which a physician must resort in order to educate a weak mother to nurse her own child? By careful observation of newly-delivered women we have learned much in regard to this question during the last ten years—I may even say during the last five years. We know now that women whose breasts, during the first week, do not yield the quantity needed by the child, may in the course of time, by quiet waiting, become fully capable of nursing. As long a period as four weeks may elapse without the child thriving at the mother's breast. I am able to give a typical example from a case occurring in my private practice.

A young mother, at her first delivery, had a robust child. On the first day I let the mother rest completely, and the child also. As a general thing it may be said that a child remains much more quiet when it is given nothing, or perhaps only a little tea, on the first day. The mother rested for two days, and the child slept. On the third day the child drank altogether 40 grams (twice 20), on the fourth day 115 g., on the fifth day 115 g., and on the sixth day 120 g. Now, nurse and mother began to despair. To this came the additional trouble that the mother developed fissures on her nipples, which also were somewhat retracted. I must here interpolate that fissures do not constitute a reason for suspension of nursing, and that, aside from careful treatment, no attention should be paid to such. Before and after putting the child to the breast the nipples should be painted with a weak solution of silver nitrate, and with this precaution nursing may safely be continued. In the case of which I speak the pains attending the nursing became so severe that, instead of silver nitrate, I employed a 1 per cent. solution of cocaine, without any ill effect on the child. By this means the mother was able to stand it, although the child on one day sucked out a whole mouthful of blood. While the milk secretion remained so inadequate, however, the child was given one small additional meal a day (at first 60 g., later 80), containing one-third cows' milk. Such mixed nourishment is far superior to wholly artificial feeding. On the seventh day, in addition to the 150 g. of mother's milk which it then obtained, the child was given 20 g. of cows' milk with 40 g. of water in one meal. It is advisable not to give the artificial food after each nursing, but rather to give it alone in one dose. This has the double advantage of sparing the mother once a day, and of avoiding overfeeding the infant. The number of meals may be placed very low. Five to six a day are quite sufficient, and satisfy a normal nursling. That this child was insufficiently nourished, however, appeared from the fact that it passed no stools. The addition of cow's milk need not be large enough to furnish the entire amount of calories required. By proceeding in this manner the secretion of milk increased gradually, and on the eighth day the breasts yielded 320 g. The fissures healed. By the end of the third week the one artificial meal could be withdrawn; and at the end of the fifth week the milk supply was 600 g. and the child's weight was increasing more than 200 g. a week.

I have reported this at some length, because in such cases the technique of feeding is of the greatest importance. The loss in the weight of the child during the first fourteen days was no greater than is usual, amounting to less than 300 g. Under certain conditions it is necessary, when the infant will not nurse properly at first, to resort to artificial means to make it take the breast.

What is the principal factor in making a breast which gives insufficient milk functionate properly? First, the stimulus of sucking; second, good nourishment for the mother. It is always advisable to give the mother plenty of milk in addition to her other food. In the case of premature birth nursing is difficult because the mother's breast cannot be stimulated to secretion by the sucking of the child. In such cases it is best temporarily to engage a wet nurse *with her child*. The vigorous child of the wetnurse is then put to the breast of the weak mother, while the latter's infant is fed with milk drawn from the nurse's breast. Where this is not possible a breast pump must be used as frequently as the child, under normal conditions, would have taken the breast, and as soon as the weak infant can begin to suck a little the breast pump must be used before the child is put to the breast. The experience gained in the homes for nurslings, to which mothers and children are admitted, has gradually taught us to avail ourselves of all these "tricks."

I have, however, a chart from a case in the clinic, which proves that a perfectly satisfactory nutrition may be obtained even in a case where it is necessary to wait a whole month before the mother's breast yields sufficient nourishment for the child. This child received, during the month of May, an insufficient amount of nourishment from the mother (70-80 calories per kilogram). With an increased secretion from the breast it gained regularly; and at the age of eleven months it ran about freely, and was in an excellent state of nutrition.

From such experiences we naturally learn how to reassure anxious mothers in cases in which the milk secretion is insufficient in the beginning. Subjectively considered, children will feel much better with scant nourishment than when plentifully fed.

The only exception to the rule that a mother should always nurse her child is when she is suffering from tuberculosis. The argument that even this might be permitted, because nursing renders the tuberculous mother stronger, is not valid, since one must take into consideration the period after the cessation of lactation. At this period, to mention an example, the sudden appearance of miliary tuberculosis was noticed in a wetnurse who had nursed for a long time. Other contraindications I do not recognize.

To demonstrate by an example that the acute infectious diseases do not constitute contraindications to nursing, I may mention that in the Charité we have let a mother who suffered from scarlet fever nurse her child immediately after the febrile stage was passed. In another case, in the second medical clinic, a typhoid patient nursed her child during the entire period of the disease, and both mother and child were the better for it. In febrile diseases, however, it is generally advisable to take the child away while fever is present, but to let it be nursed again as soon as the temperature has become normal. The breasts then begin to secrete anew. In the Charité we have observed a case in which the glands began to give milk again six weeks after suspension of nursing, the children (twins) being then nursed until the end of the normal period of lactation. These are all facts which make it the urgent duty of physicians always to urge mothers to nurse their children. In the case of the twins mentioned at the beginning of this paper, a comparative experiment was made. The weaker child—the boy—was nursed by the wetnurse, while the stronger child the girl—was given artificial food, consisting of extra good, diluted cows' milk. The breast-fed child progressed at once, while the bottle-fed infant did not develop at all during the early period, when it received an abnormally low amount of calories. Even in the further course of the treatment the originally robust bottle-fed child developed more slowly than the breast-fed child, which was weaker at birth.

I would therefore urge, in conclusion, on all who find themselves in the position of advisers to nursing mothers to be insistent in counseling their charges to do their duty in the matter of breast feeding, no matter what may be the initial difficulties, and thus to help them to achieve this blessing of true motherhood.

SOME ASPECTS OF STERILITY AND ITS TREATMENT.*

By A. J. RONGINSKY, M.D.,

NEW YORK.

INSTRUCTOR IN DISEASES OF WOMEN AT THE POST-GRADUATE MEDICAL SCHOOL, ADJUNCT GYNECOLOGIST, LEBANON HOSPITAL.

In writing on the subject of sterility in women one is embarrassed by dealing mainly with one half of the matter, as those who have had a wide experience are more and more convinced of the greatness of the part playing by the male, not only in absolute sterility, but in all the other forms. It is not only important from a medical standpoint, but the sociologist should be equally interested, as it is a matter of no small importance to the community at large, that at least one million women in this country are absolutely sterile. These women sooner or later seek the advice of the physician. The subject is therefore of prime importance to the general practitioner as well as the specialist. Personally, in the short time that I have been engaged in the practice of medicine, I have had a fairly wide experience with this particular gynecological condition, and the greater my experience the more I have been impressed with how little our knowledge extends in this direction and what an amount of scientific work yet remains to be done.

Sterility is equally dominant in all classes, particularly in the absolute form, but it seems to me that the greater the intellectual faculties of a woman the more likely is she to be relatively sterile. In the lower classes absolute sterility sooner or later will interfere with the general morale of the home, and if the woman is religiously inclined she considers herself as one cursed by Providence, and at times as one unworthy of enjoying the pleasures of life of this world and the world to come. This condition constantly preys upon her mind, so that eventually it becomes more or less in a state of perversion, and quackery in all its forms very naturally has its greatest outlet among this class of patients. Even the Bible has an authentic case in which prayers helped to open a womb that had been shut, the woman conceived and Samuel was born as a result.

Sterility is generally divided into absolute and relative. By absolute is meant when the individual is incapable of bearing a child to the period of viability. It is termed relative when child-bearing is not in accordance with the length of time the individual has been married. Ordinarily a woman should give birth to a child every three years during her child-bearing period.

From the above you will see that the question of conception is entirely left out from the discussion, and therefore, I think the definition is not entirely complete either from a scientific or a clinical standpoint. A more scientific classification would be to term sterility *complete* when the woman has never conceived, *incomplete* when she *does* conceive but habitually aborts before the child is viable; and relative when children are not produced in a number, in accordance with her condition, age, and length of married life.

Before we commence to consider the causes that may prevent conception, we must decide that no two cases have the same etiological or pathological factors—at least this has been my experience in about sixty cases that I have seen both in clinical and private practice. And the sooner one is able to appreciate it the more apt is he to cure the patient—sterility and curettement have been too long associated in the minds of medical men, and the result of this association I need not tell you.

In order that conception may take place, the most essential factors are, first the deposit of healthy semen in the upper segment of the vagina, second an uninterrupted passage, or still more definitely, a patent, relatively healthy female genital tract, at some point of which the spermatozoon and ovum may meet and find a resting place for their growth. From the above it can be seen that any thing that will interfere with the general health, or any local pathological condition of both the male and the female, may either prevent or postpone conception.

The male aspect of this condition is not as complicated as the female. Here our diagnosis can be more exact and our line of treatment more definite. Aside from the many organic lesions in the male that cause sterility, I find that sterility is very common among habitual masturbators, who by virtue of their having practised masturbation for a long time, have suffered the glandular structures of the testicles to become functionally inactive, and on examination one finds that the semen of this class of patients contains no, or very few, small, dead spermatozoa. Again excessive coitus, especially practised by recently married couples, leaves the male partly in the same condition as that of the masturbator. This is very well illustrated clinically, when one observes that if conception does not take place soon after marriage, it is usually postponed until a time when probably the husband is taking the proper rest and during which time the glandular structures of the testicles become reinvigorated and commence to secrete healthy spermatozoa.

The so-called vague term of incompatibility or want of sexual affinity is a very important factor in sterility. I find among some patients that either the husband or the wife is sexually weaker,—usually it is the husband. The act of copulation is not satisfying to both alike, an element which is very essential and must not be overlooked. Our duty in such cases is to try to equalize conditions, either by building up the one who is weaker, or if that is impossible, we have to go to the extreme, of depressing the one whose sexual powers are stronger. I have carried out this mode of treatment in one of my cases with the result that the woman conceived at the end of nine weeks after being sterile over five years.

Occupations which tax the nervous system, so that the individual is mentally tired on completing the day's work, are also conducive to sterility. Such a state of the nervous system is not conducive to healthy intercourse, and sterility is quite likely to be prevalent among this class. We can readily overcome it by instructing patients to have no intercourse before some rest in the form of sleep is taken, during which time the general nervous system is likely to have resumed its normal state. A man with a congenitally small penis, especially when the woman is of large stature, finds it difficult to perform the act of copulation, with the result that conception does not take place. This condition is almost always relieved, by instructing the woman to have it so arranged that her pelvis is on higher plane than the rest of the body during intercourse and also to remain perfectly quiet for at least one hour after, as the semen is probably deposited very low in the vagina and any undue motion on her part may cause its escape from the vaginal vault.

Another important element of sterility in the male is varicocele of one or both sides, no matter how

*Read at a meeting of the Alumni Society of the Lebanon Hospital, February 5, 1907.

small it may appear to be, but which still may produce enough passive congestion of the testicle to render it functionally inactive. I had this condition most beautifully illustrated in one of my patients only a short time ago. The wife of the patient came to see me about her sterility with the following history: twenty-eight years old, menses began at the age of fourteen years, were regular every four weeks, of three days duration. Married six years and never conceived. Two years ago the cervix was dilated and curetted by a prominent gynecologist of this city with no beneficial results. On examination I found her genital organs apparently normal. I immediately asked to see the husband and a specimen of the semen. On physical examiation I found that he had a small varicocele on the left side. The semen on repeated examinations showed no spermatozoa. I suggested to him that his varicocele might be a cause of his azoospermia and advised removal of the same. He was operated in this hospital last July, and three months later his wife conceived, and now is in her fourth month of pregnancy (spermatozoa were present after operation).

Finally it is the duty of the physician to examine a great number of seminal specimens, in order thoroughly to familiarize himself with the microscopical appearance of spermatozoa and to be able to satisfactorily pronounce a given specimen as being normal, for it is not sufficient that spermatozoa are found. It should as far as possible be established that some of the spermatozoa will reach their point of destination fully viable, active, and in condition to impregnate the ovum. Many specimens that are examined are found to contain spermatozoa that appear very feeble, some that hardly posesss life at all, some that are broken up and some that are dead. With such semen no matter how normal the woman may be, conception may not take place, for in order to impregnate the ovum, the individual spermatozoon will have to travel a distance of at least 24 centimeters and the time it will consume in doing so, no matter how moderately rapid it will progress, will be one hour and a half. Many obstacles will delay its journey and the time consumed will be much longer. Now many specimens of semen that I have examined and which showed living spermatozoa although not of the very active variety, when the same specimens were examined two hours later after keeping them in a warm, normal salt solution, showed no trace of a living spermatozoon. would it not be logical to conclude that such spermatozoa will die during their travels before they will meet the ovum to impregnate it? Such a condition is generally the result of a debilitated state of the individual and naturally calls for treatment that will improve the general condition of patient, but in addition to it, the patient must have thorough sexual rest for a given time. Usually I prohibit any sexual excitement for at least ten weeks.

In seeking the cause of sterility in women not only the whole range of diseases peculiar to women must be considered, but as well the physical and social conditions of the individual. No other condition requires a more detailed knowledge of the physiological and pathological processes that take place in the female genital tract, and depending upon one's ability to differentiate the various processes will depend the success met in the treatment. Once healthy semen is deposited in the upper segment of the vagina and conception does not take place, clinically the woman is at fault. At times the cause is very obscure, but aside from the many pathological lesions that may be present, functional disturbance no matter of how mild a nature will cause the woman to be sterile. Particularly is this true in that class of women who suffer from a general muscular relaxation, are ill nourished, and highly nervous. For in order that the spermatozoon may reach its destination, two mechanical forces besides its own motile power are directly engaged in compelling it to travel in the direction of the uterine cavity. From below we find that the perineal body or pelvic floor by the constant contraction and relaxation of its muscular structure produces a wave in the direction of the cervix, hence the spermatozoa are carried along with this wave. This function of the perineum is probably one of the most important factors in holding the uterus in its normal position. From above the uterus constantly undergoing some contractions, must, by virtue of its being hollow, have some suction power which also aids the spermatozoon in its uphill travel. In patients who suffer from a general muscular relaxation these mechanical processes are greatly diminished with the result that conception does not take place, for in addition to it, we must not overlook the fact that the wave produced by the ciliated epithelium lining the uterus is outward, and certainly must hinder such a minute body as the spermatozoon from progressing in an opposite direction.

In patients in whom I suspect this to be the condition my aim is to improve the local muscular structure, and the method I adopt is as follows: The patient is instructed to loosen all her bands, particularly the waist bands; to stand on the floor in an erect posture, hands elevated above head, feet drawn together, then take a deep inspiration to be followed by a sitting posture with body hanging on the knees; remain in this position for about five seconds and then return to the original erect position. This is to be performed three times daily for about ten minutes at a time. You can very readily see how this form of exercise not only acts upon the pelvic floor but will also indirectly make the uterus and practically all the abdominal viscera functionate more properly. This form of treatment I have recently followed out in a patient who after being married three and a half years never conceived. She appeared at my office about six months ago. On examination I found nothing that seemed abnormal, her husband also being in perfect health. After following this plan of treatment for about three months she became pregnant and is now in her tenth week of pregnancy. In addition to the exercise I gave her 6 grs. of the black oxide of manganese per day.

Another class of patients who require a good deal of attention are those women who marry at an advanced age; whose generative organs are likely to have undergone some changes, at any rate they do not functionate well. This class of patients I instruct to have intercouse during the week preceding menstruation only, when the generative organs are at the height of functional activity, and therefore conception is more prone to take place.

In the course of our work we meet a class of patients in whom the relation of the cervix to the posterior vaginal wall is changed, due either to malposition of the uterus, to a large elongated cervix, or to a particularly small vagina. In these conditions correction of the deformity is always the indication, but we are all aware how unkindly such a suggestion is received, especially if one happens to be first to give such advice. In these conditions we must search for some means that will bring the spermatozoa nearer the external os. This can be

accomplished by advising the husband to have intercourse with the woman in the knee chest position at least twice a month during the week preceding menstruation. You can readily see how the relation of the spermatozoa with the external os is changed in the same manner as if the axis of cervix had been corrected by some operative interference. Such advice certainly does not appeal to one's esthetic senses, but in the practice of medicine we are very often compelled to overlook it. This method of treatment, although very simple, has brought on conception in two of my patients, one giving birth to a mature viable child, while the other aborted in the third month. One had been sterile four years, the other two and a half years. I admit that these patients might have suffered from some slight organic lesion causing obstruction at some point of the genital tract, which has cured itself during the interval; but from a clinical if not from a scientific standpoint it certainly cured these patients.

The marriage of near relatives is said to be a cause of sterility. Personally I do not find this to be true, and in races where the religion permits the marriage of near relatives, sterility is not more prevalent. On the other hand some of the women are very prolific.

The lack of sexual desire or the absence of sensation of pleasure during intercourse are also given as causes of sterility. Personally I have had no experience with this class of patients, but I believe that it is not purely a functional disturbance as is generally assumed, but that there is some organic lesion underlying this condition which we at present are not able to diagnose. Excess of sexual excitement on the other hand is certainly prejudicial to fertility in so far as it induces certain pathological results, such as congestion of the uterus and its appendages, leading to ovaritis and defective ovulation; or to salpingitis and with it to more or less obstruction to the descent of the ova and ascent of spermatozoa, or to metritis and with it a tendency to the occurrence of abortion.

The organic lesions that cause sterility may be divided into congenital defects of an irremedial character and acquired abnormalities. The congenital causes we may dismiss from our discussion as at present we are not in a position to improve the condition. The operation of transplantation of a section of the human ovary is yet in its infancy, although the case of Dr. Morris has proved successful, but I think that the time is not very far off when many more authentic cases will be reported. It is not very difficult to diagnosticate these congenital cases. Usually these patients show a train of symptoms which are quite characteristic. The masculine appearance, the small undeveloped mammary glands, associated with an irregular menstrual history regarding the age of onset, the intervals at which it appears, the scanty flow and its duration, all these together with a small vagina, particularly a short anterior wall, at once establish to my mind the fact that the patient is suffering from a lack of development of some part of the genital tract and my prognosis is unfavorable.

Of the acquired causes of sterility the whole range of diseases of women must be considered. I shall only touch upon a few, which I believe are the most important to the general practitioner. I believe that one of the most frequent causes of both the complete and relative forms of sterility are the various leucorrheas, whether specific or not. A vaginal leucorrhea of a strong acid reaction will certainly kill the spermatozoa in a short time. I usually test the degree of acidity with a piece of litmus paper, and if found markedly acid the indication of course is to neutralize the secretion, which is best done by tamponing the vagina with equal parts of bismuth subnitrate and sodium bicarbonate on a non-absorbent cotton tampon every other day for two weeks. The patient is not allowed to remove the tampons until one hour before she is supposed to call again. At the end of a short time you will find the degree of acidity quite changed. It is necessary that these patients douche themselves with some mild alkaline fluid, sodium bicarbonate usually answering the purpose, and in addition to their general douching a small douche of sodium bicarbonate must be taken a short time before intercourse to make sure that the secretion of the vagina is of an alkaline reaction.

Stenosis of some part of the cervical canal is surely an important factor, but I believe it is not as common as it is generally supposed to be. Complete stenosis cannot exist as long as menstruation takes place, and if menstrual blood escapes through the canal the spermatozoa can certainly pass through it. Clinically I have not seen a case where the os has been so completely obstructed that I could not introduce a small probe into the uterus. What is usually associated with a small cervical opening is an endocervicitis. It may be of a very mild degree, hardly perceptible, but enough is secreted by the mucous membrane to occlude this small opening, making it impossible for the spermatozoa to pass through. This condition is very common, and these are the patients that we are able to cure. I have operated on a number of patients for sterility due to this condition with great success. The method I used was simple dilatation of the cervix, scraping it somewhat if found necessary, and introducing a small intracervical pessary which I have kept in from two to three months, removing it when necessary and introducing it again. The pessary prevents the cervix from contracting again and sooner or later the muscular structure in the cervix accommodates itself to its new surroundings, with the result that the canal remains a good deal enlarged long after the pessary has been removed. If the endocervicitis still persists, it is very readily cured by intracervical applications of some astringent; usually 6 per cent. solution of silver nitrate will answer the purpose.

The infantile uterus, unless associated with other conditions, does not cause sterility as often as is attributed to it. A small uterus is only a relative term. The smallest uterus that I have seen was in a woman who gave birth to a child and since then has conceived again.

The various displacements of the uterus with the probable exception of extreme anteflexion are seldom causes of absolute sterility. Conception in these conditions does not take place on account of the change of the axis of the body of the uterus, but is due in the majority of cases to a change of axis of the cervix. It is certainly one of the most important causes of incomplete sterility and therefore should be corrected.

Recent investigations by competent observers have proven that in the majority of cases, inflammatory processes of the lining membrane of the genital tract are of gonorrheal origin, and it is a very singular fact that at times these gonorrheal inflammations are so mild that the woman is troubled very little, and the physician is not consulted early enough to prevent further progress of the disease. The Fallopian tubes, if already attacked, will surely cause the woman to be sterile in the majority of cases. Women

who are apparently normal may fail to conceive on account of some slight tubal affection which can only be detected after the abdomen is opened at the time of an operation. There are two main indications in the treatment of these patients suffering from gonorrheal infection of a milder degree, first to reduce the existing inflammation: second to prevent reinfection. In all our therapeutics for reducing inflammations of the pelvic organ nothing equals glycerin, if properly used; glycerin as generally used in various clinics is absolutely useless. In order that the patient may derive any benefit from it, large quantities must be used, a cupful at a time, that will fill up the entire upper portion of the vaginal vault, to be followed by a gauze or non-absorbent cotton tampon to prevent the escape of the glycerin. This is repeated every other day until the active inflammation or congestion is removed. To prevent reinfection intercourse must be strictly forbidden for at least six months.

In conclusion I want to say that although with the lapse of every succeeding year after the third from marriage, without the occurrence of conception the prospect of child-bearing becomes less, yet if no apparent cause for sterility is discovered the patient should be encouraged to entertain some hope. Any improvement in the local condition, which time in itself may rectify, will result in conception. With our present knowledge of the subject we are not in a position to make a positive prognosis, for as long as our diagnosis is not always accurate it follows that our prognosis cannot be exact, but it is the duty of every physician to try to convince these patients that the earlier they carry out the doctor's advice the more likely are they to be cured, and that a lapse of a little time may cause permanent sterility. Personally, from the number of cases I have already seen, I am thoroughly convinced that gonorrhea in all its forms is the greatest factor in the production of sterility, and that if anything is to be done to relieve this condition the education of the future husband must be commenced at an early date, that parents, teachers, and educators must constantly point out to the young adult the danger to which he is exposing himself, his future wife, and probably the offspring. As long as these dangers are not realized by the public at large, so long will sterility be on the increase.

154 Henry Street.

WHAT ARE ACID FASTS?*

By STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

A few years ago Koch himself maintained that the only bacilli likely to be confounded with the tubercle bacillus were the bacillus of leprosy and the smegma bacillus. All the world held with him that when one had eliminated the possibility that the material under consideration had been contaminated by the leprous or by smegma, any slender rod-shaped germ, one-half or one-quarter as long as a red blood cell, that retained the fuchsin red after half a minute's decolorizing with twenty-five per cent. mineral acid was the tubercle bacillus.

An immense amount of time and energy was expended in elaborating modifications of the ordinary carbol-fuchsin and methylene blue staining methods for the purpose of differentiating the tubercle bacillus from the lepra bacillus in order that the tragic diagnosis of tuberculosis might be free of every shadow of doubt. The result of all this work was not entirely satisfactory, but still the profession had settled back into a somewhat smug conviction that since as a rule the smegma bacillus was more readily decolorized, and the lepra bacillus less readily decolorized, than the tubercle bacillus, the microscope was a sufficiently reliable guide.

Nine years ago Petri and Lydia Rabinowitsch while searching for tubercle bacilli in the butter and milk of Berlin discovered and isolated a bacillus which answered the staining requirements of tubercle bacilli, but which did not cause tuberculosis in injected guinea pigs, and which differed from tubercle bacilli in many cultural ways. About the same time A. Moeller at Gorbersdorf discovered that a flask of bouillon into which a few days before he had put some green timothy grass from his garden contained a great number of bacilli which in shape and size and staining were like tubercle bacilli, but which on isolation seemed to have markedly different biological characters. These two discoveries were quickly followed by confirmatory and supplemental findings by bacteriological workers in various parts of the world. During the last few years a whole literature has grown up about the subject, whose importance and interest are everywhere recognized. All these germs which, with the ordinary staining methods, resemble the tubercle bacillus are now known in English as "acid fasts," in German as "saurefesten Bacillen," and in French as "bacilles acido-resistants." They have now been found in so many places and under such different conditions that it seems desirable to classify them according to their various sources:

Class I.—The acid fasts found in nature. Moeller's timothy bacillus is the type of this class. It or bacilli closely akin to it have been found in hay and dung and street dust, wherever it has been looked for, and it has been cultivated from various kinds of grasses. Moeller has found acid fasts also in sand, soil, and mold. They can readily be found in the dust in dark barns and chicken coops. Moeller claims that in all the researches he has made he has never found the tubercle bacillus in nature. The acid fasts he has found have always been the quickly vegetating timothy bacillus or some of its relations. This timothy bacillus is not distinguishable from the tubercle bacillus in form, size, or staining, except in very old cultures when it loses some or all of its acid resistance. Like the tubercle bacillus it does not change milk nor liquefy gelatine. It differs from the tubercle bacillus in that it grows as much in twenty-four hours as the tubercle bacillus does in two weeks. It grows also at room temperature, and does not need sweetened media for its sustenance. Its colonies vary from a deep yellow to a brick red or even a rose red, and by a little sophistication they can be made to grow white or gray.

Class II.—The acid fasts of milk and butter. How frequently acid fasts can be found in milk and butter has been a subject of dispute. They have been isolated from the butter of Milan by Coggi; from the butter of Fribourg-en-Brisgau by Korn; from the butter of Zurich by Mme. Marie Tobler; from the butter of Vienna by Markl; from the butter of Paris by J. Binot, and from the milk of Belzig by Moeller. The technique of finding these acid fasts consists in injecting the suspected butter or milk into guinea pigs and after a few days planting the resulting pus or peritoneal exudate on various cul-

*Read before the New Haven Medical Association, April 3, 1907.

ture media. Lately Rabinowitsch, Grassberger, and Markl have isolated acid fasts from oleomargarine.

These butter and milk acid fasts often differ from one another in morphology and in the color of their cultures and in their resistance to the decolorizing power of acids and alcohol. Some of them are as acid fast as the hardiest tubercle bacilli, while others seem to have no acid resistance unless they have been cultivated in milk. They all grow best at 37° C. in from two to five days. All develop slowly at room temperature except the one isolated from the milk of Zurich by Mme. Tobler, which usually does not grow at room temperature.

Class III.—The harmless acid fasts of man. These consist of the well known smegma bacillus first described by Alvarez and Tafel in 1885; and the cerumen bacillus—possibly the same organism as the smegma bacillus—found by Gottstein in 1886; and the bacilli found by Karlinski in 1901 in nasal mucus in fifteen out of twenty cases examined; and the various acid fasts found in comedones, in the secretion about the toes, on coated tongues and teeth, in the tonsillar crypts, and in saliva by Laabs, A. Moeller, and Rabinowitsch. Moeller, by injecting smegma bacilli under his own skin, was able to procure a pure culture, and Lazer and Czaplewski have, according to Cornet, been able to grow the smegma bacillus on agar mixed with human blood. Karlinski, himself, has recently shown that his bacillus is the same organism as that isolated from butter by Petri, Rabinowitsch, and Korn. The others have not been grown in pure culture. The fact that they do not cause lesions when injected into guinea pigs of course offers a reliable method of differentiating them from the tubercle bacillus.

Class IV.—The pathogenic acid fasts of man and beast. The tubercle bacillus and the lepra bacillus are the most important of this class, but their consideration is not within the scope of this paper. Stefansky has described a short acid fast bacillus that he found in the giant cells of the rats of Odessa sick with a disease that looked like leprosy, but he was not able to infect guinea pigs or other rats with injections of this organism. In 1900 A. Moeller made an interesting find in the depths of the tuberculous nodules on the breasts of cattle and hogs. He isolated and cultivated a beautiful acid fast rod larger than the bovine tubercle bacillus, which grew at 18° as well as at 37°. At the latter temperature the culture reached its full development in twelve hours. This bacillus is very pathogenic for guinea pigs, but kills them on hypodermic injection, as do so many other of the acid fasts, without any signs of the development of tuberculosis. Moeller claims that if it be mixed with butter before injection, this bacillus will cause the formation of true tubercles in guinea pigs. Potet repeated the experiment and failed to get any nodules in his guinea pigs. Nobody has yet been able to cultivate the true Hansen bacillus of leprosy, but many workers have isolated and cultivated from the leprous nodes a bacillus that grows well at room temperature, is poorly acid fast, and in old cultures loses entirely its power of resisting acid. It is important to remember these two findings, for they have been and they still are the foundation for many attempts at explaining the acid fast problems.

When acid fast bacilli are found in great number at or near a seat of disease in human beings not sick with tuberculosis they have been until recently considered to be smegma bacilli, but as smegma bacilli cannot be grown on ordinary media, and as in many cases these other bacilli have been readily isolated and cultivated, much discredit has lately been thrown on the old, simple classification. For instance, acid fasts, not tubercle bacilli, have been found on the surface of chancres and mucous patches by Lustgarten; in gonorrheal pus by Lazer and Czaplewski; in urine of the syphilitic by Rappin and Hernot; in a suppurating ovarian cyst by Dietrich; in the urethra of a woman suffering from a post-partum ascending pyelonephritis by Stolz; in two cases of panophthalmia showing non-caseous giant cells in the nodules in the retina and iris by Ginsberg; in the sputa of a patient suffering from a disease that clinically seemed to be tuberculosis, but whose autopsy revealed no tubercles, by Zalin; in a case of bronchial dilatation by Melchner; in acute bronchitis by A. Moeller. Of course there is no satisfactory proof that in any of these cases the acid fasts were the cause of the diseased conditions in which they occurred.

Ravenin three years ago isolated from the filtering beds of the water system of Nantes an acid fast streptothrix which was feebly pathogenic for laboratory animals. Flexner has reported a case in which the patient had all the symptoms of tuberculosis and post mortem had nodules in lungs, liver, and peritoneum that contained no giant cells, but did contain a beautiful acid fast branching streptothrix.

In non-tuberculous gangrene of the lung acid fasts, some resembling the smegma bacillus and some the Rabinowitsch butter bacillus, and others having only a slight resistance to acids, have been found by various observers, Folli, Ophuls, Pappenheim, Benenuto, and Fraenkel. Klein of Amsterdam and his assistants claim that from practically all cases of pleurisy they are able to cultivate acid fasts closely resembling tubercle bacilli, but having much less, and often no pathogenic power for guinea pigs. Many other workers, Besançon, Griffon, Philibert, have found acid fasts, probably not tubercle bacilli, in serous effusions and in blood clots.

In view of all these facts, how shall we differentiate the tubercle bacillus from the other acid fasts?

Not by its staining reactions alone. Many of the others are just as resistant to the decolorizing power of nitric, sulphuric, or acetic acid, or alcohol, as the most typical tubercle bacillus. And the tubercle bacillus can be deprived of most or even all of its acid resistance, as has been conclusively proven by Arloing and Courmont and by Auclair. Again such common bacilli as the anthrax and subtilis, if grown on agar to which butter or fat has been added, take on a waxy capsule that makes them acid fast. (Flexner, Brenstock, Gottstein, and Gibier.) I have repeatedly conferred acid fast properties on a large proportion of Klebs-Loeffler bacilli by simply growing them for two weeks at room temperature in equal parts of sugar bouillon and normal salt solution.

I treated a patient last year with signs of apical and laryngeal disease who for several months expectorated an almost pure culture of pseudo-Klebs-Loeffler bacilli until I gave her some intracheal injections of sterile oil and ordered her to use this oil in an atomizer. Then I began to get specimens that contained what apparently were tubercle bacilli. When the treatments with oil were stopped the acid fasts disappeared from the spittle. The experiment was repeated later with the same result.

Not by the form alone. The shape and size of

the tubercle bacillus vary greatly according to its age and environment from short rods, almost cocci, to actinomycotic branches. Many of the other acid fasts are morphologically identical with the tubercle bacillus.

Not by the appearance of the cultures alone. Usually the other acid fasts have more chromogenic power than the tubercle bacillus, and their cultures are usually more moist. But the tubercle bacilli transplanted on to solid media from homogeneous fluid cultures develop in moist creamy heaps like many of the other acid fasts.

Courmont exhibited at the last international congress cultures of human and avian tubercle bacillus, some red and some yellow, exactly like many of the butter and grass bacilli.

Not alone by the determination of the temperature necessary for growth. The tubercle bacillus usually will not vegetate on ordinary media below 37° C., whereas most of the acid fasts will develop slowly at 18°. Nevertheless, even on ordinary media, the tubercle bacillus, by careful cultivation, has been led to grow below 30°, and the bacillus of fish tuberculosis grows at much lower temperature. The tubercle bacillus of human type injected by Moeller into slow worms and frogs and afterwards recovered from these animals was found to grow luxuriantly at room temperature and poorly or not at all at 37°. I have grown these slow worm and frog tubercle bacilli many times on various ordinary media, not only at room temperature, but exposed during all their period of vegetation in the bright light of the laboratory windows.

Not alone by agglutination tests. Courmont and Descos claim that the serum of tuberculous animals fails to agglutinate many of the acid fasts and that the serum of animals injected with acid fasts fails to agglutinate the tubercle bacillus. But they also admit that many strains of even homogenized tubercle bacilli are not agglutinated by the serum of tuberculous patients. Koch, Moeller, Nobele and Beyer, Becker and Rabinowitsch, have held that all the acid fasts are agglutinated by the serum of the tuberculous.

Not alone by consideration of the lesions produced in guinea pigs. Of course, ordinarily there is a marked difference. The tubercle bacillus produces tubercles, and when recovered from these tubercles can be again injected and again recovered, and so on, indefinitely, whereas the acid fasts usually produce only a local abscess with or without enlarged glands and acute septicemia when injected under the skin, and a general peritonitis when injected into the peritoneum. The mixing of the acid fasts with butter before injection intensifies their pathogenic power.

Nevertheless, Moeller, Korn, Mayer, and Lubarsh caused the development of true tubercles with giant cells in guinea pigs injected with the timothy or Korn bacillus, and Abbot and Gildersleeve and Schultze have shown that the intrarenal or intravenous injection of the timothy bacillus into rabbits causes the production of true tubercles with giant cells. As I reported last year, I have been able to produce tuberculous nodules in rabbits by the intraperitoneal injections of acid fast rods and cocci developed from *Baccillus mycoides* and to cause other tubercles in a second series of rabbits by injecting the recovered acid fasts into the second series. Courmont and Descos have produced a generalized tuberculosis without giant cells by injecting small doses of Binot's bacillus into a dog.

On the other hand, the tubercle bacilli of the homogenic cultures of Courmont can be entirely deprived of their power to produce tubercles on subcutaneous injection.

Practically one must, here as in most other diagnoses, consider not only one, but all the facts of the problem in order to decide wisely whether or not the bacillus in question is the tubercle bacillus or one of the less important acid fasts.

The subject of the relationship of the tubercle bacillus to the other acid fasts, and the arguments that have been advanced for and against the theory that tubercle bacilli are merely saphrophytic acid fasts which have evolved special characters necessary for their existence and growth in animal cells, I refrain from discussing to-night. It is too big a subject, and it demands much more study before one man's opinion of it will be worth more than the opinion of any other man.

212 Orange Street.

REMARKS ON THE TREATMENT OF DISEASE AND SO-CALLED "AUTHORITIES."

By GEO F BUTLER, M.D.,

CHICAGO.

PROFESSOR AND HEAD OF THE DEPARTMENT OF THERAPEUTICS AND PROFESSOR OF CLINICAL MEDICINE, CHICAGO COLLEGE OF MEDICINE AND SURGERY (MEDICAL DEPARTMENT, VALPARAISO UNIVERSITY).

"Mastery of all the sciences upon which medicine is founded does not make the physician. He would be helpless without them, but he is worse than helpless with them until he learns how to use them, how to construct out of them the special art which enables him to cure disease." So said Draper, and never was there a truer utterance. Yet there are men in the profession—men who like to be looked upon as authorities in medicine—who belittle therapeutics and oppose nearly every therapeutic suggestion not offered by a member of the "Four Hundred."

I believe, however, that the great majority of practising physicians heartily endorse the words of the late J. Milner Fothergill, M.D., M.R.C.P., who said in the very first paragraph of "The Practitioner's Handbook of Treatment": "The ultimate aim of all medical research is the treatment and prevention of disease. It is eminently desirable that a medical man should be generally well informed; but what is to be still more devoutly wished for is that he should be a skilful practitioner. It is quite possible to be the one without being the other. The combination is what we hope to see accomplished. The tendency of modern medical teaching has been rather to produce the first, leaving the second quality to develop itself, or to remain in a condition of imperfect evolution. We constantly hear it asserted that the highly educated medical men of the present generation are not more successful in practice than their less accomplished but more practical predecessors. Even members of the profession are to be found who assert that the man under whose treatment they would place themselves, if seriously ill, is the old-fashioned general practitioner. This is a serious reproach to our recent advances in scientific medicine; to our modern instruments of precision in diagnosis; and even to our progress in rational therapeutics, in late years."

With the marvelous progress in diagnosis, and under the influence of the German school, we have come to attach, not perhaps an exaggerated importance to diagnosis, but an importance which has re-

sulted in placing therapeutics in a very subordinate position. It is all very well for a patient to feel that his medical man is a skilful diagnostician, but the essential thing after all is confidence in his power to aid him when stricken and prostrated by disease or accident. It will occur to the minds of most men that the physician's principal duties are to prevent and cure disease. "The real physician," said Broussais, "is the one who cures; the observation which does not teach the art of healing is not that of the physician, but of the naturalist."

We should do more than classify diseases, as a botanist might sort and classify plants and attach to them their proper names. We are dealing with human beings, not some dried specimens which we label and place in their proper places in a herbarium. Although I sometimes think there are many ultra scientific physicians who would prefer to confirm their diagnosis by an autopsy, and preserve some of the pathological specimens than to assist the patient to recover when the diagnosis is in doubt.

I remember a story told by "Uncle" Allen, formerly president of Rush Medical College. He was being shown through a large pathological laboratory in Paris, and was wearied looking at shelf after shelf loaded with pickled specimens of organs and tissues from people long since dead. At last he turned to the great pathologist and said: "Great God! Where are the people you have cured?"

To prevent and cure disease is the physician's actual business in life; and it is here that success is most to be desired. Our success is measured by our ability in this direction, for the public cannot be expected to estimate us by any other measure than that of our usefulness. Even Dr. Osler, who is not much of a believer in therapeutics, says: "There is no one measure which can compare with the decrease of physical suffering in man, woman, and child when striken by disease or accident. This is the one fact of supreme personal import to every one of us. This is the Promethean gift of the century to man."

We should not look upon each patient who calls upon us for aid as a "case" of this or that "disease," of interest only as the victim of some morbid process furnishing us an opportunity to demonstrate our diagnostic skill, but as a suffering human being possessing the attributes of humanity collectively, together with some variations which form individual peculiarities, and who should be relieved if in our power to relieve him. Shall we be so "scientific" that we shall refuse to treat symptoms because we may be unable to name the "disease," or because, for instance, the patient is suffering from pneumonia, or some other acute, self-limiting disease, so called?

It is rarely possible to destroy the cause of disease. In the majority of diseases, perhaps, it is impossible to overcome or remove the cause, but we can counterbalance many of the primary effects. For example, since we are unable to dissolve a urinary calculus, we must endeavor to annul the spasm and the pain which are due to the presence of the calculus, and by proper diet and therapy do something, not against the calculus itself, but against the causes which have made it grow. Although we cannot make new heart valves out of imperfect ones, nor rarely restore a degenerated heart muscle, we can by proper treatment relieve the symptoms resulting from failing compensation.

We often see certain symptoms accompanied by certain others, and we observe, in general, a constant succession in certain groups of symptoms. Disease is nothing but a new manner of being of the organs, which present either new phenomena or different modalities of normal ones. Herein lies the difference between clinical medicine and pathology: The latter shows us the species and genera of disease; the former compels us to bear in mind that it is not a disease, but diseased persons, with whom we have to deal.

The morbid phenomena determined by numerous and different conditions vary unceasingly, according to the varying combinations of these conditions; it is, therefore, impossible to refer diseased conditions to certain types which shall be invariable and uniform. If all individuals had organs constituted in the same manner, and endowed with the same dynamic energy, if climacteric conditions were the same for all, and all could be subjected to the same physicopsychical life, the same perturbation would then produce the same effects in all, in the same invariable order of succession. In such a case there would be as many diseases as there are varieties of initial perturbations, and they could be classified as one classifies chemical reactions.

Indeed, no less an "authority" than a Committee of the Royal College of Physicians, London, has arbitrarily given us a grand total of one thousand one hundred and forty-six (I wonder they didn't make it an even fifty) variations from health as making up the conditions and the phenomena of disease to which the human family, at this period of its civilization, may be subjected. And to these "diseases" have been given grotesque and fantastic names, as if they were entities, or individuals. Indeed, we rather look upon them as personalities. "Pneumonia attacked him." "He had an attack" of this or that. It is like a "footpad" "attacking" one. A classification of diseases, of some sort, however, has an advantage; it is, that the presence of certain symptoms and signs leads us to anticipate others, and that their order of succession reveals to us the existence of latent perturbations, as well as the nature of the causes which have aroused them.

Disease is made up of morbid symptoms and effects. But the relation of causality and dependence which unites these elements often requires that a system of treatment should take cognizance principally of symptoms, not so much on account of the value of the symptom in itself, as on account of the symptoms which depend upon it, and the morbid effects which it may produce.

Every symptom represents a constituent element of disease, but all symptoms have not the same hierarchical value, and do not all deserve to be placed in the class of morbid elements. In annulling a symptom one does not confine himself to destroying its effect, and to simplifying the morbid conditions, for by this means many others can be avoided, which would naturally and physiologically follow from the existence of the one which was to be suppressed. Symptomatic therapeutics is, therefore, in my opinion, not only curative of a portion of the disease, but preventive besides, of ulterior morbid phenomena, complications, and aggravations.

If we are called to treat a sick person, our first thought should be to discover the cause of the disease. That cause, when discovered, will be either still in existence or will have passed away. If it still exists we must do our best to destroy it, to neutralize it, or to prevent its results. If the original cause has disappeared or if it is not amenable

to treatment, we can not operate upon it, but we can and should direct our efforts upon its results. These results may be primary, secondary, tertiary, etc., and it will be our duty to fight them, choosing for particular attention ones which are the most grave, the most perturbant, and the most insupportable.

By drugs alone we can restore some of the normal constituents of the blood when they are defective; we can remove abnormal substances present in the blood, and if we have reason to suppose that the products of imperfect metabolism are present we can greatly facilitate their excretion by the kidneys and bowels. We can antagonize and destroy the effects of certain toxic matters which cause disease. We can mitigate or limit both external and internal inflammations. We can act, for example, on the inflamed mucous membrane of the bladder by sedatives, or stimulating germicidal substances; we can also influence the lining membrane of the tubes of an inflamed kidney. We can increase secretion in the neighborhood of an inflamed part, and can alter the general tension of the vascular system. The local vascular condition can be modified by dilating vessels in adjacent parts, and we can exercise a sedative influence on the mechanical conditions affecting an inflamed part. It is thus that morphine is used in peritonitis.

The products of ordinary inflammation which interfere with the functions of tissues may, when consisting of cell growths, be broken up and absorbed under the influence of mercury and potassium iodide, as the products of syphilitic inflammation certainly are. There is reason to believe also that we can cause the absorption of inflammatory deposits by stimulating the nerve endings in adjacent areas. Arsenic can be shown to have a very decided effect on the nutrition of the skin, and it often distinctly influences inflammatory deposits therein.

Drugs such as chloral, atropine, physostigmine, and strychnine act on the tissues of certain parts of the brain and spinal cord, and thereby increase or decrease the functions of those parts. We can depress the functions of the motor nerve endings with conine, and the sensory nerve endings with aconitine. We can paralyze the involuntary muscle fibers directly with the nitrites or indirectly with chloral hydrate, drugs which depress the functions of the vasomotor center. In valvular affections of the heart we cannot remove the chief pathological condition, but by acting on the cardiac muscle and its ganglia we can so strengthen and moderate the beat as practically to restore its normal function. We can stimulate or depress the tissues of the various glands. We can improve the nutrition, and therefore the function of almost all the tissues. I might go on for almost an indefinite period telling what can be done in the treatment of disease. In short, we can do as much with our medical cases as surgeons can do with surgical cases. Yet surgeons, as a rule, and many so-called authorities among medical men belittle therapeutics.

With the evolution of medicine from fetichism, medicine developed into lay and clerical practice, the ecclesiastic being forbidden to shed blood, naturally tended to internal medication, while surgery became the province of the layman. This separation of the branches of the profession led to the surgeons being affiliated with the barbers, while the internal medicine men became apothecaries and through plutocratic influences were at one time affiliated with the grocers. Through this evolution, the mutual contempt of the cleric and the layman persisted. As the search for truth became the object of the medical man, surgical and medicinal therapeutics as the end of medicine sank into the background and were overshadowed by diagnosis. Under this principle receipt-book therapy gave way to the science of internal medicine. The physician then appeared and drove commercial quackery from both surgery and pharmacy. The gap that had been created between the two branches of the healing art is well illustrated in the chaotic titles given in England to medical men. There are members of the colleges of physicians and surgeons and licentiates of the society of apothecaries practising side by side with M.D.'s. Surgery dominated for awhile therapeutics and led to the abuses of venesection. Of necessity surgery adopts either the wild reflex theory or the equally abused gross lesion, these two being the most profitable from the monetary standpoint. It requires less diagnostic skill and less scientific acumen to discover a gross lesion or a reflex disorder than it does to find remediable derangements of physiological balance. The gross lesion and the reflex have a good deal of the mechanical principle of the nickel-in-the-slot machine. The body on this principle is not a delicately balanced mechanism, but an appendix to some of its organs, removal of which or of a gross lesion in which will create recovery. The surgeon ignores the metabolic changes produced by an operation irrespective of its seat. He owes his immunity from malpractice and other serious consequences because medicine has found for him antiseptics and anesthetics. This gift of medicine has been notoriously abused for the benefit of the surgeon. Perhaps no greater evidence of this can be found than the marked change which has occurred in the position of the greater surgeons toward oöphorectomy and allied genital surgery performed for nonsurgical reasons. From the outset of Battey's operation it was opposed by neurologists and internists as dangerously and brutally useless. This position is accepted by all great surgeons, although for years the evil results of oöphorectomy were suppressed by "authority."

Authority in medicine, as in science, does not exist. No man in science is justified in claiming aught that will not be supported by control experiments. "Authorities" are men who have written textbooks most of which are antiquated when they appear and most of which are published through favor. For this reason the courts will not receive any book as authority, regarding it as a mere expression of individual opinion. The scientific spirit of the day disclaims as false and misleading authority which will not submit to test and criticism of its truth.

The self-constituted authorities in medicine have opposed every advance in therapeutics, every remedy, every method. The introduction of such valuable drugs as cinchona, colchicum, mercury, and nearly all our indigenous drugs encountered violent opposition by the alleged "authorities" of the regular school. So-called physiologic therapeutics, such as electricity, massage, hydrotherapy, were first used by "irregulars" and opposed by the "authorities." And only when they were forced to recognize their value did they "get into line." Even "suggestive therapeutics" and hypnotism, now recognized as valuable, were once denounced as unscientific and "quackish" by the "authorities." It is a strange irony of fate that resuscitated with

honor a discovery once buried in disgrace. Mesmer published his theory of animal magnetism in 1775. Ten years later the French Government appointed a commission composed of eminent physicians and savants ("authorities") to investigate his system; an adverse report brought irretrievable disrepute upon its author, and Mesmer returned to Germany to perish in oblivion. To-day his apotheosis is sealed in the generally admitted fact of the power of one mind over another, and in hypnotism is recognized a positive therapeutic force. Strangest of all, the very nation which laughed to scorn the early promulgator of this mysterious agency, but lately claimed its most ardent advocate—Charcot.

"The world moves" in medicine as in other things. The treatment by drugs becomes more simple and direct every year; in place of the old unreliable Galenical preparations, the active principles used with definite intention and a distinct aim to produce a certain effect, are being generally employed by "up-to-date" practising physicians. The *raison d'être* of the bulk of the Pharmacopœia has passed away. The active principles are now being recognized as the fixed stars in the firmament of medicine, around which a multitude of inferior lights revolve in various subordinate relations. To these remedies of unvaried and uniform strength we may trust implicitly. Contrast with these the alarming array of nauseous, unreliable mixtures, recommended from week to week in the department of "Therapeutics" in the *Journal of the American Medical Association*. Yet the erudite editor of the above-named journal and its corps of pharmacists constituting the Council of Pharmacy and Chemistry of the American Medical Association, together with a few bacteriological enthusiasts and professors assuming an omniscience prompted by limited experience, assume to dictate to the great body of active practising physicians what they should and what they should not use in the treatment of the sick. These "authorities" look upon alkaloidal medication as a menace to humanity. The learned "Council" says that up to date there are 250 odd preparations we may use. Of these there are but sixty American products and twenty-three of these are from one manufacturer. No active principles are mentioned—to me a very significant fact. If we use a remedy not "passed" upon or endorsed by these "authorities," we are considered to be "unscientific," if not an actual menace to the people generally.

Not infrequently we find that certain "professors," to say nothing of editors of medical journals and pharmacists, are men of restricted observation and not nearly so well versed in clinical experience as the average doctor who is actively engaged in bedside practice.

The time has passed when a few men can successfully set themselves up as authorities, or dictators, or arrogate to themselves any special theory or procedure. Candid practitioners to-day recognize good in all systems based upon scientific thought and pursued with intelligence and sincerity. By means of release from the shibboleths of the past, and adherence to a given "authority" or "school" the freedom of present practice is greatly enhanced, to the immense benefit of the patient and the lasting honor of the physician.

I cannot too strongly deprecate any tendency to discord and contention among a body of men to whom is accorded the highest privilege decreed by the genius of science—that of alleviating human misery. Whenever the physician's range of study and practice becomes limited by prejudice, or narrowness of intellectual vision, he falls below the standard set by the canons of Christian sympathy and the dictates of steadfast devotion to the amplest interpretation of his calling.

ABNORMAL RESPONSE TO AN IRRITATION OF THE MOTOR AREA OF THE BRAIN.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

ASSOCIATE IN NERVOUS AND MENTAL DISEASES, JEFFERSON MEDICAL COLLEGE, EXAMINER OF THE INSANE AT THE PHILADELPHIA GENERAL HOSPITAL.

The present contribution is for the purpose of placing on record a very interesting and curious observation concerning an abnormal response to an irritation of the motor area of the brain.

It is a case of Jacksonian epilepsy in a boy of sixteen. At the age of twelve he began to have convulsive movements which from the beginning up to the time of the operation have been confined to the arm, neck, and face, on the left side. He never lost consciousness, and always witnessed the seizures. At first they would occur once a month, but later they became more frequent.

The patient's general condition was fairly good. In view of the strict localization of the symptoms, an exploratory operation was decided upon. A large osteoplastic flap was made on the right side of the cranium and the largest part of the Rolandic area was exposed. Dilated and tortuous veins, reminding one of angiomatous blood-vessels, were found over the upper part of the uncovered area, but the cortex appeared normal.

Dr. Da Costa, who performed the operation, put a number of ligatures on these dilated blood-vessels.

For the purpose of studying the exact localization of the motor area, I decided to irritate the cortex with a faradic current.

The unipolar method was used, as advised by Sherrington and Grünbaum. The blunt end of a very small metallic electrode was covered with a very thin layer of absorbent cotton, and during the procedure was carefully and very superficially applied to the cortex. An extremely small current was used. Every time the electrode would touch the brain tissue, contractions would be noticed on the same side. Application to the upper angle of the exposed area would produce distinct contractions in the arm and very slight in the leg; when the electrode was applied to the middle area, the arm alone would twitch and faradization of the lower angle brought on contractions of the arm, neck, and face. The remarkable phenomenon was the fact that at no moment convulsions or any twitching was noticeable on the left side. Incidentally I may add that the application of the electrode was made on the ascending frontal convolution as well as in the fissure of Rolando, and on the ascending parietal convolution. While the response was decidedly marked upon irritation of the ascending frontal, it was much less pronounced when the ascending parietal was faradized. Nevertheless, irritation of the latter gave some twitching of the extremities. I wish also to mention that, in view of the well-known precaution indicated by Grünbaum and Sherrington, the application was

*Read before the Philadelphia Neurological Society, April 23, 1907.

first made to the ascending parietal, and only then to the ascending frontal.

The striking feature in this case is the muscular contractions on the same side where the motor area was irritated. The only explanation, in my judgment, is an anomaly of the pyramidal tract. There are two kinds of abnormal arrangements of this tract. One is a bilateral absence of decussation; the crossed bundles are wanting on both sides of the cord, and the pyramidal bundles are represented by very enlarged Türck's columns. This is a very rare occurrence. The other is a unilateral absence of decussation; the crossed bundle is absent only on one side; the pyramid has never been divided, and forms one large bundle of direct fibers. This is also not frequent.

As the opposite hemisphere in my case was not exposed, and therefore not experimented upon, it is difficult to say which of the two anomalies may be the cause of the unusual phenomenon. All mammifera possess a decussation of pyramidal bundles except the elephant, but in man it is extremely rare.

1430 Pine Street.

A CASE OF MULTILOCULAR GLANDULAR CYSTOMA COMPLICATING PREGNANCY.*

By B. S. TALMEY, M.D.,
NEW YORK.
GYNECOLOGIST TO THE YORKVILLE HOSPITAL, FORMER PATHOLOGIST TO THE MOTHER'S AND BABIES' HOSPITAL.

Mrs. M., 24 years of age, mother of three children, was always healthy. Her menstruation was always regular since her fourteenth year. Five weeks previous to her coming to my office she had given birth to a healthy child, the labor having been perfectly normal, assisted only by a midwife. The patient was able to sit up in bed three days after her confinement, and a week later she left her bed and attended to her regular duties. Five weeks after her confinement the patient was suddenly seized with acute violent pains in the right inguinal region, extending to the back. The physician called in thought of appendicitis and advised the patient to go to New York to be ready for an operation.

Upon her arrival in New York she consulted Dr. M. Cisin, who felt a tumor in the pelvis, which appeared to be the subinvoluted uterus, and he sent the patient to me for treatment.

At the examination on September 16, 1906, I found the patient to be a well-nourished woman, the face somewhat flushed and respiration quickened. She was suffering from constant pain, mostly in the back, but not so excruciating as on the first day of the attack. The abdomen was somewhat enlarged and tympanitic. The entire lower abdomen was very sensitive to the touch. The combined examination showed the tumor to be distinct from the uterus, which was in a normal position, the tumor lying higher up on the right side. It was composed of several lobules of varying consistency and size. Some of them showed distinct fluctuation, others were soft to the touch, while the rest was of a solid, hard consistency. My diagnosis, therefore, was multilocular glandular cystoma of the right ovary, and I recommended an operation. Two days later the patient was seized with another attack, with almost unbearable pains in the back and in the right inguinal region, and she then entered the hospital.

The abdomen was greatly distended and tympanitic, with ascites on both sides when the patient was lying on her back. The pulse was now 110, the temperature 102° F., and the patient showed symptoms of a beginning general peritonitis. The diagnosis was "torsion of the pedicle of the cystoma."

The next morning, September 19, the patient was operated upon, with the usual incision in the linea alba. Upon opening the peritoneal cavity about a quart of a bloody fluid escaped, so that the assistants at the first sight exclaimed "extrauterine gestation." The tumor was now freed from its bed and brought forward to the abdominal opening. It was of the size of a child's head and could not pass the comparatively small incision until I perforated the longest cystic lobe and allowed the amber colored serum to escape. The entire tumor was thereupon brought outside of the abdominal incision, when it was found that the long pedicle was twisted, having two corkscrew turns and causing gangrene of some parts of the tumor. The pedicle was now compressed with the angiotribe, ligated, and the cystoma excised. The stump was thereupon covered with peritoneum by embedding it beneath the ligamentum latum, after Segond's method.

The examination of the tumor showed a number of different lobes, two of them were cystic in character, containing a clear amber-colored fluid, one lobe enclosed in its cavity a gelatine-like mass and another one had a very small cavity with thick fibrous walls, containing calcareous incrustations on the interior surface. Some lobes were almost solid. The entire tumor was, therefore, unmistakably a multilocular glandular cystoma of the ovary.

The case is interesting from the point of view of the previous delivery. The patient was confined by a midwife without any artificial aid, and a few hours after the labor pains had begun, five weeks previously. Yet she had within her abdomen a tumor of the size of a child's head. For it is scarcely probable that the glandular cystoma had materially increased within the last few weeks after the confinement. The only explanation why this large tumor did not cause any dystocia is that the rising uterus gradually raised the tumor above the pelvis. Thus the location of the tumor at the time of delivery was high above the pelvic rim and did not interfere with the child's head. After the confinement the normally involuted uterus dropped back within the small pelvis and with it also the tumor, the latter now being located in the right pelvic fossa, directly upon the muscles ischio-coccygeus and coccygeus. In this position the torsion of the pedicle is not to be wondered at. The two attacks coincided with the two turns of the pedicle.

The history of this case shows that even large tumors do not always cause dystocia. In Niebergall's case* of a fibroid complicating pregnancy a spontaneous delivery also took place after the tumor was raised out of the pelvis in the seventh month of pregnancy. In Pollosson's case† a dermoid cyst was diagnosed during the first pregnancy and its removal advised. This pregnancy ended with an abortion in the fifth month. But the second and third pregnancies terminated normally and only during the third month of her fourth pregnancy a torsion of the pedicle took place, and the patient had to be operated upon.

Such cases serve to show that even large tumors complicating pregnancies are not always an indication for the removal of the tumor during the period of gestation, thus endangering the lives of mother and child by the complication of a possible miscarriage.

62 West One Hundred and Twenty-sixth Street.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, June 22, 1907.

ARE THE SETTLERS OF WESTERN CANADA DOOMED TO FAILURE?

A FEW years ago little was known of the Canadian provinces to the west of Manitoba, and indeed of Manitoba itself, and all this vast region was thought of only as a frigid waste from which came the cold waves which periodically sweep across the United States, carrying frost into Texas and even to the orange groves of Florida. But lately it has been found that that country is one of exceeding fertility, the richness of soil and the brightness of sunshine combining to make it admirably adapted to the growing of wheat, despite the pitiful brevity of its summer. A migration of large proportions has been setting in from the United States and Europe, and this region now promises to become one of the great granaries of the world. The cold of winter is long continued and intense, but the heat of summer is ample in intensity and duration for the ripening of grain, the soil is rich, and the unoccupied land is of almost limitless extent and capable of supporting a very large population, so that the prosperity of this new territory would seem to be assured. There is but one cloud overshadowing this hoped-for prosperity, and this is, to abandon the language of metaphor for that of fact, the absence of cloud. The country is one of almost continuous sunshine, the brilliancy of the light equaling that of the tropics, and if it is really the light rather than the heat which bars tropical lands to the white man, as Woodruff contends, the prosperity of the Canadian Northwest promises to be shortlived.

As those who have read Major Woodruff's interesting book* know, he holds that the failure of the white races to colonize the tropics is due, not to the heat of these regions, but to the excess of light which there prevails. The Europeans who have been most successful in colonizing tropical regions, that is, who have themselves peopled the colonies and not merely ruled them by a constantly changing staff of officials, are the natives of the Iberian Peninsula, a dark-skinned race; and to blonds, Woodruff asserts, tropical lands are fatal. If it is the heat rather than the light that is injurious, the white man should prosper more than the black man, and the blond more than the brunette, since the presence of pigment in the skin distinctly favors the penetration of the heat rays. But the white man, especially the blond, suffers in the tropics; after a period of exhilaration and sense of well-being, he becomes disinclined to labor, grows neurasthenic, and finally breaks down physically and mentally. This Woodruff attributes to the action of the actinic rays of light, which penetrate the more readily the less of pigment there is in the skin and hair, and he therefore concludes that it is the light rather than the heat which bars the white man from the tropics.

In the *Western Canada Medical Journal* for February, 1907, the Rev. E. C. Heustis asserts that the inhabitants of Manitoba and the adjacent territories are unduly neurasthenic, and, adopting Woodruff's theory, attributes this condition to the excess of sunshine with which that country is blessed—or cursed, according to the point of view. In the issue of the same journal for May of this year, Dr. A. G. Welsford controverts Mr. Heustis' contention, and asserts that sunlight is a blessing. He concedes that sunlight is destructive to protoplasm, but says that the actinic rays do not penetrate the skin to any extent, the deeper tissues being protected by the epidermis and especially by the dermis, which is suffused with red blood offering a barrier as effective as the black pigment of the negro's skin. The reason why Europeans do not thrive in the tropics is, he maintains, that they are attuned to colder climates, and when transplanted to warm regions live under abnormal conditions of heat rather than of light. He does not deny that the denizens of the sunlit regions of Northern Canada suffer from neurasthenic states, but he asserts that these depend "in no way upon the sunshine," except as this may have an indirect effect by reason of its tonic properties which lead to the undue expenditure of energy. In another part of his article he admits, indeed, that intense and long continued sunshine may prove exhausting, but he rejects Woodruff's theory of its action, attributing its possible evil effects to eyestrain, resulting from the glare. We fear Dr. Welsford has not proved his case, for he concedes that intense sunlight may be injurious, differing from Woodruff and Heustis only in his explanation of its action. The farmers who are now peopling western Canada are not going to wear colored glasses to prevent eyestrain, and they are not going to take life easy, for they must work hard to reap their harvest before the winter frost, and they will not work the less hard because the light stimulates them to greater endeavor.

An interesting experiment is being worked out in Manitoba, and it is one which should in its results confirm or refute Woodruff's theory. If he is correct, the movement of wheat growers, most of whom are Scandinavians or men of other blond races, to northwest Canada is doomed to failure. Those who are now building up the country will fall by the way and their farms will be abandoned or will be taken by fresh immigrants ignorant of the forces against which they will in vain contend. If the prosperity of the Northwest continues, if the population is permanent, and if success rewards the labors of the settlers in this land of sunshine, Major Woodruff will have to add a chapter to his interesting book explaining the antidotal effect of cold, or of some other natural force, upon the deleterious action of sunlight.

*The Effects of Tropical Light on White Men, by Major Charles E. Woodruff, A.M., M.D., Surgeon, U. S. Army. New York: Rebman Company, 1905.

AN UNOCCUPIED FIELD OF PRACTICE.

THERE is an enormous amount of suffering among the rural population of this country, especially the wives and daughters of farmers, due to uncorrected astigmatism and other ocular defects. On first thought one may be inclined to doubt the correctness of this statement, for the farmer is supposed to lead an outdoor life and to be little given to literary pursuits. But this is not true of many, if not the majority, of the rural population. In most farm houses of the better class one will find the weekly political paper and one or more agricultural or poultry journals, and in not a few several of the magazines and weekly story papers are also taken and faithfully read from cover to cover. Moreover, the women have their sewing and their mending and their fancy work—more eyestrain, in fact, than many of their well-to-do and perhaps better educated sisters in the city. Numbers of these poor women are martyrs to headache, gastric disorders, and other ocular reflexes, ignorant for the most part of the cause of their suffering and unable, even if they suspect that their eyes are "weak," to obtain relief. At the best, or worst, they go to the country store and select from a small assortment the spectacles which they think they need, and their last state is perhaps worse than the first. The country doctor is seldom able to help them, for as a rule, up-to-date, sensible, and skillful practitioner as he is, he lacks the practical training and experience necessary for the correction of errors of refraction, and even if he has the qualifications needed for such work the demands of a country practice leave him no time for the tedious work of testing eyes.

Herein lies an opportunity for relieving suffering and attaining material success which is worthy of the consideration of the recent graduate in medicine. Specialists must, from the nature of their restricted practice, live only in the cities and larger towns, where the number of consultations are sufficient to occupy their time and afford them a living practice. But in the case of refractive errors especially, which are still so wrongly regarded as among the minor ills, the farmer and his women folk cannot afford the time and expense of a journey to the city in search of relief. There is need here for missionary effort, and, contrary to the rule of most missionary endeavor, the man who undertakes such a needed work will reap an ample reward. There is an opening in nearly every county of every State in the Union for a thoroughly trained and skillful oculist who will establish a circuit of small towns in each of which he has an office in which he may be consulted, say two days a month or a fortnight, by the country people in the district. The man should be an educated physician, with hospital training—as should be every specialist—and preferably with an experience of several years in general practice, during which time he has devoted his unoccupied hours to a study of the eye and its diseases and of refractive errors and the means of their detection and correction. He should indeed, be the equal of any of his fellow specialists practising in the city. His way at first may not be easy, for he will be a missionary and his task will be to educate the people, through their medical advisers, to an appreciation of the rôle of eyestrain in the causation of many of the headaches and "dyspepsias" from which they suffer. He must be tactful in his relations with the practitioners in the towns embraced in his circuit and should of course confine himself strictly to his specialty and not encroach on the general practice of his colleagues. It will not be long, however, before such an "itinerant oculist," if he is skillful, and as honest and tactful as he is skillful, will make his way. One successful case in each town will establish his reputation, for farmers' wives are great gossips, and if he is careful to respect the rights of the local physicians they will be only too pleased to send him their teazing cases and "chronics" that their medicines have not relieved and which they will themselves soon learn to recognize as "eyestrain" cases and gladly refer to the oculist for relief.

There is nothing unethical in such a practice. Traveling quacks have caused honest physicians and intelligent laymen to regard the "itinerant" with suspicion, but the origin of all specialism was in quackery and it was only when reputable practitioners began to devote themselves exclusively to a study of special diseases that the stigma attaching to special practice was removed. There are even now many reputable physicians and specialists who have offices in two or more places in the same city or in different cities, and a slight extension of this principle by educated, earnest, and honest young ophthalmologists will cause the itinerant oculist (not optician) to be regarded as a valued and honorable member of his profession.

THE SIGNIFICANCE OF QUINQUAUD'S SIGN.

THE sign to which the above title was given by Maridort after the death of Quinquaud consists in an exceedingly fine crepitation to be perceived when the person under examination places the tips of his slightly separated fingers against the palm of the examiner's hand which is held horizontally. According to its originator this crepitation is to be perceived only when the patient is a chronic alcoholic, and numerous observers who have tested the matter on large numbers of persons of various types have concurred in this statement. For example, Fürbringer who examined 468 persons, Levienik who examined 200 persons, and Hoffmann and Marx who examined 1,018 persons, all expressed themselves favorably in regard to the sign, though with certain reservations. Contrary opinions have not been lacking, however, and Lauschner has asserted that neither the presence nor the absence of Quinquaud's sign has any bearing on the question of the amount of alcohol consumed by the patient.

A recent and very exhaustive consideration of the question is that of Minor of Moscow (reported in the *Berliner klinische Wochenschrift*, May 6, 1907), who has investigated the subject on a very large number of persons of all classes and types, including many patients suffering from a variety of nervous diseases. This author has sought to simplify the matter by rendering the detection of the phenomenon independent of the observer's tactile sense. This is accomplished by transforming the sign into

an auditory phenomenon. The patient's fingers are applied to a small wooden resonator which is in contact with the diaphragm of a phonendoscope, and in this way the experiment is always carried out under similar conditions, and the existence or absence of the crepitations is rendered unequivocal. Minor comes to the conclusion that Quinquaud's phenomenon is neither specific nor pathognomonic for alcoholism, and that it is frequently present in well-marked form in moderate drinkers and total abstainers. It is rarely seen in exophthalmic goiter, paralysis agitans, arthritis deformans, hemiplegia, and Dupuytren's contraction, but is exceedingly frequent in tabes. Hysteria comes next to tabes in the frequency and intensity with which the crepitations are to be detected, and alcoholism occupies only the third or fourth place. Alcoholic tremor of the permanent form, as distinguished from the trembling immediately consequent on a debauch, is less often encountered than the phalangeal crepitations, and is entirely independent of these in nature and causation.

Apparently this phenomenon is one of hypotonicity and is a very delicate test for neuromuscular fatigue. What muscles are concerned in its causation is still an open question, but the fact that it sometimes is present when there is extreme atrophy of the interossei seems to indicate that the long forearm muscles are implicated in its causation.

THE CAUSE OF ASEPTIC PURULENT INFLAMMATION.

Inflammation may be caused by bacteria, chemical substances, or traumata. While, as a general rule, the time-honored dictum, "no pus without bacteria," holds good, it has long since been proven that certain chemical substances injected into the tissues can cause an aseptic purulent inflammation. Heretofore no experiments have absolutely proven that a purulent inflammation can be brought about by the products of an aseptic disintegration of tissue, caused by a trauma. As all purulent inflammations are caused by the chemotactic influence of the pyogenic substances on cells, the question arises whether aseptically destroyed tissue contains positive chemotactic substances. To determine this point, L. Burkhardt (*Deutsche Zeitschrift für Chirurgie*, Vol. 85, 1907) has conducted several interesting experiments. Under aseptic precautions a piece of muscle tissue was removed from a rabbit and ground up into a pulp, decinormal salt solution was added to it, and the mixture was allowed to stand for 24 hours. At the end of that time it was filtered and the extract of the muscle pulp was carefully sealed in small sterile tubes. Cultures of this extract on bouillon, agar, and gelatin showed no growth. The small tubes were buried under the skin of other rabbits and their ends were broken off subcutaneously. In all cases, aseptic pus was found at the ends of these tubes after three days. Control tests were made with tubes containing decinormal salt solution and an extract obtained by immersing intact muscle tissue in salt solution; in neither case was any pus found. Crushed muscle tissue therefore contains substances which have a positive chemotactic action, the extent of the aseptic purulent inflammation depending, as these experiments would appear to prove, upon the degree of trauma and the rapidity of resorption.

Burkhardt also made similar experiments to ascertain what effect heat had in the production of positive chemotactic substances. A piece of muscle was charred superficially and an extract obtained and enclosed in sealed tubes as before. The tubes were again placed under the skin of rabbits, where they were broken subcutaneously. After from four to six days aseptic pus was found at the ends of the tubes. The fact that crushed and charred tissues were found to contain positive chemotactic substances, which, experimentally at least, produced an aseptic purulent inflammation, should be borne in mind during the course of an operation, in which the excessive use of sharp retractors and much unnecessary handling of the tissues, as well as an unduly extensive employment of the galvanocautery, may sometimes be the cause of a local purulent inflammation.

Septic Infections and Acute Leukemia.

A number of observers have reported cases in which septic infections of various sorts were associated with blood pictures corresponding to that of acute lymphatic leukemia, and it has been suggested, for example by Türk, that in these cases the septic condition is primary and stands in a certain etiological relationship to the blood disease. This opinion has not as yet, however, been universally accepted, and Erb in a posthumous communication (*Deutsche medizinische Wochenschrift*, May 23, 1907) expresses the opinion that so far there is no conclusive experimental or clinical evidence to prove that sepsis may give rise to general lymphomatosis. He prefers to accept the view that the septic infections sometimes associated with acute leukemia are secondary complications, and points out that patients suffering from this blood disease are unusually prone to such infections. Why this should be so is difficult to say, but it is not impossible that the reduction in the number of polymorphonuclear leucocytes may in some cases favor the invasion of infectious organisms.

The Etiology of Pemphigus Neonatorum.

It is sometimes considered that this affection, leaving aside the syphilitic form, is not a disease *per se*, but is a condition of complex etiology representing simply the reaction of the infantile organism to infectious agents of various sorts. A case in point is reported by Kaupe (*Münchener medizinische Wochenschrift*, May 21, 1907), who found a ten-days-old child exhibiting the classical picture of pemphigus neonatorum. There were no indications of syphilis in the other members of the family, and on investigating it was discovered that at the time of the infant's birth the mother was suffering from an eruption which was later found to be chickenpox. The infection had been brought into the house by the midwife, and two other children also were subsequently infected. In this case it appeared that the pemphigus eruption represented the varicella exanthem in an infant whose blood had not yet developed sufficient protective substances to cause the lesion to assume its ordinary form.

Thymol in the Treatment of Goiter.

In the treatment of cases of endemic goiter, the use of a pure water and removal from the affected localities are recognized as among the most important steps, and have given better results than most of the drug treatments. According to McCarrison, however, thymol may be employed with good success in this type of goiter, its action being explained by the fact that it is an intestinal antiseptic, for the disease is regarded by many as parasitic in character with the infection taking place through the medium of the digestive tract. McCarrison reports twenty-five cases successfully treated by this drug, and in especially favorable instances a disappearance of the struma was noted within seventeen days after the beginning of treatment. The thymol is given in doses of 1.8 gram twice a week, followed by a cathartic in the evening, and on the intervening days it is given in doses of 0.6 gram morning and evening. Its administration may be continued until the goiter has disappeared. In none of the cases thus treated by the writer did a period of more than two months elapse before a favorable effect was evident.

A Rare Histological Finding.

It is very often by mere chance that microscopical structures of great interest and value are discovered. As an instance of this attention is directed to a recent communication by Welch (Bulletin of the New York Lying-In Hospital, March, 1907) in which he describes and illustrates a human Graafian follicle containing two ova. Considering the manner of development of these structures, it is rather surprising that multiple ova are not more frequently found. The description of this process given in Quain's textbook leaves the impression that where there is more than one primordial ovum included in the Graafian follicle fusion results. And most writers state that only one ovum occurs, although a few others deny this without, however, citing concrete instances in which such a condition has been found. Dr. Welch's discovery is of considerable interest from the embryological standpoint.

News of the Week.

Retirement of Dr. Andrew H. Smith—Dr. Andrew H. Smith, for many years one of the foremost practitioners and consultants of this city, has retired from practice and removed his residence to Geneva, N. Y. Dr. Smith began his professional career as an army surgeon and upon his return to civilian life, soon after the close of the Civil War, entered upon practice in this city, where he has filled many positions of prominence in the profession, including the presidency of the New York Academy of Medicine. He was also attending physician to St. Luke's and the Presbyterian hospitals and surgeon to the Manhattan Eye, Ear, and Throat Hospital, and held the position of consultant in a large number of institutions. He has been a frequent contributor to medical literature.

Centennial Anniversary of the College of Physicians and Surgeons.—Over two hundred guests were present at the dinner of the alumni association of the College of Physicians and Surgeons of Columbia University given last week in honor of the hundredth anniversary of the school. Dr. T. M. Cheesman presided and among the speakers were President Nicholas M. Butler, Dean S. W. Lambert, Rev. Dr. Aked, Dr. Darlington, and Mr. Geo. L. Rives. In connection with the anniversary celebration demonstrations and clinics were held in the college building, in the Vanderbilt Clinic, and in the Roosevelt and other hospitals. Addresses were also delivered at the college by President Butler, Prof. John G. Curtis, and Professor W. H. Welch of Johns Hopkins University.

Compliment to Dr. Grenfell.—Mr. Wilfred T. Grenfell, L.R.C.P., M.R.C.S., on May 28 received from the University of Oxford the honorary degree of M.D.; this is said to be the first time in the history of the university that this honorary degree has been conferred. The honor was given in recognition of Dr. Grenfell's self-sacrificing work among the fisherfolk of the Labrador coast. At first he worked on board the mission vessels in the North Sea, but in 1892 he initiated work of a similar kind among the fishermen in Labrador, where, having obtained his certificate as a master mariner, he commanded his own vessel. In Labrador and Newfoundland he has helped in establishing four hospitals, besides various cooperative stores and other institutions for the good of the inhabitants. Recently Dr. Grenfell delivered several lectures in this city descriptive of the life of the people among whom he does his work.

Strauss Milk Booths.—The fifteenth season of the Strauss pasteurized milk booths began on Monday, when eleven new booths were opened in addition to the six that were operated last year. The stations are located as follows: 151 Avenue C, 47 Monroe street, 441 West Thirty-third street, 329 East Fifty-ninth street, 303 East 111th street, 38 Macdougal street, Battery Park, City Hall Park, Tompkins Square, Central Park, Mount Morris Park, Hebrew Educational Alliance, East Broadway and Jefferson street, Recreation Pier, East Third street; Recreation Pier, East Twenty-fourth street; Recreation Pier, East 112th street; Recreation Pier, Barrow street; Recreation pier, West Fiftieth street.

International Red Cross Conference.—At the final session of the International Red Cross Conference in London, Lieutenant-General Bessim Omar Pasha announced that he represented the Mohammedans and owing to the fact that the symbol of the cross opposed every religious belief of his people, he demanded that the organization in future adopt the crescent as a symbol instead of the cross and be called the Red Crescent instead of the Red Cross. The proposition was disposed of by ruling the speaker out of order. In addressing the conference Baron Ozawa, Vice-President of the Red Cross Society of Japan, said the Japanese Ambulance Corps during the Russo-Japanese War had to deal with 622,688 cases, and the number succored in hostile camps and on hostile ships raised the number to far above a million. This was all done at an expenditure of less than $2,500,000. The small cost was due mainly to the strict centralization of the Japanese system. No women nurses were employed. The conference also passed resolutions declaring it within the province of the society to care for and succor prisoners as well as the ill and wounded, and relating to the treatment of soldiers discovered to have tuberculosis.

Charcot's Library.—Dr. Jean Charcot has presented to the Salpêtrière in Paris the entire library of his father, which is considered one of the foremost collections of neurological literature in the world. Dr Charcot has also presented to the same

institution with which the elder Charcot was so long connected, the furniture of the celebrated scientist's study.

To Destroy Anthrax Germs.—A technical chemist of Dewsbury, England, has discovered an electrolytic process by means of which it is possible to sterilize rags, etc., in large quantities, and it is claimed that in this way wool workers may be freed from the risk of contracting anthrax, as the process can be used to kill the anthrax bacilli and spores in the crude material.

Eyeglasses for School Children.—The Board of Education has passed a series of resolutions requesting the Board of Health to make a systematic investigation of the eyesight of the children in the public schools, with a view to the free distribution of eyeglasses to those whose sight is found defective.

Mechanotherapy Appliances for the German Hospital.—The German Hospital has installed in the gymnasium of the dispensary in the Anna Ottendorfer Building of the hospital at Seventy-sixth street and Park avenue, twenty-four pieces of apparatus for the purpose of giving mechanical treatment and medical gymnastics.

Typhoid Fever in Pittsburg.—The occurrence of numerous cases of typhoid fever at several upriver points has alarmed the health authorities of Pittsburg and warnings have been issued to the people to use only boiled water. On June 18, forty-one new cases of the disease were reported in the city, and during the first eighteen days in this month there were 228 cases.

Plague in Trinidad.—Owing to the increase of bubonic plague in Trinidad, Venezuela has suspended traffic with the island.

The New Harlem Hospital.—The new Harlem Hospital at Lenox avenue and 136th street was formally opened on June 15, although it has actually been in operation for some weeks and nearly a hundred patients are at present in its wards. Dr. John W. Brannon, president of the board of trustees of Bellevue and Allied Hospitals, presided, and Comptroller Metz made the principal address. The hospital is a large five-story brick building, accommodating 150 patients. Its cost, including that of the power house and ambulance stables, was $624,000. In the fall the erection of another building on the same plot for a nurses' ward is to be commenced.

American Association of Medical Examiners.—At the meeting of this organization, held in Atlantic City on June 3 and 4, the question as to the amount of the fees that should be allowed by life insurance companies for the proper examination of an applicant was considered and it was the unanimous opinion of the association that life insurance companies should pay a minimum fee of five dollars for each and every examination. A resolution was presented and adopted in which the Association recorded itself as being in favor of a portfolio of Health to be established by the Federal Government, with the Secretary a physician and ranking in authority with the other members of the President's Cabinet. It was decided to hold the next annual meeting of the Association at Chicago, the time to be determined later. The following officers were elected to serve for the ensuing years: *President*, C. H. Harlow, Philadelphia; *Vice-Presidents*, Liston H. Montgomery, Chicago, Frank E. Allard, Boston, B. J. O'Connor, Louisville, Ky., E. O. Kinne, Syracuse, N. Y., T. Millman, Toronto, Canada; *Secretary-Treasurer*, John Guy Monihan, New York.

Association of American Physicians.—The next meeting of this organization will be held in Washington, D. C., May 12 and 13, 1908. The president is Dr. James Tyson of Philadelphia and the secretary remains Dr. Henry Hun, 149 Washington avenue, Albany, N. Y.

Toronto Academy of Medicine.—Under this title the Toronto Pathological Society, the Toronto Clinical Society, the Toronto Medical Society, and the Ontario Library Association have been united in a single organization and the separate constituent societies have been disbanded. The officers of the new Academy are as follows: *President*, Dr. J. F. W. Ross; *Vice-President*, Dr. McPhedran; *Hon. Secretary*, Dr. H. J. Hamilton; *Hon. Treasurer*, Dr. D. J. G. Wishart; *Council*, the above mentioned officers and Drs. Irving H. Cameron, H. A. Reeve, H. A. Bruce, J. T. Fotheringham, A. A. Macdonald, H. P. Anderson, W. P. Caven, E. E. King, John Amyot, F. M. G. Starr, R. D. Rudolf, R. J. Dwyer.

Maine State Homeopathic Society.—The forty-first annual meeting of this organization was held in Augusta on June 11. It was decided to hold the next meeting in Portland, and officers were elected as follows: *President*, Dr. R. S. Graves, Saco; *Vice-Presidents*, Drs. John T. Palmer, Portland, and W. H. Kennison, Madison; *Recording Secretary*, Dr. Luther A. Brown, Portland; *Corresponding Secretary*, Dr. Carrie E. Newton, Brewer; *Treasurer*, Dr. William S. Thompson, Augusta.

New Hampshire State Homeopathic Medical Association.—At the annual meeting of this organization, held in Concord, officers were elected as follows: *President*, Dr. J. E. Willis, Somersworth; *Vice-President*, Dr. C. A. Sturtevant, Manchester; *Treasurer*, Dr. Herman Christophe, Manchester; *Secretary*, Dr. R. V. Sweet, Rochester.

Dr. William Seaman Bainbridge of New York City received the degree of Doctor of Science at the annual commencement of the Western University of Pennsylvania, June 7.

Obituary Notes.—Dr. Lamar Seeley of Portland, Ore., died suddenly on June 14 in St. Luke's Hospital at the age of twenty-six years. Dr. Seeley was a graduate of Williams College and received his medical education at Johns Hopkins University, from which he was graduated in the class of 1906. He had been an interne in St. Luke's Hospital for about six months.

Dr. Samuel S. Wallian of this city died of pneumonia on June 12. He was born in Brookfield, O., in 1835 and spent his early life in Wisconsin. He served through the Civil War and subsequently studied medicine. He had practised in this city for over twenty years.

Dr. John A. Robinson of Elmira, N. Y., died on June 14, ten days after an operation for appendicitis. At the time of his death he was City Coroner of Elmira.

Dr. Cyrenus A. David of Chicago died on June 12 of septicemia due to an infection received in the course of an operation. He was born at Olney, Ill., and was sixty-two years of age.

Dr. Charles Evert Cadwalader of Philadelphia lately a resident of London, England, died suddenly of heart disease in that city on June 12.

Dr. William J. Swinton of Somerville, N. J., died on June 14 at the age of fifty-eight years. He was born at Florida Springs, N. J., and received his early education in France. In 1872 he was graduated from Bellevue Hospital Medical College and

he then completed his medical training in Paris. For many years he was physician for the Central Railroad of New Jersey.

Dr. JOHN J. MORRISSEY of this city died on June 14, following an operation for depressed fracture of the skull. While attempting to board a car last Monday he fell and received the injury. Dr. Morrissey was born in Hartford, Conn., forty-eight years ago, and was graduated from Villanova College and the College of Physicians and Surgeons. He was visiting physician to St. Joseph's, St. Vincent's, and St. Francis' Hospitals, and the Metropolitan Hospital and Dispensary.

Dr. GEORGE EMERSON KING of Kalamazoo, Mich., died suddenly on June 6 of apoplexy. He was born in Erie, Pa., forty-seven years ago, and was graduated from the Western Reserve Medical College at Cleveland in 1882. He began practice in Mattawan, where he resided for fifteen years, and then removed to Kalamazoo.

Dr. J. P. HAMPTON of Meridianville, Ala., died on June 8, after a long illness. Dr. Hampton was eighty-two years of age and had served with distinction in the Civil War as captain in the Forty-third Mississippi Infantry. He was several times representative for Madison county in the State Legislature and served many terms as president of the Madison County Medical Society.

Dr. HENRY C. IDE of McIndoes, Vt., died in Burlington on June 5 at the age of thirty-eight years. He was a graduate of Dartmouth Medical College and Bellevue Hospital. He had practised in McIndoes for about ten years.

Dr. SYLVESTER D. LEWIS, formerly of Amsterdam, N. Y., died on June 16 at the home of his son, Dr. George Griffin Lewis, in Syracuse, at the age of seventy-nine years. Dr. Lewis was a member of the class of 1857 of Union College and received his medical education in the Albany Medical College.

Correspondence.

INDICANURIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The article by Dr. Porter on Indicanuria in your issue of June 15 is on a subject to which, I think, too little attention has hitherto been paid. This article, read in connection with Herter's recently published "Bacterial Infections of the Digestive Tract" (New York, The Macmillan Co., 1907), sufficiently indicates the importance of the subject. For a long time I knew of no means of combating the condition other than restriction of the amount of protein in the diet, and it was not until I read the following in Metchnikoff's "The Nature of Man" that it occurred to me to use any other means. This writer says: "Investigations recently made by Bienstock and confirmed by Tissier and Martelly have proved the existence of certain microbes that sour milk, *i.e.* cause the formation of lactic acid, and which are antagonistic to the microbes of putrefaction. The latter multiply only in an alkaline medium. The lactic acid microbes produce large quantities of acid and so hinder the multiplication of the organisms of putrefaction. . . . Such facts explain how it is that lactic acid frequently stops some cases of diarrhea, and why treatment with lactic acid is so useful in maladies associated with putrefaction of the intestinal contents. It makes intelligible, moreover, the medicinal value of fermented milk."

This suggested the thought that possibly the lactic bacteria would measurably control the indicanuria. For some time past I have used them with this object in view, and am now thoroughly satisfied that they accomplish the object sought. The observations have been made both on myself and on patients, and the result has been a notable decrease of the indicanuria in the majority of cases. I have experimented with several different bacteria of the acidifying type—both coccal and rod forms—and have taken and administered the pure cultures direct, but prefer to "dope," say a quart bottle of sweet milk with the culture. If this be kept for twenty-four hours or so at a temperature of 80° to 85° F. it will be ready for use. A little of this (15 to 20 c.c.) added to a bottle of fresh milk will acidify it in like manner. This may be kept up for a week or ten days, when it will be well to start a fresh series by resort to a pure culture.

It is only recently that I learned that Dr. C. A. Herter ten years ago, experimenting with dogs, markedly reduced the amount of indican in the urine by feeding them with cultures of lactic bacteria. Dr. Herter's observations were published in the *British Medical Journal*, December 25, 1897. Here was a discovery made by a physiological chemist that appears to have been passed unnoticed by the majority of clinicians. I have not looked very thoroughly into the literature of indicanuria, and it is possible that some may have made practical clinical use of Herter's observations, or, like myself, have been led in the same direction through the influence of Metchnikoff's writings.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—GOVERNMENT VACCINATION BILL—MEDICAL SOCIETY; THE ORATION, HEART DISEASE, MOVABLE KIDNEY—MALTA FEVER—DR. WOLLASTON'S RETURN FROM CENTRAL AFRICA.

LONDON, May 31, 1907.

THE General Medical Council met for the summer session on Tuesday, when the president, Principal Macalister, delivered an address, in which he expressed satisfaction at the completion of the negotiations for reciprocity with Nova Scotia. The provincial authorities had shown every desire to meet the requirements of the Council, and Nova Scotian degrees will now be registrable. An incidental consequence is that Canadian medical graduates who have complied with the conditions applicable to the Maritime Provinces will be eligible for commissions in the R. A. M. C. As to the Province of Quebec some further inquiry respecting the conditions of admission to its register is being made through the proper channels.

The International agreement on the unification of Pharmacopœia formulæ will necessitate some alterations to the British Pharmacopœia, but probably not so many as some other countries will have to make. The action of the British Medical Association in becoming complainants in cases that may be brought before the Council has been submitted to the legal advisers, who have recommended that Councillors should withdraw from the Association.

The old dispute about the Apothecaries' Hall of Dublin again came up, and a good deal was said about the returns asked for as to the number of licenses of that body. Several regarded it as a flank attack. The truth is that the Council has no authority to consider whether the Hall should be a qualifying body or not. That has been decided by Parliament, and although I know of no one who would assert that it is a necessary, or even a useful institution, I know many who would say that there are other authorities represented on the Council which they look upon as of about the same value.

There was also a discussion on clinical teaching, in which it was alleged that practitioners are turned out by the licensing bodies full of theoretical knowledge, but sadly deficient in practical resources. No doubt much is to be said on this point, but the discussion at the Council contributed nothing of importance.

The Government Vaccination Bill has been read a second time. It aptly illustrates the way in which the boasted "strongest government" panders to any group of fanatics who make noisy assertions. Sir J. B. Tupe pointed out the many objections to the measure and the utterly illogical character of its provisions. No honest, "conscientious objector" would be materially affected, as he was willing to take the trouble to obtain the exemption provided for, but a great number of people were dragged in his train who had no convictions, but followed the agitators to the danger of the public. There was no justification for endangering the whole people at the request of a small number of persons.

Sir H. Craik, another University member, denounced the bill as a dangerous concession to prejudice and ignorance. The investigations of science should have some weight. He asked how far we were to go in concessions to whim of this or that man might call a conscientious objection. Mr. John Burns, who defended the bill for the government, made rather an apology for it than a defence, and one, to which shows that it is a mere party move to conciliate the faddists, with utter carelessness as to the danger to the

people. He said they had promised a reduction in cost; they had also promised some form of declaration, instead of the magistrate's certificate; they had also promised the postponement of vaccination to a later period. These promises (made to get votes) are obviously the only reasons why the government has brought forward the bill, unless perhaps the hope he expressed that it would go far to end the nuisance of the controversy. It seems a shocking instance of setting the success of party before the good of the country, and the indifference of politicians to the public health.

The reception of the Medical Society of London on Monday evening was attended by some 200 fellows and members of this and sister societies. In the absence of the president, Mr. C. A. Ballance, through illness, which was much regretted, the guests were received by Sir John Tweedy and Sir E. Venning, the first named of whom made sympathetic reference to the loss lately sustained by the Society through the death of Sir Joseph Fayrer, one of its most distinguished past presidents. The oration was delivered by Dr. George A. Gibson of Edinburgh, who took for his subject "The Cause of the Heart Beat," after which there was the conversazione with music. Dr. Gibson has taken a share in recent researches on the subject of his oration, and was therefore prepared to speak with some authority, and was naturally listened to with special interest. He gave an account of the two opposing theories—the muscle and nerve origin, as one may say. The former, Engelmann, Gaskell, and others have upheld with no little ability, and their views were fairly considered, but the evidence in favor of myogenesis was not satisfactory, and at present the conclusion seems to be for neurogenesis. Embryology cannot decide on either side, for neither muscle nor nerve are to be found when the heart begins to beat. So anatomy supports neither view, nerve and muscle being too closely interwoven. Pathology is equally indecisive. Clinical observation, however, the orator pronounced to be distinctly in favor of neurogenesis, the esoteric cause of contraction seeming to him the rhythmic discharge of the nervous elements.

At the previous ordinary meeting of this Society, Dr. Walter Broadbent read a paper on some heart affections without murmurs. He dealt with myocarditis, fatty degeneration, and cloudy swelling. He insisted on the gravity of changes in the condition of the cardiac walls, and said that during acute diseases whenever the heart was weak from any previous cause there was great danger from the supervention of distention of the stomach.

Dr. Hector Mackenzie also communicated to the Society a paper on the mobility of the kidneys based on an examination of nearly 4,000 persons. He seems to have found an abnormal degree of mobility far more frequently than many observers seem to have thought possible. He admits that the kidneys may be abnormally movable without causing symptoms, and indeed that most cases require no treatment. He gave elaborate directions for palpation. When able to feel the greater part of the organ he called the case "palpable" kidney, reserving the term "movable" for cases in which he could feel above the upper border. In 2,801 women he found palpable cases in 16 per cent. and movable in 18.4 per cent. In 1,067 males there were 2.3 per cent. palpable and 1 per cent. movable.

The Commission on Malta fever which was arranged three years ago by the Royal Society at the request of the War Office, has lately completed its labors, and the net result seems to be that the disease will soon be stamped out. The Commission consisted of medical officers of the Army and Navy under the direction of a committee of the Royal Society, and though from time to time we have had statements as to some lines of research with which it was occupied, we have only lately received full reports. The discovery of the *Micrococcus melitensis* in 1887 was a starting point, as it were, for further research, and it was long before the additional discovery was made as to its mode of entrance into the body. When it was shown that goats were liable to the disease, a key was furnished to the mystery, for there are some 20,000 goats in Malta, and they supply the milk consumed on the island. The Commission found that 50 per cent. of these animals were affected by the fever, and that in about 10 per cent. the microbe can be found almost constantly in their milk, although there may be no other symptoms of the fever. The crucial test thus became to eliminate goats' milk from the dietary, and this could be done effectively so far as the soldiers and sailors were concerned. In June, 1906, this was done, and the fever cases thereupon fell to one-tenth of their average number. The enormous gain from a mere financial point of view should satisfy the government—bent as it is on cutting down expenses—that a few thousands spent on scientific research may prove a most profitable investment.

Dr. A. F. R. Wollaston has returned to England after a journey through central Africa, traversing much unknown country. In the region devastated by the sleeping sickness he describes the roads as peopled with the dead and dying, almost every village presenting a revolting spectacle, as it is the custom to drive out the victims of the disease to die. The population of an extensive region is thus dying in thousands in utter destitution. In Uganda, since the disease broke out a few years ago, he estimates that over a quarter of a million of the natives have succumbed to sleeping sickness. In the Manyuema country it would seem that the scourge threatens to completely depopulate vast regions.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

THE BACTERIOLOGY OF WHOOPING COUGH—FATAL HEMORRHAGE FROM THE EAR—HYDROPHOBIA IN FROGS—GASTRIC SYMPTOMS FROM A FOREIGN BODY IN THE NOSE—PLASTIC OPERATIONS FOR INFANTILE PARALYSIS—INFANTILE TETANY.

VIENNA, May, 15, 1907.

ALBRECHT has carried out a series of observations relating to the bacteriology of whooping cough. In 200 cases of pneumonia in pertussis patients and in 70 cases of pertussis he found the *Bacillus Eppendorf* in the sputum. This bacillus does not differ from that of influenza, so that it may possibly be identical with this. It also appears to play a rôle in measles, for it was found in 80 per cent. of children dying from this disease. By injecting rabbits with the bacillus it was found possible to secure a serum which agglutinated the same strain in a dilution of 1-1400 and other strains in a dilution of 1-800. The animals so treated developed a well-marked degeneration of the right ventricle, accompanied by calcific areas in the muscles, and similar changes were found in the liver. After several months rabbits treated with influenza material showed endocarditic vegetations of the mitral valve containing influenza bacilli. This observation is of interest in view of the well-known deleterious effect of influenza on the heart.

Török has recently observed a case of fatal carotid hemorrhage from the ear. In dangerous hemorrhages from the ear the carotid and sigmoid sinus may be involved. Erosion of the carotid may be caused by malignant growths, cholesteatoma, syphilis, scarlatina, and in the greater proportion of cases by tuberculous necrosis of the bones. The patient, who was a man of fifty years, was suffering from advanced tuberculosis on admission. For several years there had been a discharge from the right auditory meatus and the internal ear was seen to be filled with thin, fetid pus. The drum and ossicles were missing and the walls of the internal ear were devoid of covering. The carotid artery was not visible and there was no pronounced pulsation of the pus to be seen, as has often been described. As the patient was too weak and cachectic to stand an operation the ear was irrigated several times a day with boric acid solution. Suddenly a profuse pulsating hemorrhage burst from the ear without any premonitory symptoms, and at the same time blood poured from the nose, the mouth, and even the auditory meatus of the opposite side. The bleeding was controlled by packing both auditory canals and the nose, after the patient had lost about a liter of blood. It was later found that the bleeding on the left side had taken place through an old perforation of the drum after the blood had entered the ear through the Eustachian tube. The patient died suddenly some hours after the hemorrhage. At the autopsy there were found large pulmonary cavities, tuberculosis of the intestine, tuberculous erosion of the bones of the middle ear, and a large defect in the wall of the carotid artery.

The question of whether or not hydrophobia is transmissible to the frog has been investigated by Lote in the University of Klausenberg. This observer inoculated 83 frogs in six series with the brains of rabbits dying of rabies. On the death of the frogs control inoculations were made in order to prove that no other infection had caused the death of the animal. Then rabbits or guinea pigs were inoculated with the brains of the animals and typical rabies was caused. Of the 83 frogs 73 died of rabies. It is plainly shown by these experiments that hydrophobia may be transferred from warm-blooded animals to frogs, from frog to frog, and from the frog again to the warm-blooded animal. The course of the disease is much prolonged in the frog and the virus in its passage through this animal

undergoes a considerable attenuation in virulence.

Dr. Glas presented before the medical society a man suffering from gastric disturbance as the result of the presence of a foreign body in the nose. For more than a year the patient had complained of eructations of foul-smelling gas and the vomiting of fetid material, which symptoms had developed since an attack of pneumonia. The gastric function was not impaired and it was found that the symptoms referred to this organ were caused through swallowing the fetid secretion originating in a suppurative process in the left nasal passage. This had resulted from the presence of an inverted tooth which had broken through into the nasal cavity, had been loosened by a blow on the nose, and had lodged below the lower turbinated bone, where it gave rise to the formation of a rhinolith, accompanied by purulent secretion. On removal of the tooth the gastric symptoms disappeared.

Moscowicz has operated on a boy of seven years who was unable either to walk or to stand in consequence of paralysis of the lower extremities and was obliged to crawl like a four-footed animal. The right lower extremity was completely flaccid, but on the left side the muscles of the leg were normal, except the tibialis anticus, and the muscles of the thigh were all normal. The glutei of both sides were paralyzed. The right leg was converted into a useful member by arthrodesis of the knee joint and the hip joint, together with tendon shortening of the muscles of the foot. The child was still unable to stand, however, as the extensors of the hip joint, the glutei, were lacking. On the left side the gluteus maximus was then replaced by the flexors of the knee joint by transplanting the insertion of these muscles from the tuber ischii to the ileum. The child can now walk with two canes and is able to stand unaided.

Escherich demonstrated in the Society for Internal Medicine and Pediatrics a child with infantile tetany accompanied by excessive mechanical and electrical irritability. For two months it had been suffering from digestive disturbances, vomiting and emaciation. For three days there had been short convulsive seizures, in which there was spasm of the glottis with stridulous breathing. At the same time there was a high degree of mechanical and electrical irritability, so that touching the cheek caused active facial contortions and gentle percussion of a muscle evoked forcible contractions. The statement of Finkelstein that in such cases the elimination of milk from the diet is a certain means for reducing the hyperexcitability did not apply in this case, for, on the contrary, the symptoms were increased in severity by this measure. Nevertheless, in most cases of tetany improvement follows resort to a carbohydrate diet or starvation.

Progress of Medical Science.

New York Medical Journal, June 8, 1907.

Open-Air Treatment of Tuberculous Bone and Joint Disease.—J. Carling claims that statistics of cure show, as between seaside and inland resorts, a preference in favor of the latter. His ideal location is a moderate altitude away from the seashore, and he advances the following reasons: (1) The air is more invigorating; (2) the absence of dampness and fog; (3) more days of sunshine; (4) better natural drainage; (5) a firmer soil for locomotion. The advantages of such an environment over home treatment are: (1) The patient is always surrounded with pure air and a maximum amount of sunshine; (2) his diet, rest, bathing, and exercise are carefully regulated; (3) he is under constant medical supervision; (4) he is educated and disciplined in the care of himself. The daily routine of life is as follows: The children are kept out of doors all day except in very stormy weather, and sleep in rooms and wards with the windows wide open. Those who are unable to walk are wheeled out in beds or invalid chairs, and the presence of fever is no bar to their going out. Not only is pure cold air not injurious to these latter cases, but it is decidedly beneficial in reducing temperature and dispelling nervous symptoms. Those who are able to go about on crutches or braces are allowed walking in moderation, others are drilled in light calisthenics, while all are taught the importance of deep breathing. Protected from the strong winds of winter and warmly wrapped in woolen blankets, patients are given sun baths when practicable, which in this clear atmosphere can be had almost daily. No medicines and no special diet are required except in emergencies.

Impetigo Contagiosa.—N. T. Beers notes the frequent occurrence of this disease, which frequently occurs in an epidemic form with symptoms analogous to those of the common eruptive fevers, most closely resembling, in fact, practically identical with the onset of varicella. When the case comes under observation, it is usually in the stage of scab formation and the full course of the eruption through the successive stages—vesicles, turning dark, and drying up—entirely discrete and with no surrounding induration or redness—is not seen. The pus from the scabs may inoculate other areas. The disease shows little tendency to itch unless the scabs are disturbed. As to differential diagnosis from pustular eczema and scabies, it may be said that eczema shows an areola of inflammation about the lesion; it is inclined to become confluent; itching is often intense; but it is not autoinoculable. Scabies is accompanied always by intense itching, especially at night; lesions are small, in large numbers and multiform, pustules, papules, and vesicles all appearing; it lasts for months; presence of burrows, and a parasite may be demonstrated; there are no constitutional symptoms. Impetigo is not communicable; it commences as pustules; lesions are deep and pustules elevated and rounded; general health is good. The treatment is even simpler: A grain of calomel in broken doses, a saline to complete its action, and then some constitutional tonic to increase the general resistance. Externally, the treatment consists in softening the crusts with olive oil and their removal with warm water and soap. As soon as this is accomplished an ointment consisting of ten grains of ammoniated mercury to the ounce is all that usually is required to complete the cure.

Case of Eyestrain Mistaken for Appendicitis and Cholelithiasis.—E. M. Alger refers to the claim of Gould that abdominal pains and functional disorders of digestion may arise from eyestrain. He refers to the unsatisfactory results frequently following operations for the relief of abdominal symptoms and declares that the whole training of the modern surgeon tends to cultivate operative skill rather than diagnostic ability. He gives the detailed history of the case of a young man of nineteen years in whom the chief symptom was chronic severe abdominal pain of several months' duration; the diagnosis of the first surgeon was appendicitis; of the second, gallstones; and of the third, eyestrain. The pain was completely relieved by the glasses of the first ophthalmologist for a period of nearly three years; recurred when they were lost; was aggravated by the prescription of the second; and finally completely relieved again by the glasses of the third.

Amyotrophic Lateral Sclerosis with Bulbar Onset.—A. Gordon refers to the various types of this nervous affection with reference to mode of onset. The most frequent is that presenting a paretic condition, with some spasticity and amyotrophy with reaction of degeneration. Or one may have a progressive muscular atrophy with the spastic element not marked, but the reflexes exaggerated. In a third form the spasticity appears first and the amyotrophy later. In all the foregoing bulbar symptoms may be a late feature. Finally a few cases have been reported presenting bulbar symptoms as the initial feature. One such case is reported by the author, whose patient was a married woman of fifty years whose trouble began with stiffness of the neck, soon followed by pain in the throat, dysphagia, and difficult speaking, with some trouble in holding up her head. When seen, certain sounds were emitted with difficulty, there was trouble in blowing and whistling and atrophy of the tongue with fibrillar twitchings. The initial symptoms were also progressive. Fifteen months after the onset of the bulbar symptoms muscular weakness and atrophy of the thenar, hypothenar, deltoid, supra and infraspinate muscles began to develop and showed R. D. The disease in this case was decided to be of spinal origin and it was believed that the motor bulbar neurons opened the pathological process.

Journal of the American Medical Association, June 15, 1907.

The Duality of Man.—G. C. Savage discusses the relations of the mind with the body in the light of the neuron theory. He argues that acceptance of this theory excludes the possibility of the nervous system, being in itself a self-acting mechanism of afferent currents directly transforming themselves into efferent ones: "The power that can make or break contact of dendrites or collateral branches, and can even present such contact, needs no physical connection, either by

continuity or contact, between afferent and efferent centers that it may control the physical being." The afferent and efferent currents are not, he thinks, directly transformable one into the other; there must be some power supervising and regulating the change, and if contact is necessary in order that there be any efferent current of neuricity, this power must bring it about. In this way the study of reflex neuroses can be cleared up, the phenomena of hypnotism and suggestion explained. According to this explanation, every function and organ of the body is directly under the control of this higher power, the mind. Hence when germs and toxins cause disease, mental stimulation can reinforce, under proper direction, the weakened bodily resistance. If the attack is too overwhelming, such external means as are suited to the case will have to be invoked. The grain of truth in Eddyism and like delusions is the fact that the mind can influence the body, but with this grain there is a ton of error. The external laboratories, under the guidance of trained minds, are supplying agents as specific, and often more effective than those the internal laboratories of the body, controlled by the mind, can supply in the fight against disease. The physician, nevertheless, should never overlook the fact that man is a dual creature, spirit as well as matter, and that the mind, through the nervous system, itself material, can influence the bodily organs.

Obscure Gastrointestinal Cases.—J. Hoelscher gives case histories of three patients suffering with intermittent gastrointestinal attacks characterized by gaseous distention, hyperacidity, pain or nausea, and vomiting; all were resistant to medical treatment. In one case there was no history of any causal disease, but there were severe pain and jaundice; cholecystenterostomy, however, revealed no gallstones. In the second case the disorder followed typhoid fever, in the third there had been a severe burn and traumatisms and the symptoms justified the diagnosis, confirmed by operation, of healed duodenal ulcer and partial obstruction. In the first two cases there were found gastric dilations and displacement, and adhesions of the stomach and intestines, which were released; in the third case a gastroenterostomy was performed. Improvement resulted in all three after operation. Hoelscher calls attention to the fact that an intestinal lesion may give rise almost exclusively to gastric symptoms, and says that the diagnosis of gastric neuroses and chronic gastric catarrhs will become fewer when surgery is resorted to. It may give prompt and complete relief, though usually the changes that have taken place in the musculature and glands of the stomach are such that it may be a long time before the patient will be altogether normal. The differential diagnosis calls for careful distinction as regards gastric ulcer, chronic cholecystitis, gallstones, and gastroptosis. Proper surgical interference gives better results than long-continued medical treatment. The usual secondary symptoms of faulty gastrointestinal chemistry included under autointoxications should not be overlooked.

Venous Angioma of Skin Showing Beginning Malignancy.—R. R. Campbell discusses the subject of venous angioma in its relation to malignant growths. He reports a case with microscopic examination of the excised tumor, which suggested epithelioma, though the absence of nests and of epithelial formation on the lateral walls or base precluded a malignant growth. He also abstracts several other cases reported by other authors and discusses the origin and varieties of these tumors. In conclusion he expresses the opinion that venous angiomas do not take on malignancy, but that, on account of the constant irritation due to their presence, the overlying epithelium may undergo carcinomatous changes.

Remote Effects of Tonsillar Infection.—P. K. Brown says that the importance of the source of infection for heart disease has been well shown. He has observed recurrent endocarditis, cholera, and muscular rheumatism occurring in certain of his old patients, and he considers that continued slight fever in children is probably a common result of tonsillar disease in San Francisco. A rather peculiar complication of pericarditis, pneumonia, and lung abscess is reported. Nephritis after tonsillitis without rheumatism is, he thinks, a commoner complication than is generally supposed, and has occurred four times in his cases. One of these, complicated by acute mania, is reported, as also one of fatal staphylococcic septicemia and one diagnosed as leukemia occurring in connection with, and presumably as the result of, tonsillar disease. The [illegible] he thinks, clinical and experimental, tends to show that more and more connection is being established between the tonsillar cervical route and lung tuberculosis. Histological studies alone are insufficient, the proportion of tonsillar involvement, as shown by Lartigau's results, in which tubercle bacilli were found in only 2 cases out of 135, and then only in small numbers, while 12 out of 75 inoculation experiments gave positive results. Brown concludes with the statement: "In the study of portals of entry of disease into the human body, the pharyngeal and especially the faucial tonsils have an importance not well enough recognized or understood, but increasingly appreciated in the light of each new clinical or experimental study."

The Lancet, June 1, 1907.

Multilocular Ovarian Cyst Successfully Removed from an Infant Aged Eleven Months.—The case is reported by C. W. McGillivray, into whose hospital service the child was sent with the diagnosis of tuberculous peritonitis calling for surgical intervention. The child was ill-nourished, cyanotic, with rapid pulse, dyspnea, some diarrhea, and marked abdominal distention. Nothing could be made out as to the abdominal contents, as the walls were of drum-like hardness. Some clear yellow fluid was withdrawn from the abdominal cavity and finally it was determined that the whole abdomen from diaphragm to pelvis was filled with a mass containing separate cavities filled with fluid. Under chloroform an incision was made to the left of the middle line just below the umbilicus. A large cyst came into view and was punctured, but only a little fluid escaped. The poor condition of the patient and the fact that a more extensive operation was evidently needed led to a prolongation of the incision upward to nearly the ensiform cartilage. A large double multilocular cyst was found, the two halves being nearly equal in size and attached to each other by loose connective tissue between their fibrous walls. Length, on removal, was nearly eleven inches and thickness four to five inches. In spite of the desperate condition of the child at the close of operation it eventually recovered. The author closes with some remarks on this class of growths in young children. Only one younger patient of this class is on record, as the intraabdominal condition began at the third month of life. Another feature was the retroperitoneal position of the tumor, as shown by the appendix, cecum, and ascending colon lying in front of it and stretched over its surface, and the fact that the posterior layer of the peritoneum had to be torn through in order to enucleate the tumor.

Congenital Piles.—J. V. Milward reports three cases in which a pile-like condition was noted from birth. Patient 1 was a male child, aged eleven weeks. There was a tumor of the size of a large pea, soft in structure and not inflamed, situated at the anterior margin of the anus, its posterior margin being flush with the anal canal. The latter was slightly narrower than normal, and I dilated it with the finger. The mother stated that the little lump had been present since birth and was giving the child pain. It was removed with scissors. Patient 2 was a female, aged four months. The tumor was situated in the same place as in patient 1 and was of about the same size. It was partially destroyed by ulceration and was somewhat indurated for the same reason. No stricture of the anus was present. The growth was snipped off. Patient 3 was a female, aged eleven weeks. The pile was in the same place and was of about the same size as in the other two cases. Its structure was perfectly healthy and consisted of fibrous and adipose tissue. The author regards these small masses as rather of the nature of a malformation than an outgrowth originating in a dilated venous radicle.

Value of the High Frequency Spark as a Local Application.—E. R. Morton refers to the benefits derived from the high frequency spark in a certain case of alopecia areata, and in certain cases also of port wine marks. In the first case the author used a vacuum glass electrode connected to the top of the resonator, rubbing the electrode over the bald patches until a bright erythema was produced, taking three or four minutes for each patch. Results were surprisingly good and after [illegible] six months the patient had a fine head of hair. The effect of the spark is merely that of a local stimulant. In the port wine mark cases the author used a metallic point electrode mounted on an insulated handle and connected with the top of the resonator. The point was held about one inch from the surface so that a hot white spark jumped across the intervening space. This was continued for several minutes until vesication was produced over the entire

surface of the patch. There was no soreness afterwards worth mentioning and in about eight days the old epidermis peeled off, leaving a smooth surface, pink from the remains of inflammatory reaction, but otherwise quite like normal skin. One great advantage in such cases is that the normal texture of the skin is quite unimpaired. There is nothing approaching a scar—thus differing from chemical agents and electrolysis. A further advantage is that it is under the most perfect control and no further reaction takes place than is desired.

Antityphoid Inoculation.—A recent editorial in the *Lancet* (June 1) calls attention to reports by three English army surgeons. This method, introduced by Wright in 1897, was tried on a large scale in India and Egypt with most encouraging results, but after the Boer war it fell into temporary abeyance. In spite of some opposition the method seems to be winning its way. Certainly collective evidence is in its favor. Certain improvements in the preparation of the vaccine have led to a much milder "local reaction." Inoculation is no longer made in the flank and hence there is no pain or stiffness in walking. Inoculation is now made in the arm or pectoral region. The dosage of the vaccine employed has been fixed at one-half c.c., containing 500,000,000 bacteria, and for the second inoculation the quantity is doubled. This has been found to give a maximum protection with a minimum severity of reaction. It has thus far been found impossible to standardize the serum. There are now on record a sufficient number of histories of protective inoculations to make a very strong showing in favor of the vaccine. Inoculation does not, it is true, invariably protect, but it does so to a very large degree. The writer in the *Lancet* considers it in every way as necessary for the protection of the health of the English soldiers in India as is vaccination against smallpox.

British Medical Journal, June 1, 1907.

Two Cases of Multiple Intestinal Obstruction.—The cases are reported by R. Ramsey, whose first patient was an old man of eighty-one, who had had a hernia for many years. Sudden abdominal pains with fecal vomiting suggested strangulation, but operation revealed no condition connected with the hernia sufficient to account for the fecal vomiting, although the hernia was found irreducible and was easily, on opening the sac, returned to the abdominal cavity. A median laparotomy was done and distended small gut presented. This was followed down and led to a loop of ileum fixed tightly behind the cecum, evidently being of the nature of an internal hernia; this loop was almost black in color, but on reduction appeared viable, so the abdomen was closed and the patient put back to bed. Fecal vomiting continued all night, and, as the patient was rapidly sinking, the abdomen was again opened in the morning, eight hours having elapsed since the former operation. Another impacted and strangulated internal hernia was discovered, this time up in the region of the splenic flexure, where the bowel had got caught in a peritoneal pocket; this bowel was also nearly black, but was treated by simply replacing it in the abdomen. Death occurred from pneumonia on the fourth day. The second patient was a boy of seventeen years, with usual symptoms of intestinal obstruction, although the abdomen was not markedly distended and no local tumor could be felt. On abdominal incision, small intestine, somewhat distended, presented and on following this down it was found to go in at the foramen of Winslow; almost three feet of bowel was pulled out through this foramen; at one part there was a slight mark of constriction, but there was nothing which seemed sufficient to account for the symptoms, so a further search was made and a long, inflamed appendix was discovered twisted firmly round a part of the small intestine and evidently completely blocking it. The adhesions were broken through and the appendix removed; the small bowel thus freed was about six inches away from the ileocecal valve, and it was much congested. Result.—He lived about six hours after the operation, and during that time his bowels moved slightly, but the patient failed to rally.

Two New Genera of Nematodes Occasionally Parasitic in Man.—R. T. Leiper refers to a certain parasite, *Ascaris mystax*, which infests our common dogs and cats and probably most carnivora. Its especial feature is the spatulate shape of the head produced by two lateral membranous expansions of the cuticle. The name given above refers especially to the species found in the cat. Other species of the same genus are found in the dog, fox, etc. The author also refers to certain specimens resembling the *A. mystax* found on post-mortem examination of human cadavers. There were certain differences, however, and he believes that the various varieties found are several species belonging to two distinct genera.

Urticaria and Influenza.—J. Reid refers to the case of a girl of eight years, with an inflamed throat and consolidation of the base of the right lung. In addition she presented in front of the neck and on the nucha large boggy urticarial patches. Other similar areas were found on the left shoulder and in the upper third of the right thigh at its inner aspect. On the following day no trace of the foregoing rash was visible, but fresh smaller spots appeared on the right abdomen. The consolidation had disappeared. On the next or third day there was no rash and the throat was but slightly red. The patient was given magnesia and a simple diet. There was some constitutional weakness, possibly rheumatic. The child had not been well since a diphtheritic attack four years previously, in which antitoxin had been given, but no rash then appeared, so far as the author could learn. He regards these localized symptoms as on a par with the ischemic processes found in connection with influenza, especially convulsive cases.

Eggs in the Diet of Infants.—W. J. Midelton regards milk as a very difficult article of diet to handle in case of sick children. He now relies largely on eggs and gives the following proportions for an infant weighing six pounds or more at birth: During the first two days after birth beat up the raw white of a large new laid hen's egg, add to this water to make 8 ounces, also 40 grains of pure cane sugar. Strain through butter muslin. Put 1 ounce of this into the feeding bottle, stand it in hot water at 110° until the food is raised to 98° F. Feed every hour and a half. On the third or fourth day add 5 minims of the yolk of the egg and 5 minims of raw meat juice to each feed. Increase the quantities gradually as the child grows older, and also add codliver oil emulsion to each feed, say 5 minims of a 40 per cent. preparation. He says that he has yet to see an infant unable to digest these ingredients carefully adjusted to the needs of each case.

Berliner klinische Wochenschrift, May 27, 1907.

Clinical Observations of the Index of Refraction of the Blood Serum.—Engel has carried out a series of observations on the coefficient of refraction of the blood serum of a large number of patients suffering from such conditions as nephritis, cardiac disorders, diabetes, mellitus and insipidus, pulmonary tuberculosis, liver diseases, etc. The index of refraction has been shown to be quantitatively commensurate with the albumin content of the serum and therefore to give a fairly correct guide to the degree of hydremia. Engel expresses himself as convinced of the value of the method, which requires only a single drop of blood, can be quickly carried out, and yields results which equal in accuracy those obtained by much more complicated procedures. While it does not obviate the necessity for performing the usual blood examinations, it supplements these in a useful manner and in many cases affords diagnostic and prognostic data of considerable importance. By means of a refractometer it is possible to carry out accurate observations on the proportion of water present in the blood serum, which by other methods is rarely practicable.

Münchener medizinische Wochenschrift, May 14 and 21, 1907.

The Treatment of Delirium Tremens.—Eichelberg presents the statistics of the cases of this sort treated in the Eppendorf Hospital of Hamburg in the past eleven years. These number in all 1,574, of which 1,043, that is about a third, were uncomplicated, whereas 531, or one-third, were attended by more or less serious complications. Of the total number of cases, 2.4 per cent. ended fatally, and, including the cases in which there was also pneumonia, the death rate was 5.5 per cent. The death rate in 173 cases complicated by pneumonia was 33 per cent. In regard to the treatment the author states that it is customary in this institution to withdraw the alcohol at once and to lay great stress on sustaining the heart action by the use of digitalis and other stimulants. Diuresis also is to be encouraged, and in cases complicated by pneumonia both digitalis and alcohol are resorted to.

Manganese Poisoning.—R. von Jaksch describes four cases of a peculiar nervous affection occurring in workmen engaged in the manufacture of permanganate of potassium. The most prominent symptoms are monotonous

scanning speech, uncontrollable weeping or laughing, palsies or contractures of the lower extremities, disorders of gait, retropulsion, psychical degeneration, and increased knee jerks. Babinski's sign, nystagmus, and contractures of the visual fields are not present. The author considers that this affection of the nervous system is caused by the inhalation of dust containing suboxide of manganese, although other factors may possibly play a rôle in its etiology. The author also describes another case in which the patient exhibited a neurosis somewhat resembling the condition just described, but which was apparently the result of autosuggestion. For cases of this sort the author proposes the name of manganophobia.

The Dorsal Foot Reflex.—Lissmann says that insufficient attention has been paid to this reflex, which apparently was discovered independently by Bechterew and Mendel. It is elicited by tapping the dorsum of the foot on its lateral aspect in the neighborhood of the cuboid and third cuneiform bones. It is best to use a percussion hammer and to deliver a blow of moderate intensity. In healthy persons a reflex dorsal flexion of the second to the fifth, or sometimes only of the second and third, toes results, but in organic nerve diseases accompanied by spastic paralysis plantar flexion results. Lissmann tested the reflex in over 900 persons free from nervous disease and found that in every instance the dorsal extension was caused. This was also the case in forty-one tabetic patients, two cases of paralysis agitans, and eight cases of sciatica. The reflex was absent in five cases of spinal infantile paralysis and in general the results corresponded with those of the Babinski reaction. Contrary to the statements made by some authors, the reflex did not appear in any cases in which the Babinski was negative. By examining a large number of infants the author learned that the disappearance of the dorsal foot reflex in young children corresponds with the time of disappearance of the Babinski reflex—that is, about the third or fourth month. This association of the two reflexes seems to indicate that, like the Babinski, it depends on the integrity of the pyramidal tracts and that it therefore deserves recognition as a diagnostic sign.

Döderlein's Method of Skin Sterilization.—Littauer says that in spite of the various methods of sterilizing the skin that have been proposed, it is still impossible to free the parts surrounding the operative field from germs with sufficient thoroughness to insure uncomplicated healing of the incision. Various methods of coating the skin with impervious substances have been proposed, but the most effective is that of Döderlein, because in this the skin is tanned as well as covered with a protective layer. The fluid used is a solution of rubber in benzine, to which formaline has been added, and the resulting membrane is easily soluble in ether, benzine, and chloroform. Döderlein's method of disinfecting the skin is as follows: The evening before the operation the patient is bathed and the operative area is shaved; a 1 per cent. formaline compress is applied to the area in question and left on over night. On removing the compress the skin is brushed over with 1 per cent. formalin-benzine and tincture of iodine is painted on. As soon as this is dry the rubber solution is applied; when the benzine has evaporated the sticky film of rubber is sprinkled with sterilized talcum powder and the excess of this is brushed away with a piece of sterile gauze. The results obtained by the use of this method are excellent and by its means all skin germs are effectually prevented from entering the wound.

Deutsche medizinische Wochenschrift, May 9, 16, and 23, 1907.

Abscess of the Liver Following Influenza.—Karewski says that Langenbach and Korte have called attention to the fact that abscess of the liver sometimes occurs as a sequel of influenza, and he reports a case of his own which was attended by this complication. The patient was a man of twenty-five years, who fourteen days before coming under Karewski's observation had suffered from an attack of influenza. This subsided in the usual way, but the patient failed to regain his strength and on examination of the chest signs were discovered pointing to empyema of the right side. After resecting a portion of the tenth rib and incising the costal pleura, a considerable quantity of sero-purulent fluid escaped and from one angle of the wound thick pus could be seen welling up from below. The pleural cavity was closed by suture and tamponade and the deeper collection of pus, which was found to come from an abscess cavity in the liver, was evacuated. After a protracted convalescence the patient recovered completely. In this case there were no other etiological factors to account for the hepatic abscess and the patient's subsequent freedom from all symptoms makes it seem certain that the suppurative process in the liver was the result of the grip infection.

Acute Myelogenous Leukemia.—Ziegler and Jochmann are of the opinion that in many cases of leukemia there is a relationship between bacterial infection and the origin of acute, and probably also of chronic, forms of the disease. This may not be the result of specific action, but may be induced through damage to such organs as the spleen or bone marrow, as the result of which myelogenous leukemia may develop. They report a case in support of this view, the patient being a boy of fifteen years, who suffered from a staphylococcus sepsis apparently resulting from a throat infection. This led to a hemorrhagic pericarditis, and fourteen days after the onset of the acute infection the blood was suddenly flooded with myelocytes, so that two days after having contained only 18,000 leucocytes to the cubic mm. the blood count revealed 240,000 leucocytes to the cubic mm. Death took place two days later and at autopsy the spleen showed myeloid changes and hyperplasia of the bone marrow.

A Skin Disease in Man Caused by a Parasite of the Dog.—Lewandowsky says that while it has usually been considered that the *Demodex follicularis hominis* is a harmless saprophyte present in the hair follicles of a large proportion of the population, it now appears that in some instances it is able to give rise to pathological changes in the skin. Several instances of peculiar circumscribed areas of facial pigmentation have been described which were apparently due to the presence of large numbers of this parasite. In one instance a peculiar form of blepharitis was caused in which the demodex was present in great number in the follicles of the eyelashes. The author's own case was peculiar in that the organism giving rise to the lesions was of the canine type, *Demodex follicularis canis*. The patient was an Italian laborer suffering from an impetigo-like eruption about the face. On examination of material taken from the lesions the organism above mentioned was readily discovered. Under the application of a mild antiseptic powder the condition quickly improved. The manner in which infection took place could not be ascertained.

The Treatment of Leprosy.—Diesing speaks highly of the use of iodoform injections in leprosy, and says that by their means all the lighter uncomplicated cases and a large proportion of the advanced cases may be cured. The preparation used consists of a mixture of 30 g. of iodoform in 90 c.c. of pure olive oil sterilized for ten minutes on the water bath. Before beginning the treatment the patient's susceptibility to iodoform is tested by giving two injections two days apart of .5 c.c. each of the emulsion. If the development of eczema or fever indicates an idiosyncrasy on the part of the patient it will be necessary to use caution in gradually increasing the dosage to the normal amount of 2 c.c., but otherwise daily injections of this amount may be commenced with at once. These are continued for fifteen or twenty days with occasional intermissions, so that a month is consumed, and then after a rest of two weeks a second course is given. Certain patients do not do well under the injections, and for them the method is contraindicated; such are patients with mental disorders, those showing leukemic changes in the blood, and patients with weak hearts.

The Traumatic Causation and Operative Treatment of Paralysis of the Serratus.—Samter discusses the subject of traumatic paralysis of the serratus magnus and comes to the conclusion that in most cases it is caused in the following way: The long thoracic nerve as it descends vertically over the side of the thorax is in such a position that it can be pinched between the coracoid process and the first rib if the scapula is forcibly pressed against the chest wall. In this way the nerve, particularly in persons in whom the muscle is poorly developed and there is inadequate padding of fat, may be damaged seriously enough to occasion a paralysis of the muscle, and somewhat similar conditions obtain in certain cases of so-called congenital serratus palsy, which probably result from manipulations during labor such as are necessary when an arm has to be brought down. The author was able to treat successfully, by means of a plastic operation, a traumatic serratus palsy occurring in a girl of eleven years, who had fallen against a ladder. After eleven months of unsuccessful electrical and other conservative treatment, the long thoracic nerve was exposed by a vertical axillary incision, but was found electrically inactive. The lower half of the brachial attachment of the pectoralis major was removed with a periosteal flap

from the humerus and transplanted to the angle of the scapula. The functional result of the operation was excellent and the deformity was almost completely eliminated. The author recommends the procedure in all traumatic palsies of the serratus, in congenital defects of the muscle, and in other forms of palsy of this type, unless there is present a rapidly progressive causative nerve lesion.

French and Italian Journals.

Inflammatory Neoplasms of the Pelvic Colon.—P. Cavaillon and Bardin include in inflammatory neoplasms tuberculous neoplasms with and without tubercles, syphilitic neoplasms, and true inflammatory neoplasms, due generally to infection by germs within the intestinal lumen. The tubercular lesions may be in the active stage, with bacilli included in tubercles, or in the cacatricial stage, when the original tissue has been displaced by sclerosed masses. These scleroses may be produced by toxins alone without bacilli themselves being present. The endointestinal and periintestinal inflammations that occur aside from syphilis and tubercle result from the microbes habitually present in the intestine, and ordinarily harmless. They are associated with infection in the intestinal diverticula and inflammatory pericolitis. The diagnosis of inflammatory neoplasms is rarely made until the abdomen has been opened for operation, or at the autopsy. Cancerous growths are small, circumscribed, and produce marked stenosis, while the inflammatory growth is much more diffused, involves a longer section of bowel, and the infiltration of the coats is more marked and of uniform contour. The bowel feels thick and softer, though coarser. The peritoneal reaction about the tumor is marked, the omentum is adherent, and there may be small abscesses in its mass. The walls are very thick and partially close the lumen, while above them the intestine is dilated and the mucous membrane ulcerated. All the coats in simple inflammatory neoplasm present lesions of simple inflammation, but the most marked are in the submucous layer, arising from mucous diverticula and glandular culs-de-sac. There are three types of tuberculosis in the sigmoid flexure: ulcerated tubercles, hypertrophic tuberculosis, with or without specific lesions, and plain inflammatory tuberculosis. In the hypertrophic form there may or may not be tubercles present. The walls are much thickened, especially the submucous layer; there is sclerolipomatous change in the walls, adhesions, and enlarged glands. The characteristic of tuberculosis without tubercles is that of submucous sclerosis with rare giant cells. Inflammatory tuberculosis arises from the defensive reactions of the intestine, and is characterized by cicatrization. Such lesions may result from retrograde changes in tubercular tissues, or from the simple action of the tubercular toxins. Syphilitic neoplasms with inflammatory tumors are most marked in the submucosa, and the sclerotic changes begin about the vessels. The pathologic differences between these types of chronic inflammation are marked. The simple inflammatory growths arise around glandular tubes and diverticula. In syphilis sclerosis is perivascular; in tuberculosis there are localized lesions in the submucosa, or diffused lesions unlocalized. The same symptoms are common to all: occlusion of the pelvic colon, or suppuration in the iliac fossa, alternating diarrhea and constipation, blood and mucus in the stools, sometimes tenesmus and distention of the intestine above the growth. Cachexia may be marked. These tumors are benign in themselves, malignant in their evolution. Treatment is generally operative. Suppuration requires drainage; perforation requires laparotomy; acute occlusion requires an artificial anus. Radical operation is satisfactory in theory, and many cases recover after laparotomy with colectomy. Some recover without operation by retrograde metamorphosis under palliative treatment. Inflammatory tumors require incision when pus collects and medical treatment afterward. Accidents demand ileoresection. Tuberculoma, outside of complications, or cicatricial metamorphosis, requires ablation in three stages.—*Gazette des Hôpitaux*, February 5 and 12, 1907.

Treatment of Ophthalmic Migraine and Ocular Troubles of Dyspeptic Origin.—Albert Robin describes several varieties of ophthalmic migraine. In the most severe the migraine is preceded by a singular aura of lightness and levity some hours after a meal; suddenly vision recedes as if a thick shadow had passed over the patient. A portion of the visual field is obscured and there is hemianopsia, temporal generally, sometimes horizontal. There is painful cardiac palpitation and agonizing intermittence. Brilliant lines appear before the eyes, which form quickly changing geometrical figures. The eye becomes painful and seems pulled into the orbit. There is formication of the opposite side of the body, the limbs weaken, speech is embarrassed, and memory fails. Gastric cramps come on and a violent migraine. In other cases the symptoms are similar but less severe. The treatment of this condition should not be given to the oculist, since the seat of the trouble is in the digestive canal rather than in the eye. In other persons who read or write much dyspepsia brings on muscular and accommodative asthenopia, which is only temporary. There is congestion of the lids, and a feeling of sand in the eye. There may be slow and painful accommodation, sensation of fog before the eyes, or abnormal perception of colors. The author rejects the theory of autointoxication as a cause of these symptoms, and believes them to be reflexes of the vasomotor enervation of the optic nerve, dut to tetanizing of the walls of the vessels supplied by the great sympathetic. These patients should be placed on a strict diet and hygiene. They should stop mental work and take physical exercise, eat plain food, and omit coffee, tea, alcoholics, and tobacco. Bitter tonics and nux vomica should be given before meals, alkalies after eating. The bowels should be kept in order and a daily bath or hot douche enjoined. For the attack large doses of bromide of potassium, washing out the stomach, antipyrin, and massage are the best remedies. For muscular asthenopia rest and prisms with the base in should be used.—*Le Progrès Médical*, February 16, 1907.

Treatment of Cancer of the Cervix.—Joseph Godart says that recurrences in cancer of the cervix occur in the neighboring glands rather early, due to insufficient removal. The glands that are first invaded in this form of cancer are the juxtauterine, sacral, iliac, and hypogastric; next come the lumbar; last, the inguinal and peri-inguinal. The glands are involved in twenty per cent. of all cases. The parametrium is involved in seventy per cent. of the cases, and should always be removed. The tendency is to more thorough removal of the glands and all structures that can possibly be involved. In some cases glands that are enlarged are only the seat of inflammatory lesions. Contraindications to hysterectomy are anemic cachexia in old subjects, albumin in urine, uremia, and edema of the legs. Hydronephrosis and pyonephrosis due to involvement of the ureters and extension to the bladder contraindicate operation. If only the vagina is involved aside from the uterus, operation may be done. Fifty-six per cent. of all cases may be operated on by the abdomen, and only thirteen per cent. by the vagina. The best method for operation is abdominal hysterectomy. A preliminary curetting will remove edema and permit of better antisepsis. This should be done a week before operation. Abdominal operation enables the surgeon to judge better of the involvement above the cervix, the condition of the adnexa, intestine, and bladder. When there is too great involvement to permit of successful removal the incision may be only exploratory. Increased gynecological knowledge among physicians, with an earlier diagnosis, and a belief in the curability of cancer, and greater knowledge on the part of women in general of the importance of medical advice for irregular hemorrhages will improve the results of operation on cancer of the cervix.—*La Policlinique*, January 15, 1907.

Interauricular Insufficiency.—H. Roger describes a syndrome in which there is no sign of cardiac insufficiency discoverable by auscultation, but still the integument of face, hands, and feet are of an intense blue, the lips are swollen and cyanotic, and this cyanosis persists. Examination of heart, lungs, and other organs gives no clue to the cause of the symptom. The condition may go on progressively increasing until death occurs. In such a case observed by the author the autopsy revealed an opening of the nature of a canal between the two auricles. It was discovered by pouring water into one auricle and allowing it to flow toward the other, when it was found to flow into the second auricle, from right to left. In most published cases of auricular insufficiency a canal has been found directed from behind forward, from right to left, and from below upward. The walls are formed by the muscular ring which surrounds the fossa ovalis and the valve of Vieussens. The valve, instead of becoming adherent, remains free. When there is pulmonary stasis the pressure rises in the right auricle, the blood is pressed back behind the valve, opens the orifice, and a communication is produced between the auricle, a current flowing from right to left. The mixing of venous and arterial blood explains the cyanosis. In order that the difficulty may occur the blood pressure must rise in the right auricle, as happens in pulmonary troubles, especially emphysema. The author believes that many apparently normal individuals have a patulous canal, and are thus exposed to these symptoms in the event of pulmonary trouble. In them we may diagnose interauricular insufficiency in the presence of an inexplicable cyanosis.—*La Presse Médicale*, February 6, 1907.

Book Reviews.

La Stérilite chez la Femme. Son Traitement par les Agents Physiques. Par le Dr. E. Hugon, Ancien Chef de Clinique Gynécologique. Paris: Vigot Freres, 1907.

This brochure enumerates the various conditions which are responsible for sterility in woman; it also gives suggestions for the treatment of the same by means of massage, electricity, or hydrotherapy.

Die Roentgenstrahlen im Dienste der Neurologie. Von Dr. Wilhelm Fürnrohr, Nervenarzt in Nurnberg, Früher Assistent der Prof. Oppenheim'schen Nervenpoliklinik in Berlin. Mit einem Vorwort von Prof. Dr. H. Oppenheim. Mit 28 Abbildungen. Berlin: S. Karger, 1906.

The majority of text-books on the Roentgen rays deal so largely in the general technique and general applications of the method that they find but little room for the special details of interest solely to the neurologist, which concern the diagnosis of diseases of the cerebrospinal and nervous systems. This defect has been amply supplied in Dr. Fürnrohr's excellent monograph. He deals with the applications of the *x*-rays in injuries as well as in diseases of the brain, the cord, the nerves, etc., and thus his book is of interest to surgeons as well as to neurologists. It is now over ten years since Roentgen told the world of his wonderful rays, and in these years an enormous amount of work has been done with this new tool of the physician. That much of this work is applied in neurology is shown very clearly in the present volume.

Beginning with some elementary anatomical notes, the author passes on to acute bone atrophy as a subject worth considering in view of the fact that this condition was but recently described (1900) by Ludek, who found that certain bones, as those of the hand, atrophy rapidly in the presence of inflammatory joint affections, etc. The next chapters deal with diseases of the cranium, brain, cord, etc., the spine, the limbs, etc. (as connected with neurological conditions) and such diseases as acromegaly and myxedema. The book shows well how much neurology owes to the *x*-rays. Thus these rays showed that the sella turcica becomes broadened in acromegaly; that in myxedema there is a retarded bone development, etc. There is no doubt that in the future the neurologist will gain much information as to the exact progress of arthropathies, etc., with the aid of the *x*-rays.

Anesthetics and their Administration. A Text-book for Medical and Dental Practitioners and Students. By Frederic W. Hewitt, M.V.O., M.A., M.D. Third edition. London: Macmillan & Co., 1907.

Dr. Hewitt's name is probably more closely connected with the science of modern anesthetics than that of any other man. The third edition of his book contains all that has been done during the last six years in this branch, the new chapters taking up ethyl chloride, the addition of many fresh and important clinical facts regarding surgical shock, and a careful résumé of the important question of the relation between general anesthesia and "acid intoxication." Dr. Hewitt's work is in a sense a demand for a more general recognition of the value of the anesthetist. The book contains practically everything of value on the subject which would be of service to the student or the practitioner. The American reader will miss, however, some of the forms of apparatus which are widely used in this country, but otherwise the work is very complete and constitutes an excellent manual on what is daily becoming a more important specialty.

Studies in Urological Surgery. The Johns Hopkins Hospital Reports. Volume XIII. Baltimore: The Johns Hopkins Press, 1906.

These studies are edited by Professor Hugh Young of Johns Hopkins, with the collaboration of his associates at the University and the Hospital. Some of the articles are reprinted from the journals in which they appeared originally, and there are in all twenty-one papers in the volume. It is only at such an institution as Johns Hopkins Hospital, where all the equipment, all the trained assistance, and all the material support needed are available, that such magnificent original work can be produced. Some of the papers are in truth classics of their kind, and while it is impossible to give the entire list, we must mention the papers on stricture by Hugh Young and John J. Geraghty, and on chronic prostatitis by Young, Geraghty, and A. R. Stevens. There is also the very thorough study entitled "The Seven-Glass Test" by Young, which opens the volume. These three articles are remarkable for the exhaustiveness, completeness, and thoroughness with which they cover their themes. The minute and painstaking research on prostatitis, with a tabulation of 358 cases, is especially worthy of notice as a most important contribution to this rather obscure subject. A detailed description of the genitourinary department of the Johns Hopkins Hospital is given in an appendix to the volume, and makes interesting reading for those who would like to know the conditions under which such excellent work as this can be done.

Nervenkrankheit und Lektüre; Nervenleiden und Erziehung; die ersten Zeichen der Nervosität des Kindesalters. Drei Vorträge von Prof. Dr. H. Oppenheim. Zweite Auflage. Berlin: Verlag von S. Karger, 1907.

These are three lectures delivered at various times and constitute excellent sermons on the relation of a number of influences during childhood on the production of nervous states. He shows that the latter may be fully controlled by proper educational means. In the third lecture it is shown that the child manifests evidences of neurasthenic states at a very early age which should be immediately recognized. Particular instruction in these symptoms should be given to those in charge of children, the knowledge of which should serve as warnings, so that proper medical authority and advice may be consulted in time to accomplish immediate good. Although it may be impossible to correct an hereditary or congenital neuropathic constitution, much may be done to reduce the chances of a further development of these latent symptoms by the application of proper educational measures.

Nierenchirurgie, Ein Handbuch für Praktiker. Von Prof. Dr. C. Garre und Dr. O. Ehrhardt. Berlin: S. Karger, 1907.

This excellent German manual is intended to furnish the general practitioner with a complete résumé of the subject of renal surgery. The writers have drawn largely from their own experience in gathering the material for the work, which is thus given a more or less personal character. Only those facts are included which have shown to be true by actual test. The illustrations are new and well selected and considerably better than those met with in most German medical books. The text is clear and concise and the book constitutes a valuable manual on the subject. A good English translation would undoubtedly meet with a favorable reception.

Medical Diagnosis. A Manual of Clinical Methods for Practitioners and Students. Fifth Edition. Greatly Enlarged and Revised to Date. By J. J. Graham Brown, M.D., F.R.C.P.E., F.R.S.E., Assistant Physician, Royal Infirmary of Edinburgh, and W. J. Ritchie, M.D., F.R.C.P.E., F.R.S.E., Clinical Assistant Pathologist Royal Infirmary of Edinburgh. With 200 Illustrations and eight full-page Plates. New York: Imperial Publishing Company, 1907.

The well-known manual of diagnosis by Brown and Ritchie appears in a new, thoroughly revised edition, adding to the already comprehensive material of the former issues the latest advances in its rather wide field. The revision has really been done with much care and with excellent judgment, and we know of no single volume that can give the practitioner and the student a more compact, yet sufficiently complete body of facts and figures, covering every important diagnostic method. The book combines the diagnostic methods used at the bedside and in the physician's office with the methods employed in the laboratory, and covers every phase of the subject of physical diagnosis, chemical, microscopical, and bacteriological examinations. Naturally, it does not go into the minutest details on some of the topics, but it is more than sufficient for all practical purposes, especially for the physician who does his own laboratory work. We might mention as an example of its up-to-dateness that Wright's method of opsonic index is quite fully described, the technique being given with sufficient detail to enable one to understand the process quite clearly. We find nothing said, however, of the spirochete in syphilis.

Régimes Pathologiques et Régime Parfait. Par Dr. F. Cayla, Ancien Chef de Clinique à la Faculté de Bordeaux. Paris: Vigot Frères, 1907.

Cayla's manual differs from other works on diet, in that it consists largely of menus for the various meals of patients with different diseases. In addition, under the heading "the perfect diet," there are given dietetic directions for convalescents and for people who are exposed to, or predisposed to, diseases of the gastrointestinal tract, etc. In the concluding chapters are given the chief facts of interest concerning the various classes of food products. But little attention is paid to ultrascientific methods, measuring calories, and the like, and the book is primarily designed for busy physicians

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Nineteenth Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(Special Report to the MEDICAL RECORD.)

PRESIDENT B. K. RACHFORD, M.D., OF CINCINNATI.

(*Continued from page* 874.)

Wednesday, May 8—Second Day.

Pseudomasturbation in Infancy.—Dr. B. K. RACHFORD of Cincinnati read this, the President's address. The detailed cases upon which it was founded included the speaker's own cases and a number reported to him by members of the Society in response to letters addressed to them. In the discussion of the disease the writer considered age the most important etiological factor, and nearly all of the cases occurred in female children. The anatomical and physiological condition of the organs of generation of the infant were considered in detail. The external genital organs were well developed in physiological function from birth, although the internal organs were not. For this reason there could be a syndrome complex closely resembling the sexual feeling. True masturbation occurred after the age of ten. True masturbation occurred oftener in males; pseudomasturbation oftener in females. Later it could be classed among the habit neuroses. Environment was of the greatest importance in keeping up the habit. Heredity played a large part in establishing the predisposition, and gouty inheritance might be one of the predisposing causes. Acid condition of the urine had been found to be a frequent cause, as was also constipation. Of fifty-two cases presented, twenty-five were cured, and in only two was treatment of no avail. The writer was convinced that pseudomasturbation occurring in children under two would in time get well under almost any form of treatment; the tendency was to spontaneous recovery. There was no connection between pseudomasturbation in infancy and true masturbation in later life, though the former might tend to develop the latter. There was no connection between pseudomasturbation and epilepsy, and the writer had never seen these two neuroses coexist.

Dr. JACOBI of New York did not agree with the essayist that masturbation in infancy and childhood was not the same as the masturbation of adult life; he believed it should be classified with masturbation of more mature life. It showed itself by the same excitement—interrupted respiration, redness of the face, staring eyes, large immobile pupils, perspiration, and convulsive twitchings, as in the adult, and he looked upon it as the same condition.

Dr. L. EMMETT HOLT of New York referred to the frequency of the habit in mentally defective children, and considered it the rule with them rather than the exception. He thought the mental defect the cause rather than the result in these cases. He had not seen any case where the mental defect was traceable to the habit. He did not look with favor upon the appliances for mechanical restraint in these cases, nor upon the methods of stripping back the preputial hood. His cases had been nearly all in females.

Dr. HENRY KOPLIK of New York did not believe that true masturbation could exist in the infant because it presupposed intention and a resulting nervous explosion. He had found, as the other speakers had, that the great majority of cases were in females. He considered that the neurotic tendency was the chief factor.

Dr. C. G. KERLEY of New York was in accord with the views expressed in the paper, except that he thought that in patients over four years of age the prognosis was not so favorable. The cases were often discouraging, and treatment had to be carried out for a long time. He exhibited an appliance for mechanical restraint that he had found useful.

Dr. MAYNARD LADD of Boston showed a device for mechanical restraint similar to that employed by Dr. Kerley, consisting of a long section with two cross bars, which kept the thighs about one and a half inches apart, while allowing free movement of the legs.

Kernig's Sign in Infancy—A Study of Two Thousand Cases.—Dr. JOHN LOVETT MORSE of Boston presented this paper, in which he concludes that Kernig's sign is almost never found in infancy, except in meningitis; that its presence in an acute disease justifies, so far as one sign can, the diagnosis of meningitis; that it occurs with equal frequency in all stages of the disease and has no connection with the degree of intracranial pressure. It has no value in diagnosticating between cerebrospinal and tuberculous forms of meningitis.

Dr. HENRY KOPLIK of New York agreed with Dr. Morse that Kernig's sign as a diagnostic element in forms of meningitis in infants under two years of age is of very little clinical value. He said the sign should not be confused with a condition of myotonic contraction.

Bacteriology of Meningitis.—Dr. F. S. CHURCHILL of Chicago read this paper. Only the known bacterial cases were reviewed. Six cases showed meningococcus; one case pneumococcus; one case pneumococcus in the spinal fluid; one case primary tubercle bacilli; one Klebs-Loeffler bacillus; one case syphilitic; four undetermined cocci; four no organisms in the spinal fluid. The meninges, like other parts of the body, might be attacked by a variety of organisms; 80 per cent. of the trouble due to meningococcus. Next to the meningococcus, pneumococcus was the most frequent cause. Mode of access to the meninges through the throat and nose. Diagnosis between the different types could not be made from the clinical picture, but only from spinal puncture. Mixed infections were infrequent. The organism could be found in the nose and throat of healthy individuals living in close proximity to patients ill with meningitis, and these patients should be isolated. The meningococcic cases should always be quarantined, and probably the pneumococcic ones.

Grip Meningitis.—Dr. SAMUEL S. ADAMS of Washington reported this case, the child when first seen being supposed to have an attack of indigestion, had a temperature of 106°, pulse 140, and the writer made the diagnosis of grip, which was confirmed by several eminent consultants. Complained of headache and of being tired. Blood examination showed nothing of importance. An otologist excluded any disease of the middle ear. Then Kernig's sign developed; symptoms of meningitis; lumbar puncture performed; two ounces of fluid withdrawn, which showed the presence of influenza bacillus. This was the first case reported by an American in which the diagnosis had been confirmed by finding the organism in the fluid of lumbar puncture.

Dr. HENRY KOPLIK of New York said he had before mentioned a case similar to this of Dr. Adams, and had since had another case.

Dr. L. E. LAFETRA of New York reported a case of tuberculous meningitis with a terminal infection of pneumococcus; also a case in which at autopsy the influenza bacillus was recovered in the pus.

Dr. L. LOVETT MORSE of Boston disagreed with Dr. Churchill as to the necessity of isolating meningitis cases; he did not believe the danger of contagion was very great.

Dr. HAMILL of Boston reported a case in which the tubercle bacillus was isolated from the spinal fluid, with recovery of the patient. He agreed with Dr. Churchill as to the necessity of isolating these cases.

Dr. JACOBI of New York agreed with Dr. Morse that it was not practicable to isolate these cases.

Congenital Stenosis of the Duodenum.—Dr. H. L. K. SHAW and Dr. LEON BALDAUF of Albany presented this case of congenital stenosis of the duodenum, exhibiting photographs of the condition and the specimen. Child born after normal labor; twelve hours after birth passed meconium; placed at breast and vomited small amount of greenish fluid some time later. During next two days

vomited greenish fluid a number of times; seemed hungry and cried as if in severe pain; nursing discontinued, and barley water and whey substituted; meconium and some brownish fluid passed. Operative procedure postponed in the hope that the condition might be spastic. Ten days after birth had lost 2¼ pounds. Died thirteenth day after birth. There was stenosis of the bowel below the opening of the bile duct.

Thursday, May 9—Third Day.

The Caloric Value of Modified Milk in Its Relation to Infant Feeding.—Dr. Maynard Ladd of Boston read this paper, which consisted of a series of cases studied by the writer, in which the rate of growth in relation to the number of calories taken had been estimated. The series comprised twenty cases, and tables were shown exhibiting the weight development. Great variation was noted between the calories taken and the gain in weight, and the writer concluded that the calories in the food of the infant in the first year of life could not be furnished by fats and proteids vicariously; that a given number of calories did not necessarily cause the same rate of growth, even when of the same age and development; that the caloric value of the food is not the most important consideration in determining the quality of the infant's food. Neither the number of calories, nor the energy quotient, could be determined accurately.

Dr. L. Lovett Morse of Boston considered the American method of feeding better than the German, but thought the good points should be taken from both. He estimated the food in calories from time to time chiefly to make sure in cases of difficult feeding that he did not get the total amount too low.

Dr. Henry Koplik of New York called attention to the amount of waste in the gut, which he said was absolutely undeterminable. He thought that the percentage method was not the only way of feeding a baby successfully; in buttermilk feeding, even though the percentage food contained more calories, the waste in the gut in liberating the food was such that the baby might do better on buttermilk.

Dr. Freeman of New York deprecated the tendency to feed the babies on proteids of less than 1 per cent., and thought that if attention were paid to the matter of caloric values better standards would be obtained.

Dr. L. E. LaFetra of New York emphasized the points made by Dr. Morse and Dr. Freeman, and thought it would be enlightening if we could determine the lower limits of caloric value to be supplied by the proteids; the upper limits could be determined by the digestive capacity of the infant.

Dr. Thomas Morgan Rotch of Boston protested against the habit of speaking of any method as an ideal method. Cases should not be treated with any one method alone. What should be insisted upon was that the method used should be exact.

A Case of Myxedema.—Dr. Geo. N. Acker of Washington presented this case, which was a child healthy until eighteen months of age, when he presented it to the society in Raleigh in 1903; it was then a typical case of myxedema. It had been upon thyroid gland treatment since, and was now a well developed child and in good condition; gained seven inches during the first year; height now forty-one inches.

The Symptoms of Status Lymphaticus in Infants and Young Children.—Dr. John Howland of New York had observed over twenty-five cases during the last year. No gland weighing less than 10 gm. was considered pathological; the average weight of the gland during the first two years being 6 gm. To be on the safe side he had included none weighing less than 15 gm. All the tissues of the body were hyperplastic, including tonsils and adenoids. The changes consisted of a hyperplasia of tissue normally present. Symptoms were sudden death at beginning of anesthesia, administration of antitoxin, or the child might die suddenly in bed; in another group, the characteristic symptoms were, with or without some indisposition the child becomes suddenly ill; rapid, gasping respiration, with cyanosis; attacks of convulsions; temperature in majority very high, 104° to 107°. The dyspnea not an obstructive dyspnea, but toxic in character. These cases were usually called acute congestive bronchopneumonia. A rarer form were those cases associated with purpura.

Dr. Blackader of Montreal had had a very painful experience with one of these obscure cases, in which death had been attributed to change of nurses; autopsy showed a greatly enlarged thymus, 18 or 20 grams.

Dr. Thomas Morgan Rotch of Boston said this was a subject the knowledge of which should be more widespread, as the cases were often not recognized.

Dr. S. M. Hamill of Boston was glad to hear the writer take the view that these cases were of toxic origin. There was great similarity between the condition and the infections—in the character of the dyspnea, its irregular nature, and in the cyanosis and convulsive seizures.

Dr. Howland, in closing, said he had not observed a case that had recovered, except the one in which the thymus acted as a foreign body, obstructing respiration.

A Study of the Early Conditions of Osteomyelitis in Young Children by the Roentgen Ray.—Dr. Thomas Morgan Rotch of Boston had been making a study of this condition by means of the *x*-ray, for he had concluded that delay in diagnosis, as in appendicitis, might mean death, or deformity that could not be remedied. To accomplish this early diagnosis the *x*-ray was of inestimable value and in a number of cases it could only be diagnosed by that means. The *x*-ray should be used at once with the earliest appearance of the symptoms. Photographs illustrating the writer's remarks were shown and he enunciated the importance of remembering that cases of osteomyelitis were not so rare and that in most cases early operation was what would save the limb from deformity and in many cases save the child's life.

Dr. Samuel Adams of Washington thought that in most cases the physician was more capable of making a correct diagnosis in these cases than the surgeon and deprecated the habit of turning the cases over to the surgeon until every means of clinical diagnosis, including the *x*-ray, had been utilized.

Dr. F. S. Churchill of Chicago agreed with Dr. Adams as to the attitude of the physician towards the surgeon in these cases, and reported a case occurring in a girl of eight years, involving both tibia, both radia and the forehead, following in the wake of a severe typhoid. Typhoid bacilli were recovered from the pus at operation.

Dr. L. E. La Fetra of New York emphasized the fact that these cases are not infrequent; he had seen ten in the last five years. Early treatment in these cases would save the limb.

Dr. Rotch thought the expert opinion of both surgeon and laboratory man was of the greatest importance, and he had a very strong faith in the surgeon. It was only by a combination of all these opinions that the best results could be obtained.

A Case of Chylothorax.—Dr. C. G. Jennings of Cincinnati reported this case, an infant, nine years of age, presented with dyspnea. An acute catarrhal affection some weeks before and following that persistent fever and symptoms that pointed to pneumonia. There were physical signs of pleural exudate and it was thought to be a case of empyema. Aspiration revealed instead of pus, chyle; first aspiration, 12 ounces. Chest aspired thirteen times and peritoneal cavity once. The child presented practically no symptoms when the fluid was not present. Tuberculin used without reaction. The fluid had all the chemical qualities of chyle and the microscopic picture was that of chyle.

The Need of Greater Accuracy in Prescribing Starch in Infant Feeding.—Dr. Maynard Ladd of Boston read this paper, which was designed to bring out one point, the

great indefiniteness of physicians in the use of the cereals. The paper presented a plea for more accurate methods of prescribing starches in percentages as with fats and proteids. In the barley water mixtures there was great variation in the amount of starch contained, and the inaccuracy due to this was responsible for many of the cases in which the child was not supposed to be able to digest starches at all. Formulas varied from 0.64 to 6 per cent. Using the minimum or maximum solutions as diluents the amount of starch varied from 0.51 to 4.8 per cent. The rational thing to do was to give the minimum starch solution in the early months and gradually increase with the age

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-second Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

(*Continued from page 795.*)

DR. CLEMENT CLEVELAND OF NEW YORK, PRESIDENT, IN THE CHAIR.

Wednesday, May 8—Second Day.

Ovarian Pregnancy.—Dr. J. CLARENCE WEBSTER of Chicago presented a specimen of ovarian pregnancy. The case was almost identical with the one he reported three years ago, though more interesting, in that the embryo was in position in this specimen. One could see the amniotic cavity with the embryo in position. The thickness of the ovarian tissue averaged about half an inch, except the placental area, where it was thicker. There were several hemorrhages in the ovarian tissue, especially in the position of the placenta.

Unique Specimen.—Dr. WEBSTER presented another specimen, which he obtained two years ago while on a vacation in New Brunswick from Drs. White and Ferguson. The patient from whom the specimen was removed was a man thirty-three years of age, who was admitted to the hospital with symptoms of acute peritonitis. He had had for many years an irreducible scrotal hernia, and it was supposed there was strangulation. The man had been kicked by a horse. An incision was made in the left inguinal region; no hernia was found, but a structure which looked like an adult uterus, tubes, and ovaries. The uterus was removed, and what appeared to be a cervix. It was adherent around the inguinal ring; the abdomen was rapidly opened, the patient being practically moribund by that time. The incision was closed, and nothing more was done. Patient died. No autopsy was made. The specimen was given to Dr. Webster, and he had carefully worked it up. On first presentation it seemed like the adult female genitalia, but careful dissection and microscopical study disclosed uterus and tubes, and what appeared to be ovaries were testicles, but occupying exactly the same position as the ovaries in the female. The mucosa resembled that found in the adult female. Microscopical examination showed the glands were complex. He emphasized particularly the adult uterus. The tubes had the characteristics of those of an adult female, except the fimbriæ were not so complex. There were fewer fimbriæ, but the relationship of the testicle was exactly the same. On one side there was more marked ovarian or testicular fimbria. On examination of the broad ligaments he found on one side there was a cyst. Both round ligaments were present, but on the side on which the cyst existed the round ligament was flattened out and thin. On careful dissection of the broad ligaments there was a marked tube, about four millimeters in diameter, slightly convoluted, extending from the upper inner portion of the broad ligament towards the cervix. It was quite firm, and had the consistence of a pipe-stem. He pointed out the Wolffian duct, and the vas deferens, also the cervix and prostate. The patient was the father of twin children.

Dr. E. W. CUSHING of Boston narrated a case of a man operated on for hernia, in which a uterus was found in the hernia.

Dr. THOMAS S. CULLEN of Baltimore said that some years ago in Baltimore there was found at autopsy in a child a complete set of both female and male pelvic organs.

The Care of the Wound and the After-Treatment of Laparotomies.—There was a symposium on this subject.

The Method of Closing the Wound.—Dr. SETH C. GORDON of Portland, Maine, read a paper on this subject. He spoke of the time required for perfect union of abdominal wounds, and also pointed out the necessity of using such sutures as can be retained at least two weeks without absorption. He emphasized the use of suture material which is not absorbable, and which can be removed at the end of two weeks, as well as the use of suture material that was least liable to infection.

The Comparative Advantages of Catgut and Silver Wire Sutures for Closing the Fascia after abdominal Incisions.—Dr. HUNTER ROBB of Cleveland, Ohio, said the ideal suture material should be smooth, pliable, but not brittle, not too costly, easy to obtain on short notice, and, above all, readily rendered completely sterile. Catgut would be an almost ideal material, but when we sterilize it to a degree short of rendering it brittle, and consequently useless, some few of the inner strands may not be absolutely aseptic; and, in fact, not a few cases of suppuration, and even death, have been directly traceable to the use of catgut ligatures. The cumol method probably gave the best results, but for the past few years he had had excellent results with the ordinary and chromicized catgut as prepared by Van Horn of New York, especially when the smaller sizes were used. When, however, the larger sizes of chromicized catgut were employed, the sutures were not always absorbed, but frequently gradually worked their way to the surface of the wound, and were then discharged. They were not always sterile. Bacteriological tests made in his service had shown that the knots and end of catgut sutures, even when the wound had healed by first intention, teemed with bacteria, and he felt sure that chromicized catgut was responsible for many of the skin infections encountered. In one case of phlebitis following an amputation of the cervix, in which chromicized catgut was used, he was inclined to attribute this complication to the suture material. He now preferred to use for the skin and peritoneum small sizes of sterilized catgut, but for the fascia he believed that silver wire offered advantages over the larger sizes of plain or chromicized catgut. These results had been deduced from recent experience, and largely also from an analysis of two series of 100 cases each, in which silver wire and chromicized catgut respectively were used in bringing together the deep fascia. This analysis showed that the relative incidence of infection in the deep fascia occurring after the use of catgut and silver wire respectively was as two to one. Moreover, it was noted that when suppuration occurred it was always larger in amount and extent in the catgut cases than in the infections met with after the use of silver wire. The main objection against the use of silver wire for bringing the fascia together was that one left in the wound a substance that might annoy the patient by sticking into the surrounding tissues. This trouble, however, could be readily averted if the suture was properly applied and the ends were turned over with a pair of thin-jawed hemostatic forceps, so that they form a ball-like end to the suture. This annoyance had to be remedied in only four out of four hundred of the silver wire sutures. Removal under cocaine was always easy and painless. So far as the occurrence of hernia was concerned, *a priori* this accident should be less likely to occur after the use of silver wire, as this material undoubtedly approximated the tissues for a greater length of time, and in his experience had given rise to suppuration less often. Hernia was not

noted in a single case in either series, but the separation of the fascia and muscle often did not take place within the first few weeks after operation, and yet sometimes if these patients were examined some months or a year afterwards a smaller or larger protrusion would sometimes be apparent. He had not infrequently noted such an occurrence in patients who had been operated upon by other men, and he had no doubt that others had met with the same thing in some of his cases. Consequently, so far as hernia was concerned, he did not believe that we should judge of the relative value of the suture material except in cases examined at an interval of six months or a year after operation.

Dr. LEROY BROUN of New York said it was his custom, in closing a wound, to bring together the fascial edges with chromicized catgut. He did not rely on this entirely, but introduced, at the same time, some safety sutures of silkworm gut at about an inch and a half apart, and he saw that these were kept in for at least two weeks to guard against the opening of the wound by coughing, a sudden jar, or sneezing.

The Use of Laxatives in the After-Treatment of Laparotomy.—Dr. HENRY T. BYFORD of Chicago said that some laparotomies were of such a simple nature that the functions of the abdominal viscera were not materially disturbed thereby, and need not be disturbed afterwards by medicine. Exploratory peritoneal section, and the removal of nonadherent ovaries, were apt to be of this nature. But the majority of laparotomies represented a different problem. When there had been considerable trauma during the operation, with consequent soreness and inability to endure the pains, he applied an icebag to the abdomen rather than give opiates. The icebag and an enema containing thirty grains of chloral would usually alleviate the pain and nervousness, and sometimes the nausea, without inhibiting peristalsis. If his only object were to save life he should not bother the patient with the laxatives unless abraded or injured tissues had been left to form adhesions; but he confessed, at the risk of being considered meddlesome, that he gave laxatives in all but the simplest cases, because in those who did not really need them the bowels were more quickly relieved of the gas, and the patient then felt much better than when not so treated. Patients who had undergone a previous laparotomy generally remarked, without being asked, that they were having a much more comfortable convalescence than after the previous one in which they had either taken no laxatives, or had taken opiates for the pains.

Care of Stomach and Bowels; Position and Rest in Bed.—Dr. LAPTHORN SMITH of Montreal did not allow anything whatever to go into the stomach of a patient during the first twenty-four hours. The bowels were moved by enema on the third day and every day after, unless they moved naturally. If there was vomiting, calomel was used generally with bicarbonate of soda. Position depended on the severity of the case. In hemorrhagic cases the foot of the bed was raised, or, in septic cases, especially after appendicitis, the head was raised. Rest in bed for three weeks was the safest so as to improve digestion and nutrition. Twenty-one days after operation the patient was allowed to get up and to begin gentle exercise, so that by twenty-eight days she could walk about freely.

Eserine Salicylate as a Prophylactic Against Atony of the Bowels.—Dr. HIRAM N. VINEBERG of New York referred to the use of this agent, saying it had a beneficial effect when given to a patient before coming out of anesthesia. It was given in doses of one-fortieth of a grain. It was the custom to give 1-4 or 1-8 of a grain of morphine, with 1-40 of a grain of salicylate of eserine. He thought there was less distention of the abdomen after the use of eserine in this manner.

The Incision and After-Treatment.—Dr. W. GILL WYLIE of New York said the location of the incision varied with the internal condition. The method of closure varied according to the site of the incision. Method also varied with the condition of the bowels due to preliminary preparation.

The After-Care of the Patient.—Dr. HERMAN J. BOLDT of New York said that mobility of the patient was begun as early as was consistent with the patient's general condition. The greater number of patients might be out of bed with advantage to them within three days. A large number, even those upon extensive and technically difficult operations had been done, might be out of bed and placed in a comfortable chair within from twenty-four to thirty-six hours after the operation. A properly adjusted plaster bandage, adhesive, was essential for the safety of the wound. Neither the stomach nor the bowels required any special consideration unless there was some particular indication for it.

The After-Care of the Patient.—Dr. J. MONTGOMERY BALDY of Philadelphia said that rest in bed, good hygiene, diet and nursing were the principal factors in the end results. Moderate early getting up after operations was all right for patients in good general condition, but it was bad for others. There was nothing to recommend getting up in twenty-four or forty-eight hours. There was nothing to be gained, but much to be lost. That prolonged stay in bed increased the frequency of embolism and thrombosis was not true. He would admit that a surgical case might be gotten out of bed and home in a week or ten days, but he denied that this was best for the patient, or that this meant that convalescence had been more rapid. The aim should not be to get patients home in the quickest possible time, but to give them the best amount of stored-up health and energy with which to successfully meet the future. One who had gotten out of bed with health fully restored was surely more competent to meet the necessities of everyday resistance than one who had been quickly put upon his feet with little regard to his general condition.

The Prophylaxis of Venereal Disease from the Standpoint of the Gynecologist.—Dr. CLEMENT CLEVELAND of New York took this as the subject for his Presidential address. He said the position of the gynecologist regarding venereal disease was one of greater enlightenment than that of his brother of the general profession, because of his greater opportunity for observing it. His responsibility was, therefore, proportionately greater. From gynecology had come all the present-day knowledge of the effects of gonorrhea in women, and the inspiration for all that was known of its lasting effects upon men. The responsibility of enlightening the public did not rest with the medical profession alone. It was not a medical or sanitary problem merely, as the causes were dependent upon social conditions beyond control of the physician. By constant study and agitation the best methods for reaching the people would be evolved. All medical schools should pay the greatest attention to instruction in veneral diseases and their consequences, and some were doing so. The student and physician could not be too often reminded of the responsibility that rested upon them, not only in the treatment of these diseases, but as regards prognosis, and sanction of marriage. Many thousands of young men with a gonorrhea uncured married, and with the sanction of their physicians, who had not been as careful as they should have been in giving approval. For himself, he was positively convinced that the gynecologist should not play over the surface of the subject, but should get right down to the foundation of the matter and display it in all its ugliness. In this way only could there be any hope of making influence felt and expect to reach any moral advancement. To overcome indifference and arouse an urgent public sentiment in favor of the movement, there was no more powerful argument than the fact that the greatest sufferers from these diseases were innocent women and children. Constant preaching of this one fact alone would gain more supporters for the cause than all others combined. In closing, Dr. Cleveland thought it would be well to have a

standing committee to report each year, to arrange for papers in symposium, to invite prominent men to read papers before the society, or in other ways to make prominent the vital interest that was felt. By so doing gynecologists would acquit themselves of any charge of inactivity, and at the same time have the satisfaction of feeling that they were doing their share in helping on the good work.

Work of Henry Garrigues Appreciated.—Dr. Brooks H. Wells of New York delivered an oration on Dr. Garrigues in appreciation of his work in introducing asepsis into obstetric practice in America.

(To be continued.)

NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS.

Third Annual Meeting, Held at Washington, D. C., May 6, 7, and 8, 1907.

Special Report to the Medical Record.

(Continued from page 918.)

PATHOLOGICAL AND BACTERIOLOGICAL SECTION.

Dr. F. F. Westbrook of Minneapolis, Chairman.

Split Products of the Tubercle Bacillus and Their Effects Upon Animals.—Dr. Victor C. Vaughan and Sybil May Wheeler of Ann Arbor presented this communication. They split up the tubercle cell into two portions—the cell poison and the cell residue. The culture medium had been concentrated and then precipitated with five times its volume of absolute alcohol and this precipitate had been broken up into two portions—the precipitate poison and the precipitate residue; and the portion of the culture medium left after the removal of the alcoholic precipitate they had designated as the final filtrate. In considering the effect of the cellular substance on animals it should be borne in mind that the cellular substance with which they were then dealing was that of a tubercle bacillus that was virulent to rabbits and guinea pigs, and that it had been thoroughly extracted with alcohol and ether. There remained, as it were, only the proteid skeleton of the bacillus. They had injected into the abdominal cavities of twenty-four guinea pigs single doses, varying in amount from 5 to 200 mg. of the cellular substance and from these experiments they made the following statements: (1) In no case was death caused directly by the injection; animals that received from 100 to 200 mg. remained apparently well four months after the injection. (2) It gave in guinea pigs no immunity to a subsequent inoculation with a virulent bacillus. (3) It did, for a short time at least, sensitize guinea pigs to the tuberculosis bacillus, an interesting and a hopeful point. The effect of the cell poison on animals was shown to be a poisonous one to the respiratory center. It developed three stages of peripheral irritation, partial paralysis, and terminal convulsions. When given in sufficient quantities it killed within an hour both healthy and tubercular animals. There was no evidence that it elaborated any antitoxin and it was harmful, with nothing to recommend it. What was true of the cell poison was equally true of the precipitate poison, and the final filtrate. The effects of the cell residue on animals were practically nil. This was the non-poisonous group obtained by splitting up the cellular substance with alkali in absolute alcohol. In this method there was one ray of hope of finding among the split products a body that might possibly be of service in the treatment of incipient and localized tuberculosis. One of the most interesting studies regarding the split products of the tubercle bacillus was that of the effect of the precipitate residue on animals. On healthy animals it had no recognizable ill effects in either single or repeated doses, large or small. Experiment showed that the precipitate residue had some specific effect upon tuberculous animals. The precipitate sensitized guinea pigs to the tubercle bacillus just as the cell residue did. Evidently their so-called residues were much alike and it was more than probable that they contained the same active constituent. Of one thing they were satisfied, and that was that no preparation from the tubercle bacillus should be used in the treatment of tuberculosis until the poisonous group of the tuberculous proteid and other proteids in the culture medium were removed. During the past two years one of them used solutions of the cell residue in the tuberculosis in man and the following statements seemed justified: (1) It was of no value in advanced cases of pulmonary tuberculosis. (2) It might prove harmful even in initial cases if the dose be too large or if small doses be too frequently repeated. (3) When properly used in initial or in localized tuberculosis its action was apparently prompt and specific. (4) When given to an individual with pulmonary tuberculosis its effect upon the sputum should be watched and should guide further treatment. He wished it to be clearly understood that in well-established cases of pulmonary tuberculosis no benefit from this treatment could be expected. He believed that in initial cases this preparation was preferable to any form of tuberculin.

Further Notes on the Technique of the Tuberculo-Opsonic Test.—Drs. Hugh M. Kinghorn, David C. Twichell and Norman M. Carter presented this communication from the Saranac Laboratory, of which Dr. E. L. Trudeau was Director. After calling attention to the technique reported at last year's meeting (see Medical Record, Vol. 70, No. 5, August 4, 1906, page 190), they said they wished to describe the technique as they now used it, hoping that it might help other investigators in this particular line of work. The following conclusions were offered: (1) The tuberculo-opsonic test was probably one of but fair accuracy. While several control tests of one serum might be almost the same, one or more of the tests was very apt to be considerably too high or too low, and they, therefore, allowed for a "probable cure" of from 15 to 20 per cent. (2) In their own judgment, based on a large number of counts, they thought that at least 100 polymorphonuclear leucocytes should be counted, and that any less number than this might not give an accurate estimation. (3) Under favorable conditions, the time required to make five opsonic tests was about one and a half hours, not estimating the time necessary to count these.

Homologous Bacteria as a Vaccine in Tuberculosis.—Dr. Albert H. Allen of Saranac Lake presented this paper, which was read by Dr. Lawrason Brown of Saranac Lake. This was a preliminary report. The object of this investigation was to obtain from sputum a standardized vaccine for tuberculosis. The product was called tubercle vaccine since it resembled closely an emulsion of a tubercle. In brief, these were the following steps: (1) Fresh sputum was carefully washed through six normal salt solutions. (2) The sputum was then thoroughly homogenized with an ordinary egg beater for ten to fifteen minutes. (3) It was then attempted to separate the tubercle bacilli from the pus cells. The least unsatisfactory method was to collect the foam after homogenizing. This foam seemed to be freer of cells and at the same time richer in tubercle bacilli. Foam was quickly liquefied by placing it under an exhaust pump. (4) Emulsion from (3) was concentrated by centrifugalization. (5) This emulsion was then standardized by a modification of A. E. Wright's method. (6) The emulsion was then sterilized by heating on two successive days for two hours at 60° C., and 0.25 per cent. lysol was added for preservation. (7) In order to preserve the toxins and ferments present from heat, a portion of the emulsion before sterilization was passed through a Berkefield filter. It would seem hard to standardize this filtrate, which might be an important adjuvant to the vaccine. This filtrate was either to be added to the vaccine or injected separately at the same time. To test the sterilization, on

March 16 one healthy guinea pig was injected with 1 c.c. of the 175 million emulsion that had been heated two hours at 60° C. one day. Another healthy guinea pig (half grown) received 0.5 c.c. of this emulsion, heated thus on two successive days. After six weeks the autopsies showed in the first guinea pig tubercle lesions, in the second guinea pig none. The injection of unaltered tubercle bacilli in considerable numbers into tuberculous animals produced ulcers at the site of injection. To test this point with tubercle vaccine, two supposedly tuberculous guinea pigs were inoculated. No ulcers resulted, but autopsies at the end of six weeks showed no lesions except caseous glands near the site of injection in the guinea pig receiving the vaccine heated only once. The influence of opsonification on the immunizing power of bacteria was still an unsettled question. To see if the tubercle bacilli in tubercle vaccine were opsonified, tubercle vaccines, sterilized and unsterilized, were added to unwashed leucocytes, appropriate controls having been made; no phagocytosis resulted; after adding serum, phagocytosis did occur. Only two such tests had been made so far. They proposed to study the action of the vaccine by various experiments on animals. Dr. Trudeau had suggested that since one of its main advantages lay in its being homologous, animal tests would not be entirely fair. He further suggested that the homologous feature could be approximated by infecting the animals to be treated with the unsterilized vaccine to be used.

Dr. Milton J. Rosenau of Washington asked whether tuberculin was present in one or all of the split products that Dr. Vaughan had used.

Dr. William H. Park of New York said that he recently had a personal letter from Dr. Wright regarding his pessimistic attitude on the subject of the occasional inaccuracies; he believed that there might be some error in the technique. All seemed to get wild counts. He used the glycerin-agar for the tubercle bacilli; the development seemed shorter. He asked Dr. Vaughan whether or not the animals receiving these large doses were afterwards immune.

Dr. E. R. Baldwin of Saranac Lake believed that the use of the poisonous part of the tubercle bacilli was unjustified; they knew that in hypersusceptibility the poisonous part of the tubercle bacilli could be removed. As a matter of clinical observation and of experimental work, they knew that animals inoculated with non-virulent bacilli, or their products, might overcome susceptibility to these products in the course of time, provided they were not overdosed in the beginning. It did not appeal to him that, after excluding the toxic part of the tubercle bacillus, it could be used as a possible therapeutic agent.

Dr. G. B. Webb of Colorado Springs recently took twelve healthy students in Colorado and made some observations. They were sent to Pike's Peak, a distance of about twelve miles, and only one failed to get there; ten came out normally.

Dr. Rufus I. Cole asked Dr. Kinghorn if the addition of formalin had any effect upon the phagocytosis.

Dr. Victor C. Vaughn of Ann Arbor, in answer to Dr. Rosenau's query, said that if he would tell what was meant by the word "tuberculin," he might be able to answer the question. He could not answer Dr. Park's question, for he had not made enough experiments to warrant a statement. So far as his experience went, he had never been able to produce anaphyloxia or hypersusceptibility with the poisonous part of a proteid.

Dr. Hugh M. Kinghorn of Saranac Lake said that formalin in a 1-1250 proportion did not influence phagocytosis.

Dr. Mayzck P. Ravenel of Philadelphia and Dr. Nathaniel B. Potter of New York discussed the paper.

The Pleural Pressure after Death from Tuberculosis. A Preliminary Study.—Dr. W. B. Stanton of Philadelphia read this paper. He said that the existence of minus or negative intrathoracic pressure was first noted by Carson in 1819, and the subject had since been further studied by Donders, Hutchinson, Heynsius, Perle, and others, and the existence of a negative intrapleural pressure might be considered as proven. This negative pressure was due to the fact that the lungs were constantly distended, and the elastic fibers of the lungs were constantly striving to regain a condition of non-tension. Hence, the amount of intrapleural pressure under normal conditions would show the amount of elastic tension of the lung. This tension of the lung and its tendency to become smaller was well shown by the collapse of the lungs when the chest was opened, either during life or after death. It was because of this condition of a negative intrapleural pressure that a pneumothorax occurred when the lung ruptured or the chest was perforated from without. The observations he reported were made upon patients dying at the Henry Phipps Institute as a part of a study of the pleura and its behavior in tuberculosis. The method employed consisted in the insertion of a hollow needle which was connected with a mercury manometer into each of the first five interspaces. This was done before the body had been touched by the pathologist. All examinations were made within twelve hours after death and one or two while the body was yet warm. When the pressure was negative the needle was pushed still further into the chest to find, if possible, the pressure conditions within the lungs. The punctures were made anteriorly along the anterior axillary margin. The skin was pulled as far as possible to one side and the puncture made through the tense tissues. The return of these tissues to a natural position acted as a valve to prevent ingress of air after the needle was removed. From these 23 cases certain preliminary deductions were justifiable: (1) In cases dying of tuberculosis, pleural adhesions of greater or less extent were practically constant over the upper lobe. The lower lobes were free in about one-half the cases. (2) The intrapleural pressure might vary in the different interspaces of the same chest. This variation was most often due to pleural adhesions which obliterated the pleural cavity at the point of tapping; it was less often due to lung conditions. (3) The intrapleural pressure varied widely in different subjects, from minus 24 mm. to plus 10 mm. (4) The intrapleural pressure might be negative or minus, while the pulmonary pressure was positive or plus. (5) The minus intrapleural pressure found in tuberculous subjects were much increased when compared with text-book standards. (6) Zero pressures were found in one-half the cases in the first two interspaces.

Dr. Lawrence F. Flick of Philadelphia said this was a subject that had been too much ignored in the past. The study of the pleura in those dying of tuberculosis had opened his eyes; they found that there was perhaps less healthy tissue left after death in the pleura than in any organ or tissue of the body. In other words, when a case of tuberculosis had reached its normal termination in death, the pleura was shown to have borne the brunt of battle to a greater degree than any tissue in the body. He believed the top of the pleura was the primary seat of the disease, and Calmet also believed and proved that the parietal layer of the pleura, in animals he had injected, showed the primary focus.

Dr. Lawrason Brown of Saranac Lake asked Dr. Stanton if he noticed in cases of pneumothorax any displacement of the heart. In one of his cases the pressure was so great that the heart was displaced to the right of the sternum.

Dr. Stanton said that he had made a large number of such observations, in which there was a displacement to the right in left pneumothorax cases, and to the left in right pneumothorax cases, and this was quite constant.

Dr. Leonard Weber of New York said that the top of the pleura could not well be the primary focus of tuber-

culosis, and in all the post mortems that he had witnessed, or had himself made, he was convinced that the infection of the pleura was secondary in a large proportion of the cases. He did not mean to deny that primary tuberculosis of the pleura might not occur.

Disseminated Focal Necroses Due to Tubercle Bacilli (Acute Miliary Tuberculosis without Tubercle Formation).—Dr. A. S. WARTHIN of Ann Arbor presented this communication.

The Frequency of Occurrence of Tubercles in the Liver in the Absence of Tuberculous Lesions Elsewhere in the Body.—Dr. A. S. WARTHIN of Ann Arbor presented this communication.

Dr. S. MARX WHITE of Minneapolis and Dr. ALFRED MEYER of New York discussed these papers.

The Leucocytes in Various Complications of Pulmonary Tuberculosis.—Dr. FRANK A. CRAIG of Philadelphia read this paper. His study was based upon the examination of the blood in forty-five cases of pulmonary tuberculosis in the Henry Phipps Institute during the past year. In summing up the findings one was forced to the conclusion that the relation of the leucocyte count to the complication could only be considered in a very general way. The average findings in the uncomplicated cases of the groups showed a tendency to a decrease in the lymphocytes and a corresponding increase in the polymorphonuclears in the more advanced cases, with a decrease in the color-index, an increase in the number of red corpuscles and an increase in the number of leucocytes. These findings, he said, should not be taken too strictly, as individual cases in any group might resemble the findings of any other group. This variation from the average type, however, did not bear any definite relation to the progress of the case. The various complications, therefore, could be said to have no effect upon the blood in producing characteristic pictures, although the decrease in lymphocytes and the increase in polymorphonuclears were associated with many of the complications.

Occult Blood Findings in Tuberculous Ulceration of the Intestines.—Dr. H. R. M. LANDIS of Philadelphia read this paper. He said that statistics as to the relative frequency of intestinal ulceration in pulmonary tuberculosis varied, but he believed that a conservative estimate would place it not lower than 60 per cent. The one symptom upon which it was based was diarrhea. Among the thirty-three autopsied cases which he reported, four had loose bowel movements, from six to nine stools daily, for several weeks before death, and yet at autopsy no evidence was shown of intestinal ulceration. On the other hand, no less than thirteen, showing ulceration at autopsy, had but one or three movements daily. From his study he was able to confirm Louis' observation, that where the diarrhea antedated death but a short time the ulcers were small in size and few in number. Also that the longer the diarrhea lasted, and the more frequent its occurrence, the greater was the ulceration. Abdominal pain was rarely present. Thirteen of the thirty-three cases were examined for tubercle bacilli, and found in every instance; two of these cases showed no ulceration at autopsy. The present study represented the examination of 222 stools in 109 patients. A great part of this work was not checked up by autopsy findings, and while he gave the results of the entire series the conclusions were based only on the cases coming to autopsy, numbering 33. Taking the entire series, but one examination was made in 75 cases; of these 10 were positive and 65 were negative. In 12 two examinations each were made; of these a positive reaction was obtained in 6, negative in 7. In 22 the stools were examined three or more times. These cases, which included the six without ulceration, gave 8 positive and 14 negative results. Considering the 33 autopsied cases alone one, which gave a positive test, was omitted because of hemorrhage and a history of the presence of blood after defecation for some months prior to admission to the hospital. Of the remaining 32 cases, 26 had ulcers and 6 were free from ulceration. The six cases without ulceration were repeatedly examined, and always with a negative result. Twelve of the remaining 26 cases showed the presence of occult blood at least once, and in four instances from two to four times each. In 7 the tests were positive at the first examination; in 12 the feces were examined from one to three times with negative results. The greatest number of negative tests showing ulcers was six. While the intensity of the color reaction was an indication of the severity of the hemorrhage, it afforded no clue as to the amount of ulceration present. The case with six negative tests had a large number of ulcers. The results as indicated by these autopsied cases showed that in every instance in which occult blood was found ulcers were present in the intestines.

Dr. LAWRENCE F. FLICK of Philadelphia said that it had been demonstrated that the tubercle bacillus could be eliminated by the bowels without an open lesion in the kidney. Some of the work done by Dr. Walsh of Philadelphia left no doubt about this. Now, if it was true that the tubercle bacilli could be eliminated by the kidneys without an open lesion, by analogy it might be reasoned that the same thing could occur by the bowels; if it was possible to have an excretion of the tubercle bacilli by one organ, he believed this was possible by another.

Dr. ALFRED MEYER of New York questioned the value of evidence presented from the study of one case. The possibility of the individual swallowing tubercle bacilli in the sputum should be considered.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, Held March 19, 1907.

DR. WARREN COLEMAN IN THE CHAIR.

Demonstration of Method of Weighing Patients in Bed.—Dr. CHARLES P. BULL made this demonstration.

Pyrexia in Tuberculosis. What It Tells Us and How It May Be Controlled.—Dr. HENRY P. LOOMIS read this paper. (See page 1019.)

Aerotherapy in Cold Weather, with Particular Reference to Tuberculous Diseases, and Demonstration of a New Model Window-Tent.—Dr. S. A. KNOPF read this paper. He said that the reason consumptive patients did better in winter than in summer was because cold air contained more oxygen to the cubic inch than warm air. The volume of air was reduced one five-hundredth part for each degree of reduction in temperature. Even if the temperature was only at freezing point the body took in one-seventh more oxygen than on a summer's day when the thermometer was at ninety degrees. This greater absorption of oxygen meant an increase in the number of red blood corpuscles. Dr. Lawrason Brown, of the Adirondack Cottage Sanatorium, had just written him regarding the endurance of outdoor life by consumptive patients, that 60 to 75 per cent. of all their patients slept outdoors and more would do so had they the opportunity. More slept out in the summer than in the winter. No difference was made as to the degree of cold. The patients had slept out when it was 20 and 30 degrees below zero. Dr. Herbert M. King, of the Loomis Sanatorium, where patients were received in all stages of the disease, said that 50 per cent. slept out this winter and 100 per cent. of incipient cases slept out. All those who slept on the verandas managed to be outdoors twenty-two hours out of twenty-four. The profession had at last learned to appreciate the value of cold air, not only in tuberculosis, but in pneumonia and certain nervous affections. The rest or "Liege" cure was best carried out in winter on a veranda with southern exposure, where the body could have the sun and the head remain in the shade. The patient de-

rived no benefit from the cold air if he was chilled, and hence should be warmly clad and give special attention to keeping the feet warm. The "Liege" cure should be alternated every hour or two by short walks and breathing exercises with or without movements of the arms. Even the febrile patient should not lie for hours on his back with shallow breathing if he wished to avoid hypostatic pulmonary congestion. He should change his position frequently and take a few deep inspirations every half hour or so. During drives or sleighrides the patient should be comfortably warm, and should refrain from conversation, so as to breathe as far as possible through the nose. The walking exercise should begin on graded walks of varying inclinations, and should never be long enough to overture the patient. The selection of patients for walking or mild sports, the duration and kind of exercise permissible, should be guided by the temperature, the rectal temperature when feasible. All those who had examined the value of respiratory exercises with unprejudiced mind had agreed to their beneficent local and general effect. The seemingly slight local harm or temporary pain was amply compensated by general improvement, owing to the increased supply of oxygen, the greater facility of getting rid of tenacious mucus, and the consequent diminution of the dyspneic condition. An important effect often overlooked was that these exercises counteracted loss of coördination of thoracic muscles. He added to each inspiration and corresponding expiration a second expiratory effort for the purpose of expelling as much of the supplemental air as possible. This meant an additional amount of a thousand cubic inches of fresh, pure air entering the system for every six respiratory movements. As to the class of patients that could be permitted to walk, take breathing exercises, and pursue light winter sports, one could not lay down absolute rules, yet one might say in a general way the incipient patient might walk and take breathing exercises when he was afebrile, when he was gaining in weight or holding his own in a general way, and if too markedly dyspneic he might try breathing exercises, but should not walk. Highly febrile acute pleuritic or very recent hemoptic cases should not take any breathing exercises at all. Skating, tobogganing, and skeeing were permissible in only a few selected incipient cases. A chronic temperature of 99.5° was indication for rest in the reclining chair in the open air, and a temperature of 100.5 called for the recumbent position. A temperature of 101° or more meant rest in bed in a well ventilated room, but such patients should gradually become accustomed to sleeping outdoors. The most important feature of aerotherapy for the tuberculous was sleeping outdoors. The requisites for this were specially built verandas communicating with bedrooms, or lean-tos, with heated dressing rooms, as were to be had in sanatoriums. In private homes the veranda should be so protected that the patient was not exposed to the wind. The sleeping shack was only desirable when it had a compartment that could be heated. A lean-to was a structure costing about $18.30, and would accommodate sixteen patients, making the cost per patient only a little more than $1.14. The lean-tos were grouped around a central administration building, and a sanatorium on this plan with a capacity for 150 patients under municipal, county, or State control and designed for early cases among the poor would cost about $80,000, exclusive of land, or about $533 per patient, much less than the present cost in sanatoriums. For those compelled to remain in the city one form of window tent was best suited for outdoor sleeping. Dr. Knopf presented a new model of a window tent which he described in detail. The advantages of this last model over former ones were that it was far simpler and cheaper in construction, offered greater facility for cleaning and disinfecting, and had a method of attachment which permitted of its removal from the wind when not in use. Drop infection was limited to a minimum and the canvas could easily be removed and the steel frame washed. With this tent there was no possibility of a draft, but the patient should be warmly clad when sleeping in the window tent. Warm night gowns and coverings were not enough. Heavy weight linen-mesh union suits seemed to him best, though wool might be preferable. To prevent cold from coming through the mattress from below several layers of newspapers laid over the springs, or a layer of linoleum, were useful. Besides this there should be a plentiful supply of blankets. Where there was a shortage in this direction several layers of newspaper sewed between two layers of blanket were of service. The covering should not be so heavy as to weigh down the body. Lightly woven blankets seemed to be better protection than loosely woven ones. The feet should be kept warm by means of hot sandbags or hot water bottles. In extremely cold weather the head should be protected by a woolen cap, shawl, or helmet. If the tip of the nose became too cold it might be protected by a piece of absorbent cotton fastened with a strip of adhesive plaster along the crest of the nose, taking care not to occlude the nostrils. If the bright light early in the morning kept the patient awake some light weight but dark colored material could be put over the eyes. Patients should always dress and undress, for a sojourn in the cold air, in a warm room. The window tent could be used for a rest cure during the day if necessary, a reclining chair being put before the window instead of the bed. There were limitations to outdoor resting and sleeping. One unaccustomed to outdoor life or outdoor sleeping, or even sleeping with the windows open, should begin with an hour before and an hour or two after the principal midday meal. Little by little the time outdoors should be increased. Outdoor sleeping should be begun with a few hours at a time. If a patient became chilled after taking all precaution the process of hardening must go on more slowly. In his own experience he had never noticed that a chronic catarrhal condition of the upper air passages had been brought about or if present had been increased through pure, cold air; but, on the contrary, had always found the condition to be benefited by judicious sleeping outdoors. He was, however, convinced that an acute coryza or acute grippe in its early stages was better treated in a moderately warm, but well ventilated room. The same might be said of an acute pleurisy or a severe hemoptysis. Unless a patient far advanced with tuberculosis wished it or felt better for it one should not insist that he sleep outdoors. When it was evident that a patient had no chance of recovery, sleeping outdoors against his inclinations was utterly useless, unscientific, and inhumane.

Dr. W. P. Northrup said he was always interested in every device which gave a sick individual the benefit of cold, fresh air. He asked Dr. Knopf what he meant by fresh air? Dr. Northrup maintained that patients were greatly benefited by cold, fresh air. They did better during the winter than the summer months. He was skeptical regarding what had been said of oxygen. The value to patients was in the *cold* fresh air. He asked Dr. Knopf if only the head and neck were exposed.

Dr. Knopf replied that one-half the body was exposed.

Dr. Northrup then maintained that if it was a question of head and neck in the tent and the rest of the body in the room, or the head and neck in the room and the rest of the body in the tent, he would prefer the trunk and legs in the tent and the head and neck in the room. He maintained that the body breathed as much as the lungs; and the question of cold fresh air was as important for the skin of the body as it was for the lungs. He referred to the experiment made with a kitten. When the kitten's head was placed in a rubber pouch, with body outside, it breathed without harm; but when the kitten's body was in the pouch and the head outside, it graduall began to stow heat and suffered from heat stowing.

Dr. Theodore C. Janeway said that they were indebted to Dr. Knopf for what he had done in the field of thera-

peutics. He was impressed with what had been done last fall in Boston in the Outdoor Department of the Massachusetts General Hospital in caring for the tuberculous patients in their homes. Dr. Pratt and Dr. Cabot ran large classes of tuberculosis, and the cases were treated on the roofs, and in the back yards. Many patients had been refused admission to Rutland because they were considered to be too far advanced. In spite of that the percentage of arrested cases in the clinic he thought would compare favorably with the statistics of the sanatoria. The whole matter rested in the conscientiously carrying out of sanatorium methods and treatment with rest, care in the open air, breathing and exercise such as Dr. Knopf had told them of. In New York City it was difficult to utilize the roofs; therefore, the device presented by Dr. Knopf was of special value. Two or three years ago Dr. King told very strikingly about the patients who slept out at liberty in the lean-to. Forty patients were out of doors in the annex. Influenza struck Liberty and most of the tuberculous patients in Liberty contracted influenza. In the sanatorium there were only nine cases, and seven of these occurred amongst the servants who were not under sanitary régime. The other two patients were very ill patients in the Infirmary. Among the forty patients in the lean-to not a case occurred.

Dr. Keyes said that from an experience in his own family he believed that acute coryza could occur from fresh cold air admitted through the window. To prevent the cold air getting down over the neck and shoulders he told of a trick he had of taking two pillows, arranging them in a V-form, and then having the covers tucked around the neck; this would keep the possible draughts from chilling one. Patients did better in cold than in warm air. The beneficial effects he believed were due to the stimulation of the nervous system which resulted in very marked and rapid changes in the blood distribution; also coincidently there was a vasomotor stimulation.

Dr. Henry G. Piffard presented photographs taken in Germany, and also some taken last summer in New Jersey, where patients spent several hours each day perfectly nude and in the open with beneficial results.

Dr. Henry W. Frauenthal said that patients in the higher altitudes developed their chest measurement and with it there was an increased ability to take up oxygen. With regard to the breathing exercises, he had found that by their use patients with lateral curvature improved, and now a number of his nurses had given up nursing and taken up teaching breathing exercises.

Dr. Henry P. Loomis said that there was one thing that Dr. Knopf had not spoken of, the possibility of doing away with the fad which was so apparent in the medical profession of sleeping out of doors; he meant out of doors in New York City. In suitable climates it would be different. One could not incorporate in the cities the methods employed in the country; if tried it would be dangerous. This device of Dr. Knopf's would enable the patient to sleep in the room and do away with the idea of sleeping out of doors. At Bellevue this had been tried by the staff, patients, and nurses, and Dr. Loomis had made visits at night and had found that the nurses, when night came on, had their tents perfectly tight. They could not stand the cold. Dr. Loomis hoped that the time would come when the pendulum would swing the other way.

Dr. George Mannheimer said that it made a difference whether the patient had fever or not, and that the patients should have their temperature taken every three hours. Those patients that awakened in the morning with general malaise, etc., had nightly fever. There was a self-retaining thermometer for use in the rectum which sh[ow]s the nightly temperatures in these cases. He also called attention to the possible use of old trolley cars or horse cars, which would be excellent, and could be had almost for the asking from street car companies. He did not think that massage of the intercostal spaces was of much value. The device of Dr. Knopf's was the best thing yet accomplished.

Dr. Warren Coleman recalled the observations made by Darwin about the skin temperature. Observations were made in Patagonia, where the individuals wore no clothing or covering of the skin, and all were diminished in stature. The conclusion was reached that because of the amount of energy required to keep alive and keep warm, they could not grow.

Dr. Knopf said that they could not treat patients without clothes. Patients must be kept warm, especially the lower extremities. They might breathe cold air, but the body should be warm, and the feet particularly. The open-air treatment of the fever was the best. He emphasized the fact, and strongly, that massage had developed the thoracic muscles and helped in the chest expansion and in the general improvement of the cases.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.*

Idaho State Board of Medical Examiners.

October 2, 1900.

SURGERY.

1. Spondylitis deformans: (a) How is it characterized? (b) Symptoms and pathology?
2. Bilateral dislocation of lower jaw: Give symptoms, causes, and treatment. Is the capsular ligament usually ruptured?
3. Fracture through surgical neck, and head of humerus. Give diagnosis, treatment, exciting, and predisposing causes.
4. (a) From what source of blood supply is extradural hemorrhage due? Subdural? (b) What are the symptoms of general brain compression from hemorrhage? Give special symptoms.
5. Castration: (a) What are the indications for the removal of the testicles? (b) Describe the method of castration in aseptic and septic cases.
6. Strangulated Hernia: (a) What three conditions constitute a strangulated hernia? (b) Where is the seat of most marked pathologic changes? and why? (c) Give the local and general symptoms.
7. Describe the operation you would employ for ectropion.
8. Tracheotomy: (a) State methods employed in this operation. What is the after-treatment? (b) Which is the more dangerous and difficult, tracheotomy or laryngotomy, and why?
9. Suppurative otitis media: (a) In a mixed infection what bacteria are usually present? (b) What is the treatment indicated?
10. Cholecystotomy: (a) Give technique, position of patient, line of selection for incision; (b) how are stones from the duct removed? (c) What are the complications to be ascertained and removed? (d) What is the definition of "Ideal" cholecystotomy?

OBSTETRICS.

1. Give differential diagnoses of pregnancy.
2. On what signs is multiple pregnancy diagnosed?
3. Give treatment of pernicious vomiting of pregnancy.
4. Give five things to be observed by a pregnant woman.
5. How do you treat threatened abortion?
6. How secure asepsis in confinements as to external maternal parts? How maintain asepsis during labor? after labor? Why is a routine postpartum douche a bad practice? Mention the indications for a postpartum douche.

***It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.**

7. Describe treatment for puerperal eclampsia.
8. Give treatment for placenta previa.
9. Define dystocia, hydrocephalus, funis phlebitis, caput succedaneum, ectopic gestation, hyperemesis, polyhydramnios, sapremia, gastrohysterotomy.
10. Forceps. (a) Indications for use; (b) conditions necessary for use; (c) describe preparation of patient; (d) use of anesthetic; (e) describe application of forceps and extraction of fetus.

PRACTICE.

1. Describe three varieties of intestinal obstruction, and give the treatment in each case.
2. Give the etiology, symptoms, and treatment of exophthalmic goiter.
3. Give the etiology, symptoms, and treatment of hay fever.
4. Make a differential diagnosis between ulcer and carcinoma of the stomach.
5. Give the etiology and treatment of chloasma.
6. Give etiology, symptoms, and treatment of cystitis.
7. Describe the symptoms and treatment of laryngismus stridulus.
8. Give the symptoms and treatment of aortic regurgitation.
9. Give the symptoms and treatment of spotted fever (tick fever) of the Rocky Mountains.
10. Describe the dietetic treatment of diabetes mellitus.

GYNECOLOGY.

1. Name five primary causes of menorrhagia. Detail the treatment of the form due to subinvolution.
2. Name the varieties of dysmenorrhea. Give the treatment of mechanical dysmenorrhea.
3. Outline the treatment of gonorrheal endometritis.
4. Give the etiology and treatment of acute oöphoritis
5. Make a differential diagnosis between fecal impaction and an inflamed ovary.
6. Give etiology, symptoms, and treatment of pelvic cellulitis.
7. Name the uses of the uterine sound. Enumerate contraindications and dangers attending its use.
8. Give etiology, symptoms, and treatment of vulvovaginal cyst.
9. Name five genital fistulæ.
10. Describe symptoms and treatment of uterine carcinoma.

ANATOMY.

1. Bones. Name five foramina and give structures passing through them.
2. Muscles. Give origin and insertion of ten muscles.
3. Nerves. Give the distribution of the cranial nerves
4. Circulation. Give the blood supply of ten structures of the body.
5. Special. (a) Name three fissures of the brain. (b) What are the chordæ tendineæ? (c) Pineal body? (d) Describe the course of the vas deferens. (e) Locate corpus callosum.

HISTOLOGY.

1. Name the three primary blastogenic layers.
2. Name the structures derived from each.
3. Describe the minute structure of the kidney.
4. Give variety of glands with example of each.
5. Define leucocyte, osteoblast, stroma, dentine, periosteum, circumvallate papillæ, Peyer's patches, discus proligerus, zona pellucida, corpus luteum.

DIAGNOSIS.

1. What is meant by the term pathognomonic? Give four examples.
2. Give methods of handling sputum to determine, microscopically, if (a) tuberculosis exists; (b) pneumonia.
3. What would be the findings in an examination of the blood in pernicious anemia.
4. Differentiate the mitral lesions of the heart.
5. Differentiate the diseases of which dropsy is a symptom.
6. In what diseases are the following conditions found: (a) Clubbing of the fingers; (b) loss of patellar reflex; (c) Cheyne-Stokes respiration; (d) wrist-drop; (e) pain in the knee; (f) barrel-shaped chest; (g) Koplik's spots; (h) pain in testicle and glans penis; (i) Argyll-Robertson pupil; (j) strawberry tongue.
7. On what signs would you base a diagnosis of large left-sided pleural effusion without resorting to puncture?
8. Give the differential diagnosis between mastoiditis and acute inflammation of the middle ear.
9. Give diagnosis of acute cystitis in a female.
10. Differentiate intestinal colic from other lesions which might be mistaken for it.

HYGIENE.

1. Name some diseases, one attack of which ordinarily renders the subject immune from subsequent attacks.
2. Name and describe the principal chemical elements of food, giving the use of each class.
3. Indicate the proper diet in a case of diabetes mellitus, obesity, typhoid fever, tuberculosis.
4. What relation have certain insects to the cause and spread of disease?
5. Give some directions for the sanitary care of a small city.
6. What is the difference between an infectious and contagious disease? Name two of each class.
7. Give some directions for the disposal of sewage and other waste matter from farm houses, and the proper protection of drinking water.
8. What is the influence of climate and altitude on health?
9. Name some diseases which may be to a large extent prevented by proper hygienic care.
10. What is the effect of alcohol upon the nerve centers, upon the circulation?

PHYSIOLOGY.

1. Describe the change that takes place in the eye in changing from far to near vision.
2. Describe the patellar reflex and state upon what its integrity depends.
3. Locate the moter centers of the brain.
4. What is the lymphatic system and what is its office?
5. Of what is the pancreatic juice composed and what part does it play in digestion?
6. How is inspiration accomplished?
7. Describe minutely the formation, elimination and passage of urine.
8. Give time and order of eruption of both temporary and permanent teeth. Tabulate, if you wish.
9. Name the different portions of the alimentary canal in order from mouth to anus.
10. What are the functions of the skin?

CHEMISTRY AND TOXICOLOGY.

1. What are (a) carbohydrates? (b) proteids?
2. What is the difference between a physical and a chemical change? To which does the emulsification of fats belong?
3. Define organic and inorganic chemistry.
4. Starch ($C_6H_{10}O_5$), grape sugar ($C_6H_{12}O_6$), alcohol (C_2H_6O). Show the chemical reaction and equivalents in the change of starch to grape sugar and of grape sugar to alcohol.
5. Give in detail two reliable tests for sugar in the urine.
6. Give chemical test for pus in the urine.
7. Give antidote for each of the following: (a) corrosive sublimate, (b) arsenicum, (c) silver nitrate, (d) iodine, (e) phosphorus.
8. Give a reliable test for arsenic in contents of stomach.
9. In what class of poisons would you consider the stomach pump contraindicated?
10. What would you consider the maximum safe adult dose hypodermically of (a) atropine, (b) morphine, (c) strychnine, (d) apomorphia, (e) nitroglycerine?

PATHOLOGY.

1. Micrococcus lanceolatus: (a) Describe process of staining. (b) What is its significance, and in what inflammatory conditions is it often observed?
2. Describe the pathological changes that take place in the liver from the effects of chronic interstitial hepatitis.
3. What are the alterations or changes that take place in a muscle while undergoing progressive muscular atrophy?
4. Carcinoma of stomach: (a) Is it usually primary, or secondary to carcinoma elsewhere? (b) Where is it usually situated, and give most common type.
5. Tuberculous enteritis: (a) What particular parts are usually involved? (b) Describe the degenerative changes. (c) In which direction to the axis of the gut does ulceration extend most rapidly?
6. Write the characters of the Bacillus anthracis, ray fungus, Bacillus typhosus.
7. (a) What is a thrombus? (b) What is thrombosis? (c) Describe the three changes that may take place in a thrombus.
8. What is your method of making a postmortem examination?
9. What is understood by the terms pathological physiology, pathological morphology, special pathology?
10. The etiology of tumors (a) What influence has age *especially* as to the connective-tissue type? (b) Sex, if a significant factor, denotes a predisposition to what?

(c) Heredity, and local predisposing factors. (d) What proportion of malignant tumors in males compared to females?

MATERIA MEDICA AND THERAPEUTICS.

1. Under what conditions would you prescribe, (a) ergot; (b) bromide of potassium; (c) iodine; (d) hyoscyamus?
2. Treat a case of apoplexy.
3. Name five sedatives and give indications for the use of each.
4. Give complete treatment for a case of dysentery.
5. Name four methods of introducing medicine into the system and give relative dose by each method.
6. Give classification, properties, dose, physiological action, and therapeutic use of Fowler's solution.
7. Same of belladonna.
8. Give treatment for vomiting of cerebral origin; (b) acute gastritis.
9. What are the therapeutic uses of iron?
10. Give official terms, the part used, and the active principles of deadly nightshade, henbane, foxglove, monkshood, dogbutton.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

IDAHO STATE BOARD OF MEDICAL EXAMINERS.

October 2, 1906.

SURGERY.

1. "*Spondylitis deformans* is the name given to a disease which affects the vertebral column, and is the same, or of the same nature, as that termed 'chronic rheumatic arthritis' when affecting other parts. As a consequence of absorption of the articular cartilages and of the intervertebral discs, and the development of osteophytic prominences from the edges of the vertebral bodies, and ossification of the ligaments, especially the anterior common ligament, the spine becomes bent and rigid, and a very characteristic deformity is the result.

"Kyphosis is produced, and as the disease frequently affects the whole or major part of the column, there is one long antero-posterior curve, the patient has a constant stoop, his stature is diminished, there is complete rigidity of his spine, and his movements are awkward and constrained. In lesser grades of the disease the cervicodorsal or the lumbodorsal regions may be alone affected, and the signs are less pronounced. With advance of the disease the spinal muscles waste, and the curvature becomes more prominent, the head is poked forward, the shoulders appear unusually round, and the patient is obliged to support himself with a stick." (Treves' *Manual of Surgery.*)

2. As a rule the capsular ligament is not ruptured.

4. (a) *Extra-dural hemorrhage* is generally from the middle meningeal artery or one of its branches, or the superior longitudinal, lateral, or occipital sinus; occasionally it is from the internal carotid artery.

Sub-durol hemorrhage is generally from the middle meningeal artery or one of its branches, small veins, capillaries, or one of the sinuses.

(b) "If after an injury to the head a patient be found absolutely unconscious, it being imposible to arouse him or to make him answer questions, with fixed dilated pupils, slow, deep, stertorous breathing with flapping of the cheeks during expiration, slow, full, labored pulse, retention of urine and involuntary passage of feces, and paralysis, general or of one side of the body only, these symptoms are caused by *compression of the brain.* . . . If the symptoms have come on gradually and at short intervals after the accident (an interval during which the patient may have been quite conscious, or showing more or less evidence of brain concussion), or if while under observation it be noted that the signs of compression are increasing, the coma becoming more deep and the paralysis more extensive, it clearly indicates *intracranial hemorrhage.* When there has been an interval of consciousness between the injury and the oncoming of the symptoms of concussion, showing that the brain has not been seriously shaken or contused; and, further, if the paralysis is or was at first unilateral, we may diagnose that the hemorrhage has taken place betweeen the bone and the dura mater from rupture of a meningeal artery or wound of a sinus; while under the other conditions we have evidence of more severe direct injury to the brain, making it probable that the blood clot is situated on or in the brain." (Gould's *Surgical Diagnosis.*)

5. The indications for castration are:—malposition of the testicle, tuberculous disease, old standing hematocele, cancer, or other tumors, and chronic enlargement of the prostate gland.

6. (a) The three conditions which constitute a strangulated hernia are: 1. A constriction so tight that reduction is impossible; 2. Interference with the circulation, which may possibly lead to gangrene; 3 If intestine is present, gas and feces are unable to pass.

(b) The most marked pathological changes are found inside the sac—on account of pressure and the interference with the circulation.

8. (b) Tracheotomy is the more dangerous and difficult operation as a rule, it takes longer, and requires more assistance. But laryngotomy cannot be performed on a patient under thirteen years of age owing to the smallness of the crico-thyroid membrane; it is also more difficult to insert a laryngotomy tube than a tracheotomy tube.

9. (a) The *Staphylococcus pyogenes aureus* and *albus*, *Streptococcus pyogenes;* sometimes the tubercle bacillus, bacillus of influenza, Friedlander's bacillus, Fraenkel's pneumococcus.

10. (d) *Ideal cholecystotomy* is an operation which includes opening the gall-bladder, removing the calculi, and suturing the incision.

OBSTETRICS.

2. Multiple pregnancy may be diagnosed by the following signs: (1) The abdomen may be irregular in shape and may show a sulcus indicating the space between the two fetal sacs; (2) persistent and increased tension of the uterine walls; (3) two fetal heart sounds may be heard; (4) multiplicity of small parts; (5) two fetal heads or backs may be palpated; (6) diminished fetal mobility Sometimes it is difficult to diagnose the condition before the birth of one child.

4. (1) The diet should be easily digestible and nutritious; (2) the clothing should be warm, and free from constrictions; (3) gentle and moderate exercise should be indulged in, if possible in the open air; (4) the bowels and bladder should be kept properly regulated; (5) sexual intercourse should cease.

5. Absolute rest in bed, with head lowered, and in a darkened room; opium or chloral should be administered; the diet should be liquid; the bowels and bladder should be attended to; if the hemorrhage is excessive the pelvis may be elevated; but ergot and tampons are contraindicated.

9. *Dystocia* means difficult or obstructed labor.

Hydrocephalus is a condition in which there is marked enlargement of the head ducts to serous effusion within the cranium.

Funis is the umbilical cord.

Phlebitis is an inflammation of the veins, generally septic.

Caput succedaneum is an edematous swelling developed on the presenting part of the fetus during birth.

Ectopic gestation is a pregnancy in which the fetus is elsewhere than in the uterine cavity.

Hyperemesis is an extreme and exaggerated condition of nausea and vomiting.

Polyhydramnios is an increased amount of liquor amnii.

Sapremia is a septic condition due to the entrance into the blood of the products of putrefactive bacteria.

Gastrohysterotomy is another name for cesarean section, or the delivery of a fetus through an incision in the walls of the abdomen and the uterus.

10. (a) *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both." (From Jewett's *Practice of Obstetrics.*

(b) *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

PRACTICE.

4. *Ulcer of stomach* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

Cancer of stomach does not usually occur before forty years of age, is more common in males, the pain is local-

ized and constant, vomiting is copious and occurs sometime after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; there is progressive emaciation; severe anemia and cachexia are also present.

5. The *etiology* of chloasma is unknown. The pigmentation may be due to the chemical action of the rays of the sun upon the constituents of the blood; another theory is that it is due to extravasated blood undergoing changes; there is also a relation between chloasma uterinum and the uterus, as is shown by the fact that the chloasma usually disappears either after parturition, the cure of the uterine disorder, or the attainment of the menopause.

The *treatment* is unsatisfactory. If possible remove the cause. Glacial acetic acid, or bichloride of mercury in one or two per cent. solution may remove the spots, but they are apt to return. Pure carbolic acid applied with a swab has been recommended. The part may be washed with alcohol, and a mercurial plaster applied. (From Jackson's *Diseases of the Skin.*)

7. The *symptoms* of laryngismus stridulus are: The child holds his breath, the face becomes congested and cyanotic, the glottis is closed, inspiration is suddenly arrested, and ends in a shrill crowing sound; there may be spasms or convulsions; the attack is sudden, and may be repeated; there is no fever, coryza, nor cough.

Treatment: Cold water should be dashed on the face and chest; ammonia may be applied to the nostrils; an emetic may be administered, bromides or chloral should be given; attention must be paid to the diet and general hygiene of the child.

8. The *symptoms* of aortic regurgitation are: Palpitation on slight exertion; dyspnea, headache; dizziness with faintness, most marked on rising quickly; precordial pain; the apex-beat is displaced downward and to the left; the heart is hypertrophied; there is a diastolic murmur over the aortic area; pulsation is observed in the carotids; the pulse has the water-hammer characteristic.

9. *Symptoms* of tick fever of the Rocky Mountains: "There is a period of incubation of about a week. The patient complains of nausea, general malaise, and a chill; this latter is followed by a fever which reaches its highest point about the tenth day, is characterized by evening rise and morning remissions, lasts about two weeks, and may be followed by subnormal temperature. In severe cases the morning remissions may be absent, and the fever remains high (from 104° to 106° F.). There are general pain and soreness, particularly during the first week, coated tongue with red edges, sordes, constipation, nausea which persists in severe cases, scanty urine with albumin and casts, and epistaxis. The liver and spleen may be enlarged. The pulse is high, and out of all proportion to the fever; the respiration is also increased. An examination of the blood shows (1) the parasite, (2) a decrease in the percentage of hemoglobin, (3) a decrease in the number of the red blood cells, (4) a slight leucocytosis, chiefly of the large mononuclears. Bronchitis is present during the second week; and in severe cases lobar pneumonia supervenes, with a grave prognosis.

"*The eruption* appears usually on the third day, first on the wrists and ankles, then on arms, legs, forehead, back, chest, and, last and least, on the abdomen. It is never very abundant on the abdomen, but the other portions of the body, in some cases, are literally covered by the eruption.

"At first the spots are of a bright red color, macular at all times, from a pin point to a split pea in size. At first they disappear readily on pressure and return quickly; but if the case is a severe one they soon become darker and in some cases are almost purple. From about the sixth to the tenth day of the disease they fail to disappear on pressure and are distinctly petechial in character. In favorable cases, about the fourteenth day, they begin to lose their petechial character and disappear slowly on pressure. In some cases the eruption consists of small, brownish spots, giving a turkey-egg appearance.

"As the fever declines the eruption begins to fade; but a slight return of fever or a free perspiration will cause it to show distinctly."

"Treatment is unsatisfactory. Quinine in large doses has been tried with some success, but must be given persistently. The treatment is otherwise symptomatic and includes cardiac stimulants, Dovers' powder for the pains and soreness, tepid baths for the fever, and plenty of water to flush out the kidneys. The site of the tick-bite should be cauterized with 95 per cent. carbolic acid." (From *Reference Handbook of the Medical Sciences.*)

10. *The dietetic treatment of diabetes mellitus*: "All sugars should be rejected The same is true of starches. Bread is the most difficult of foods to deal with. The purer gluten flours may be used, but they are difficult to obtain. Aleuronat or almond flour may be substituted. Most meats and fish are permissible, and the greens and relishes may be taken freely. Farinaceous foods and potatoes or other vegetables rich in carbohydrates must be avoided. Eggs, butter, cheese, and milk are allowed. Saccharin may be used in place of sugar for sweetening.

"*The chief articles prohibited* are liver, wheat bread, corn flour, rice, sago, arrow-root, barley, oatmeal, tapioca, macaroni, puddings, beet root, sweet vegetables, potatoes, carrots, peas, beans, parsnips, turnips, all sweet fruits, apples, pears, plums, grapes, oranges, apricots, peaches, gooseberries, dates, watermelon, sweet wines, cordials, porter, lager beer, cider, mustard, honey, sweets, ices, jams, treacle." (Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

GYNECOLOGY.

1. Five primary causes of menorrhagia: Tumors, uterine displacements, endometritis, tubal and ovarian diseases, and subinvolution.

2. The varieties of dysmenorrhea are: Congestive, neuralgic, obstructive, ovarian, and membranous.

3. Dilatation of the cervix; curettage; the uterine cavity is then to be flushed out with some antiseptic solution, and then swabbed with iodine or carbolic acid to prevent reinfection; the patient must remain in bed for from seven to ten days after the operation.

5. In fecal impaction there will be a history of constipation; a vaginal examination will also demonstrate the presence of this condition; active purgation will clear up any doubt on the subject.

7. The *uses* of the uterine sound are: (1) To demonstrate the mobility of the uterus; (2) to show the size of the uterus; (3) the presence of intrauterine growths; (4) deviations in the cervical canal; and (5) as an aid in the diagnosis of uterine displacements.

Contraindications: (1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (5) acute pelvic inflammation.

Dangers: (1) Abortion; (2) sepsis; (3) peritonitis; (4) hemorrhage; (5) perforation of the uterus.

9. (1) Vesicovaginal; (2) rectovaginal; (3) vesicouterine; (4) urethrovaginal; (5) vesicouterovaginal.

10. *Symptoms* of uterine carcinoma: Irregular hemorrhages, pain, and offensive discharge; advancing years; microscopic examination of intrauterine scrapings will clinch the diagnosis.

Treatment: Complete abdominal hysterectomy, unless contraindicated by the debilitated condition of the patient.

ANATOMY.

1. (1) *Foramen magnum*: The medulla and its membranes, vertebral arteries, spinal accessory nerves, anterior and posterior spinal arteries, and the occipitoaxial ligament.

(2) *Jugular foramen*: Inferior petrosal sinus, lateral sinus, meningeal branches of occipital and ascending pharyngeal arteries; glossopharyngeal, pneumogastric, and spinal accessory nerves.

(3) *Inferior dental foramen*: Inferior dental vessels and nerve.

(4) *Foramen rotundum*: Superior maxillary division of fifth cranial nerve.

(5) *Foramen ovale*: Inferior maxillary division of fifth cranial nerve.

5. (a) Fissure of Rolando; fissure of Sylvius; parietooccipital fissure.

(b) The *chordæ tendineæ* are tendinous cords attached above to the segments of the tricuspid and mitral valves, and below to the musculi papillares of the ventricles of the heart.

(c) The *pineal body* is a small conical body situated in the brain, between the anterior corpora quadrigemina and immediately behind the posterior commissure.

(d) The *vas deferens* begins at the lower part of the globus minor of the testis and proceeds along the posterior border of the testis and inner side of the epididymis, along the back part of the spermatic cord, through the external abdominal ring, inguinal canal, and the internal abdominal ring. It then curves round the outer side of the epigastric artery, crosses the external iliac vessels, and goes to the side and base of the bladder, passing to the inner side of the ureter. It lies between the base of the bladder and the rectum.

(e) *Corpus callosum* is situated at the anterior part of the base of the great longitudinal fissure of the cerebrum, and connects the two hemispheres together.

DIAGNOSIS.

1. *Pathognomonic* is a term applied to signs and symptoms which are specially characteristic of a disease, and the presence of which makes its diagnosis absolute.

Examples: (1) Escape of cerebrospinal fluid in fractures of the base of the skull; (2) Koplik's spots in measles; (3) hearing the fetal heart sound in pregnancy; (4) water-hammer or Corrigan's pulse in aortic regurgitation.

3. In *pernicious anemia* the blood would show: (1) A diminution in the number of red corpuscles; (2) a relative increase in the amount of hemoglobin; (3) poikilocytosis; (4) the presence of nucleated red cells; (5) variation in the size of the red cells; (6) the leucocytes *may be* diminished.

6. (a) *Clubbing of the fingers* is found in pulmonary phthisis, emphysema, pulmonary osteoarthropathy, valvular cardiac disease (sometimes).

(b) *Loss of patellar reflex*, in locomotor ataxia, anterior poliomyelitis, peripheral neuritis.

(c) *Cheyne-Stokes respiration*, in apoplexy, uremia, cerebral tumors, tuberculous meningitis.

(d) *Wrist drop*, in lead, or arsenic, or alcohol poisoning, multiple neuritis, pressure from crutches, etc.

(e) *Pain in the knee*, in hip joint disease, obturator hernia.

(f) *Barrel-shaped chest*, in emphysema, chronic bronchitis, bronchial asthma.

(g) *Koplik's spots*, in measles.

(h) *Pain in testicle and glans penis*, in renal calculus.

(i) *Argyll-Robertson pupil*, in locomotor ataxia, cerebral syphilis, progressive paralysis of the insane.

(j) *Strawberry tongue*, in scarlet fever.

HYGIENE.

1. As a rule one attack of the following diseases conveys immunity: Whooping cough, rotheln, scarlet fever, typhoid, typhus, smallpox, varioloid, chickenpox, yellow fever, mumps.

4. Malaria and yellow fever are transmitted by the mosquito; bubonic plague may be conveyed by fleas, flies, and bugs; typhoid may be conveyed by flies; tick fever (or spotted fever) is carried by the tick; sleeping sickness is generally transmitted by a biting fly.

9. Typhoid, tuberculosis, smallpox, cholera, yellow fever, ophthalmia neonatorum.

PHYSIOLOGY.

1. In accommodating the eye for near vision the ciliary muscle contracts, the suspensory ligament relaxes, and the lens bulges and becomes more convex.

2. The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patella is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

10. The functions of the skin are: Protection, sense of touch, excretion, regulation of body temperature, absorption, and respiration.

CHEMISTRY AND TOXICOLOGY.

1. (a) *Carbohydrates* were formerly defined as substances of unknown constitution, composed of carbon, hydrogen, and oxygen; the last two being in the proportion to form water

(b) *Protcids* are substances of very complex composition and of unknown constitution, and are necessary to the phenomena of life. The molecule contains carbon, hydrogen, oxygen, nitrogen, sulphur, and sometimes phosphorus, iron, or some other element.

2. In a *physical* change the composition of the substance is not altered. In a *chemical* change the composition of the substance is altered. The emulsification of fats is a physical change.

3. *Organic* chemistry is the chemistry of substances which contain carbon. *Inorganic* chemistry is the chemistry of substances which do not contain carbon.

4. (1) $C_6H_{10}O_5+H_2O=C_6H_{12}O_6$.
(2) $C_6H_{12}O_6=2CO_2+2C_2H_6O$.

5. The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1.) *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2.) *Boettger's test:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry.*)

6. Chemical test for *pus* in the urine: Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

7. The antidote for (a) corrosive sublimate is white of egg, in not too great a quantity; for (b) arsenicum is freshly prepared ferric hydroxide; for (3) silver nitrate is salt and water and white of egg; for (4) iodine is starch solution and emetics; for (5) phosphorus is old French oil of turpentine.

8. *Test for arsenic*: Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

9. The stomach pump is contraindicated when *corrosives* have been taken.

PATHOLOGY.

1. The *Micrococcus lanceolatus* is better known as the *Diplococcus lanceolatus*, or the pneumococcus of Fraenkel and Weichelbaum.

(a) *Process of staining*: Spread a cover glass with a smear containing the bacteria, dry it, then fix it in a flame. It can then be stained for from five to ten minutes in Ehrlich's solution; it is then to be washed in water and afterwards immersed in Gram's solution for two or three minutes. It is then washed in 95 per cent. alcohol. While in the Gram's solution the specimen is very dark brown, but it becomes violet or blue again on application of the alcohol.

(b) It is found in lobar pneumonia; it has also been found occasionally in cerebrospinal meningitis, pleurisy, peritonitis, pericarditis, acute abscesses, otitis media, and other conditions.

3. The alterations or changes that take place in a muscle while undergoing progressive muscular atrophy are as follows: "The muscles become pale and rather flabby. Microscopically the fibers show various forms of degeneration. Fragmentation in a longitudinal or in a transverse direction, coagulation necrosis, and occasionally fatty degeneration of the fibers may be seen. Sometimes the fibers seem to grow smaller by a simple atrophic process. Coincidently reactive proliferation is seen in the connective tissue between fibers, and doubtless this to some extent causes further muscular degeneration. The muscle cells themselves may proliferate quite extensively." (Stengel's *Pathology.*)

4. *Carcinoma of the stomach* (a) is usually primary. (b) It is usually situated at or near the pylorus, and the most common type is the cylindrical celled adenocarcinoma.

5. According to Osler, "The affection begins in the solitary and agminated glands or on the surface of or within the mucosa. The caseation and necrosis lead to ulceration, which may be very extensive and involve the greater portion of the mucosa of the large and small bowels. In the ileum the Peyer's patches are chiefly involved, and the ulcers may be ovoid, but in the jejunum and colon they are usually round or transverse to the long axis."

7. (a) A *thrombus* is a plug or clot in a blood-vessel remaining at the site of its formation.

(b) *Thrombosis* is the coagulation of the blood within the vessels or heart during life. The changes that may

take place in a thrombus are: Organization, calcification, softening, infection, and putrefaction.

9. *Pathological physiology* is that branch of science which deals with the study of disturbances of function.

Pathological morphology is that branch of science which deals with the study of the structural changes in disease.

Special pathology deals with pathological processes in individual or special diseases, or organs or parts.

10. *Tumors*: (a) Connective tissue tumors are most common in early life when the connective tissues grow most vigorously.

(b) Sex has little bearing on the etiology of tumors, except in the case of cancer, which is more common in females.

(c) *Heredity* is considered by some to be an etiological factor; but the more probable view is that the *predisposition* to tumors and the *weakened resistance of the tissues* are hereditary.

Local predisposing factors are slight. Places where various different embryological structures meet are the most liable to malignant tumors.

(d) Malignant tumors are more common in females than in males.

MATERIA MEDICA AND THERAPEUTICS.

5. By mouth, by hypodermic injection, by rectum, and by inhalation. If the dose by mouth is one grain, the hypodermic dose would be about one-half a grain, and the dose by rectum about one and a half grains.

10.—

	Official Name.	Part Used	Active Principle
Deadly nightshade.	Atropa Belladonna.	Leaves and root	Atropine and Belladonnine
Henbane	Hyoscyamus Niger	Leaves and flowering tops	Hyoscyamine and Hyoscine
Foxglove	Digitalis Purpurea	Leaves	Digitalin, Digitalein, Digitin, Digitonin and Digitoxin.
Monkshood	Aconitum Napellus	Root	Aconitine

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 15, 1907:

	Week of June 8		Week of June 15	
	Cases	Deaths	Cases	Deaths
Tuberculosis Pulmonalis	393	175	318	166
Diphtheria	306	37	393	48
Measles	681	21	777	26
Scarlet Fever	543	24	541	28
Smallpox	5	1	2	1
Varicella	105	—	100	—
Typhoid Fever	55	7	39	9
Whooping Cough	51	12	22	12
Cerebrospinal Meningitis	23	16	20	10
Malarial Fever				
Totals	2102	293	2212	300

Empyema.—By connecting a Politzer bag with the drainage tube in cases of empyema the discharge of pus is greatly facilitated. The bag is compressed and its tip inserted into the end of the drainage tube, a short section of rubber tubing intervening if necessary. The bag in expanding exerts constant aspiration in the abscess cavity, and the discharge is all collected in the bag, which is emptied at regular intervals.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended June 14, 1907:

MASSAGE OF THE PROSTATE AND STRIPPING THE SEMINAL VESICLES.*

By FERD. C. VALENTINE, M.D.,

AND

TERRY M. TOWNSEND, M.D.,

NEW YORK.

The usefulness of massage of the prostate and stripping the seminal vesicles is daily in evidence, when these organs are involved in acute, subacute, or chronic urethritis. Indeed, the urethra is not safe from autoreinfection while its adnexa harbor noxious bacteria. Massage of the prostate has a place also early in prostatic hypertrophy. This naturally embraces no claim for complete *restitutio ad integrum*, but experience shows many a case in which judicious massage, with other treatment, has saved the risks of a cutting operation.

Massage of the prostate and stripping the vesicles are not negligible in the first evidences of abscess of these organs. True, it is unsurgical to attempt to empty pus from the adnexa through the urethra, yet there are enough successful cases in every practitioner's experience to justify the procedure, when the patient's condition makes operation hazardous, or when he refuses to take the risks thereof. Naturally when rupture of an abscess into the tissues is imminent, none but operative intervention may be considered.

The value of prostatic massage and stripping the vesicles in aberrations of the sexual function is still *sub judice*. Yet the practice forms a useful adjuvant to other treatment in these cases.

The present paper does not embrace recital of the indications for massage and stripping, further than the above mere suggestions. The exclusive object in view at present is a study of methods used in the procedures indicated by the title.

Standard writers assume that every practitioner is familiar with the technique under consideration. The consequence has been the evolution of several methods, most of which are unnecessarily difficult and painful, to a degree dangerous, and more or less ineffective. These results have led many practitioners to discard altogether digital treatment of these adnexa to their patients' disadvantage.

The various methods alluded to will be sketched to illustrate the value of the procedure which personal practice has shown to be most recommendable.

In *the knee-elbow position* the patient rests upon the operating table, his chest placed upon his crossed arms, his pelvis supported by his thighs, the knees resting upon the lower margin of the table. This position promptly causes hyperemia of the facial and cerebral vessels and painful throbbing thereof, difficulty of breathing, due to compression of the chest contents from pressure of the abdominal viscera on the diaphragm, and gravitation of the prostate and seminal vesicles following the abdominal and other pelvic contents, thus so increasing their distance from the anus as often to place them beyond the reach of the finger in the rectum. This latter fact gives the patient unnecessary pain from the operator's efforts to push the perineum upward, in endeavoring to express the contents of the prostate and vesicles.

It is self-evident that the knee-elbow position increases the surgeon's work and diminishes its efficacy. The augmentation of effort would not be objectionable, were its effectiveness increased or the patient's comfort enhanced thereby. The prostate and vesicles gravitate away from the finger's tip and the abdominal walls, becoming pendulous, offer a distinct impediment to that counter-pressure which is essential in fixation of the organs.

It is small wonder, then, that patients who have been examined, or for whom treatment has been attempted in this position, are apprehensive when brought for consultation involving examination of the major adnexa. The inefficiency of work in the knee-elbow position is well demonstrated when the patient's physician reports his inability to express any of the contents of the organs mentioned, and when, the patient being conveniently placed, a copious extrusion is easily and relatively painlessly obtained.

In *the Sims position* the patient is placed on his right side, with his buttocks at the edge of the table. It certainly is not nearly so uncomfortable for the patient as the position before described. In it, however, the surgeon's work is rendered difficult, as he is obliged to use his left fist to make counterpressure upon the prevesical region, to force the prostate and seminal vesicles towards the finger in the rectum seeking them. Moreover, the thighs being drawn up upon the abdomen, serve as a hindrance to free action of the left arm that partly encircles the patient's body.

The *erect flexed position* is the one most in use. The patient stands before the operator, bends over the back of a chair, or over a table, or rests his hands upon his knees. To approximate the prostate and vesicles to the finger pushing up in the rectum, the operator must pull the pelvic contents towards it with his left hand. Some works recommend that the operator, to give greater force to his right index finger, rest his right foot upon the rung of a chair and let the knee give the elbow increased propulsive power.

Aside from the unnecessary difficulty that this position puts upon the operator, it is a strain upon the patient which does anything but contribute to the muscular relaxation which must be invited to aid in the work. Moreover, there is always a danger

*Read before the Manhattan Clinical Society, March 15, 1907.

that the patient will faint and pitch forward or sidewise upon the floor. This occurred in the experience of a colleague who was endeavoring to demonstrate to us the superiority of this position over the one we advocate. The patient lost consciousness and in falling thrust his face through the window of an instrument cabinet before he reached the floor. Numerous large scars on the patient's head and face loudly protest against this method of examining and treating the prostate and seminal vesicles.

The *gynecological position* is in all regards the normal one for the class of work now under consideration. Its steps may be concisely laid down as follows:

1. *Preparation of the operator.* The physician should be prepared for this class of work, as for any other genitourinary procedure. The principal points to be kept in view are that a patient without urethral discharge or other manifestations of disease may harbor gonococci in the prostate or seminal vesicles or both. Moreover, in some cases the prostate or the posterior urethra and the detrusors have acquired an extraordinary projectile power. In that event the merest touch of the prostatic region through the rectum may send forth to quite a distance drops or even small streams of prostatic juice. If the operator's garments are not protected they may become soiled with this sort of "ejaculation." It may, and probably will, not be convenient to change garments at once, while the soiled ones are sent to be cleaned. The possibility of infection from such a source is not remote, when keeping in mind that most of us unconsciously pass our hands over our garments and with equal recklessness wipe our eyes with our fingers. The manifest indication herefrom is that no genitourinary work should be performed unless when properly dressed in a gown. The choice of the gown is purely one of personal taste. Even at the risk of exposure to facetiæ we confess preference for what is known in the clothing trade as "market coats." The white material is sufficiently dense to protect the ordinary garments in the frequent hand washings extensive genitourinary work entails, and the form is such as to make a change easy whenever one garment becomes soiled.

As desirable as it is to keep one's clothing covered, so imperative is it also to have the hands and forearms bare to the elbows. Pus, blood, or infected secretions soiling any part of the exposed skin may be at once washed off, which would not be feasible if the arms were covered by sleeves. The arms can be conveniently bared for our work if the shirt sleeves are especially made for the purpose. Their ordinary slit is extended to 2 1-2 inches beyond the olecranon; the cuff should not be over 2 1-2 inches wide. To keep the sleeve out of the way of the day's work, the cuff is opened and *not* turned upon itself, as is usually done when rolling up the sleeve. On the contrary, its anterior margin is kept downward as the cuff is laid in its normal position, as close to the shoulder as possible. The shirt sleeve projecting beneath is then smoothly folded twice or three times, according to its length, around the cuff, as it lies upon the arm. The undershirt sleeve is then so folded around the cuff and turned over the shirt sleeve that the lower part (cuff) of the undershirt is reversed upon the entire mass. The operator who devotes fifteen seconds to deliberately preparing each arm as above suggested will not be encumbered with his shirt sleeves throughout the day. When the work is finished, merely reversing the undershirt's cuff will allow the entire sleeve to drop to its place, without any crumpling of the starched cuff.

An important advantage of the careful preparation suggested is that, with arms bare and garments covered, the operator has no hesitancy in closely approaching his work. The thoroughness thereof is consequently greater than if he were risking infection, as before detailed.

2. *Protecting the hands.* The operator accustomed by long practice to the use of very thin rubber gauntlets will be adequately protected thereby. Of course, they must be in perfect condition and properly sterilized. The sense of touch will not be impeded if the operator uses a very tight glove, while it will be if he endeavors working with a glove that is too large for his hand. Whether a glove or the finger varnish (to be described) is used, the nails of the genitourinary specialist should always be kept so closely filed as to entirely obliterate the subungual space. Moreover, the skin about the nail beds should always be kept free from rough projections or irregularities (agnail, or hangnail) which may tear the glove or render finger varnishing sufficiently ineffective, to add to the patient's discomfort.

Those not accustomed to the use of gloves can perfectly protect the examining finger by dipping it into the finger varnish alluded to above. This consists of: Copal, 2.0; Venetian turpentine, 4.0; sulphuric ether, 100.0; collodion, 100.0; acetone, 8.0.

This varnish dries almost instantly into a perfect sheath for the finger, and in nowise obtunds its tactile sense. It does not break when the finger is bent or manipulated in any manner. After the work in view is finished, the finger varnish can be scrubbed off with a brush with soap and hot water. Any small flakes that may remain adherent to the skin can be readily rubbed off with a towel moistened with alcohol.

3. *Preparation of the table.* Common cleanliness commands that a fresh towel be placed upon the pillow to receive the patient's head and another upon the lower edge of the body of the table, where his buttocks are to rest. It is a crude but effective lesson in caution to place these clean towels as above suggested, in the patient's presence.

4. *Preparation of the patient.* It is wise to appoint a time for examination of the prostate and vesicles or for their treatment, shortly after the rectum has been evacuated. The presence of fecal masses primarily increases the inevitable unsavoriness of the procedure and further disturbs precision of work by the finger impinging upon them. It is true that such masses, if present, usually keep moving above and behind the finger's tip, still their presence is annoying enough to cause one to hasten his work.

The unesthetic character of the procedure need not be enhanced by an occasional patient's lack of cleanliness. One may find such disregard of cleanliness in particles of dried excrement adherent to the anal hairs, even among men whose garments portray the most fastidious care. It is charitable to say to such a patient that the hard fecal bits, if carried into the rectum, would injure it and to refer him to the toilet room, where he may cleanse himself with soap and hot water. The senior writer, confessedly less cautious than his associate, gave an unclean patient a handful of gauze squares to use in the suggested cleansing. His lesson came in a plumber's bill for $15, charged to remove the gauze with which the patient clogged the water closet.

Another, a smaller matter, in which the patient is not at fault, may assist to render the work unpleasant. It is a fecal soiling of the undergarments by patients with hemorrhoids. The obtrusiveness thereof is remediable in a manner that will be mentioned when discussing disposal of the patient's garments on the table.

5. *The patient's garments.* The patient's comfort demands removal of his coat and vest; these may be substituted, if he feels chilly on the table, by covering his chest and abdomen with an examining sheet or a light blanket. His trousers and drawers are dropped midway to his knees and he is requested to sit upon the clean towel placed to receive his bare buttocks. While he lies down the footboard of the table is raised to support his legs. The trousers and drawers are drawn down to the patient's ankles and a towel placed upon the thus exposed fundament of the drawers, so that no soiling thereof be perceptible and to protect the operator's elbow from contact therewith.

6. *The patient's posture.* The head should rest upon the towel covering the pillow, whose lower margin supports the patient's neck. The shoulders, however, must rest flat upon the table; the whole body so placed that the spine is in perfect line with the mesial line of the table.

The knees are well bent and allowed to hang apart as widely as they will fall. The left foot is rested on its outer margin, and the heel of the right foot is placed in the hollow of the left.

Both hands are closed into fists and stood upright on the table, beneath the buttocks. The fists are so held that the circles made by the thumbs and index fingers receive the tuberosities of the ischia of the corresponding sides.

This posture not only makes the perineum nonresistant, but by the upward bend given the pelvis relaxes the abdominal walls.

7. *The operator's position* may be at either side of the table if he is ambidextrous, as he should be. As the majority, however, can do more effective work with the right hand, it will be well to stand at the right of the patient, facing him. The exact place for the physician to stand is so that his chest is diagonally transversed by the patient's bent right leg.

8. *Preparations for penetrating the anus.* Before inserting the finger, it will be well to separate the anal hairs to avoid the unnecessary pain that would be produced by dragging them into the anus. The left fingers then raise the penis and scrotum, to save their being soiled with the lubricant used on the right index finger.

9. *The lubricant* must be sufficiently coherent that much of it will be carried into the rectum by the finger and not swept off as the anus is penetrated. Glycerin is too hygroscopic for this purpose and in some cases acts as quite an irritant to the rectal mucosa. Olive oil is very much thinned by the temperature of the rectum and thus loses much of its efficiency as a lubricant. Gomenol, 33 per cent., serves both as a lubricant and local anesthetic in hypersensitive cases. Gouley's lubricant, however, serves admirably in the majority of patients. If properly prepared, it has all the characteristics required.

10. *Lubricating the finger.* Whatever lubricant is employed, as large a quantity as possible is taken on the finger and the excess deposited upon the anus.

11. *Inserting the finger.* The prepared index finger is thrust through the mass of lubricant that has been placed upon the anus and pushed into the rectum without gyratory motions, following the curve of the sacrum, and slightly to the patient's right side. It will be observed that if the finger traversing the rectum is pressed against the posterior aspect thereof, the discomfort of the procedure will be materially reduced. When the finger is inserted as deeply as possible, the left hand releases the penis and scrotum, allowing them to hang towards or rest upon the right hand.

As the index finger progresses upward into the rectum the tips of the other right fingers are closed upon the palm, while the thumb is extended to reach as high as possible alongside the left side of the patient's scrotum. The right wrist is held as straight as possible, and the elbow brought as close to the table as is necessary to maintain this position.

12. *Counter-pressure.* The prostate and seminal vesicles being movable organs, it is necessary to fix them and while doing so to press them as far as possible toward the finger in the rectum. This fixation and pressure are attained by the left fingers. These are curved and their tips held ready to push down upon the prevesical region. The patient is then ordered to take a very deep breath and just as he has finished the following expiration, the finger tips are sunk into the relaxed lower abdominal walls, about an inch above the insertion of the recti into the pubis. The palm rests over and barely touches the pubic hairs. The finger tips are firmly pressed into the pelvis, as if to force its contents out through the perineum. At first efforts of this kind some patients develop quite a rigidity of the recti and other abdominal muscles. After a few treatments, however, they learn to so completely relax as to satisfactorily cooperate with the surgeon.

13. *Locating the prostate and vesicles.* The operator continually occupied in this class of work and he who has recently refreshed his studies of anatomical relations, will recognize the apex of the prostate the instant his finger tip has traversed the rectal covering of the *pars nuda urethræ.* The finger then passes successively around each outer margin of the organ to its base and then down between the lobes to outline the interlobular cleft, when it exists.

The finger will then pass up from one outer side of the prostate's base to search for the seminal vesicle of that side, repeating the procedure for the opposite side. In health, these organs can be felt only with great difficulty, and then only as soft strings.

In disease the vesicles may be considerably enlarged and yet not be palpable, when a very much enlarged prostate rises as an obstacle below them. It must be kept in mind also that the ampullæ of the vasa deferentia lie close to the seminal vesicles and in fact join them to form the common ejaculatory ducts. In consequence, inflammatory swelling of the ampulla of a vas, which exceptionally occurs, may convey to the examining finger all the appearances of a vesiculitis.

14. *Order of stripping and massage.* It is generally accepted that the vesicles should be stripped and the prostate massaged in the order mentioned. This proves erroneous in practice. When the prostate requires massage it holds material which it is unable to unload without mechanical aid. It then is likely by pressure to occlude the common ejaculatory duct; consequently it should first be emptied as much as possible, to allow free transit through the ducts of such contents of the vesicles as can be

stripped therefrom. It is therefore wise to massage the prostate, before stripping the vesicles.

15. *Technique of prostatic massage.* The apex of the prostate should be the first point of attack. The finger is partly bent and slightly withdrawn with each downward stroke. The strokes at first are performed very gently and their force gradually increased until the point massaged is felt to grow softer under the compressing finger. The same process is repeated for each lobe, extending the manipulations higher and higher until the base of the organ is reached, whenever this is possible. Ordinarily extrusion of prostatic juice from the meatus will begin before the finger has attained the middle of either lobe.

16. *Stripping the vesicles.* After the prostate has been sufficiently massaged, stripping the vesicles is performed in the same manner, except that lateral strokes are added to those from above downward. These lateral strippings must be performed on each side from without to the median line, on account of the angle which each vesicle forms upon itself. Without these lateral strippings only the lower part of the vesicles could be relieved.

17. *The force to be employed* in massage and stripping is incapable of general description. Experience and judgment can be our only guides. It is safe to let each patient's sensations govern the work. If the finger's contact with certain points in the prostate and vesicles give more pain than when other parts are treated, the sensitive ones should be more lightly pressed upon. Under cautious digitization the sensitiveness of these points will soon disappear. As in all similar procedures, gentleness does not exclude thoroughness. Indeed, special caution should be exercised, lest excessive zeal and energy convert subacute or chronic prostatitis, or vesiculitis, into acute inflammation of these organs.

18. *The number of strokes* to be employed in massage and stripping is governed by the local effect. When a region stroked upon is felt to yield its hardness, even to a slight degree, attention may be given to other parts of the organ, in the succession mentioned before.

19. *Duration of each stroke.* According to the region massaged or stripped, one to two seconds are devoted to each stroke.

20. *Length of séances.* The success attained and the patient's tolerance are the guides for the length of each séance in the beginning. Later, when the patient is well on the road to recovery, his tolerance to stripping and massage may exceed the operator's physical endurance.

21. *Intervals between séances.* In exceptionally acute cases the treatments may demand daily, very gentle repetition. As the acuity subsides, the intervals will advantageously be extended to every two or three days, and in chronic cases, every four or five days is the period that will be required.

22. *Immediate results.* When the prostate or vesicles are found to yield to digitization, it is due to extrusion of their contents into the posterior urethra. When there has been no recent coitus or seminal emission, the quantity of these contents may be so large that the merest contact will produce a copious overflow. Even without such an excess, the detrusors may be so active as to violently force the expressed juice through the urethra and out of the meatus. This is more likely to occur when posterior urethritis coexists. In other cases, especially while acute prostatitis or vesiculitis renders the organs tense, no visible juice can be immediately expressed from the adnexa in the first or second séance. This also happens in mild chronic prostatitis or vesiculitis.

In every case it is well to let the patient lie on the table for a few minutes after treatment, for the reason to be mentioned later. Juice will then generally ooze or drip from the meatus, having been retained by reflex spasm of the compressor, evoked by digitization. In some cases no external evidence of success is manifest before the patient's first urination after treatment. The urine, which may have been clear before, will then be turbid and contain coarse flakes, filaments, and shreds, in accord with the condition of the adnexa and the amount of juice expressed therefrom. Some patients never present the contents of the prostate or seminal vesicles except in urine as above conveyed.

23. *Massage on a sound.* When the posterior urethra is not especially sensitive, and when the condition to be overcome causes the prostate to project more into the bladder than into the rectum, it will be well to perform massage, while as large a sound as can comfortably be inserted is held against the lobe that is being treated. Effective as this aid to treatment is, its use cannot be recommended to any except those who have gained considerable experience in genitourinary instrumentation.

24. *Danger of syncope.* Some patients, who have never fainted before, may lose consciousness if allowed to arise from the table immediately after massage or stripping. It is therefore a wise rule not to allow a patient even to raise his head until the pulse has regained its regularity and vigor, and the pupils react promptly to light. No matter how staunchly the patient may assert his perfect well-being, this precaution should always be observed.

25. *Spasm of the compressor.* Whatever be the after-treatment indicated, the patient should empty the urine that has accumulated in the bladder while he has been on the table. In so doing he washes away any of the expressed juice that may remain in the urethra, or may have regurgitated into the bladder. If irrigation or instillation with silver nitrate is to follow the massage, its efficacy would be much reduced if not entirely inhibited by the thick precipitates that will be produced with the residual expressed juice. It must be remembered, however, that in most patients reflex spasm of the compressor has been induced by the digitization. This spasm rarely ceases in less than five minutes after treatment. This condition is productive of considerable unnecessary alarm, especially when a desire to urinate is present. The desire is apt to be very marked in neurasthenics whose kidneys at times excrete an immense amount of urine, especially under the excitement of being treated. When assured, however, that it will be impossible for them to urinate until after the time mentioned, their fears will diminish and upon the expiration of the given time they will void their bladder contents satisfactorily.

26. *After-treatment.* The conditions for which massage or stripping or both are required must govern whether there shall be any treatment at all thereafter, or whether irrigations or instillations with silver nitrate, protargol, or any other of the silver salts, or potassium permanganate shall be employed. The indications for each belong in separate chapters on diseases of the prostate and seminal vesicles and not in a paper like this, devoted exclusively to the technique of massage and stripping.

27. *Over-treatment.* As in all affections of the organs under consideration, much harm can be done by over-treatment. Singularly enough the patients in this regard are most at fault. Past experience having shown them that the general depression, lassitude, etc., that accompanied their condition was promptly relieved by the massage or stripping then required, they are wont to attribute for a more or less extended period after discharge from treatment all the unpleasant manifestations that may be due to business cares, family annoyances, indigestion, constipation, etc., to engorgement of the urethral adnexa. Then they importune their physician for massage or stripping. To these importunities the experienced operator will not yield when no such treatment is needed.

The complete indications and contraindications for massage and stripping, and the collateral medication required therein, are subjects for separate consideration.

No pretense at instructing or imparting anything new to the urological specialist is embraced in this paper, except perhaps to remind him that the office of specialist is largely educational. Progressive general practitioners study the writings of specialists. If the patients of but one of these colleagues derive benefit herefrom, the authors' hopes will be realized.

A NEW METHOD OF IDENTIFICATION SUPERSEDING DACTYLOSCOPY.

By PAUL PRAGER, M.D.,

VIENNA, AUSTRIA.

REGIMENTAL SURGEON OF THE IMPERIAL AND ROYAL ARMY OF AUSTRIA-HUNGARY.

I HAVE made numerous investigations regarding dactyloscopy and its employment for purposes of identification, but it has always appeared to me that it suffers from drawbacks which are due partly to the ready changeability of the epidermis of the fingers and partly to the difficulty encountered and large amount of experience necessary in correctly reading dactylograms.

It is possible for the epidermis of the fingers to be changed in various ways—pathologically because the hands, and especially the fingers, are subject to injuries which, upon healing, leave scar tissue; and artificially because a person whose finger imprints have been taken may readily obliterate the dactyloscopic picture by means of acids or other reagents, thus rendering reidentification impossible.

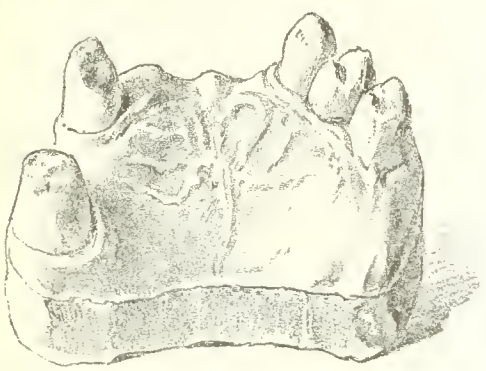

FIG. 1.

It may also happen that a criminal, availing himself of a previous experience with dactyloscopy, in his future operations renders the imprint deceptive by wearing gloves.

In order to evolve a method which might overcome these drawbacks, I have for several years examined the impressions made by human jaws. I have collceted several hundreds of such impressions, principally of the upper jaw; and whenever I make

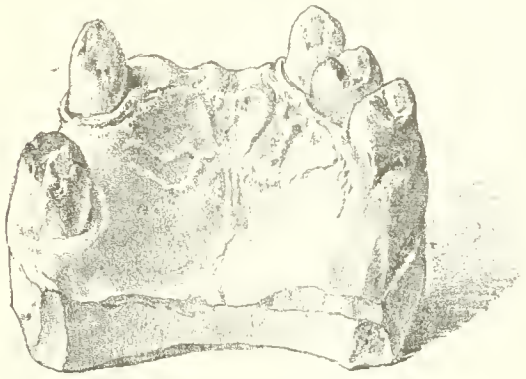

FIG. 2.

comparative examinations of these it becomes more and more evident to me how distinctive and characteristic is the impression made by the upper jaw of each and every individual. Not two impressions among thousands are alike in regard to the number, length, and breadth of the teeth, and the curvature and radius of the maxillary arch. The height, breadth, and depth of the upper jaw present equally many striking and readily recognized differences.

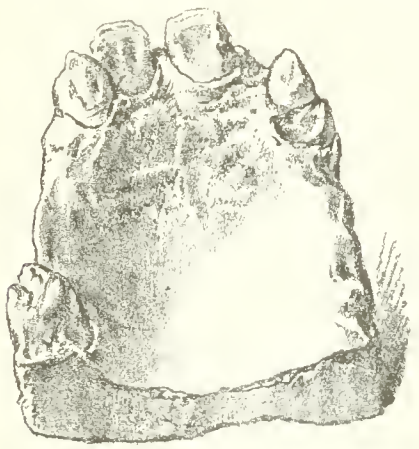

FIG. 3.

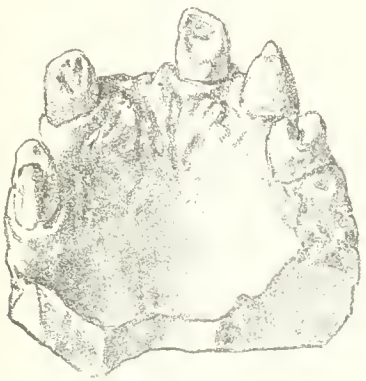

FIG. 4.

To these distinguishing features may be added also the possible gaps in a row of teeth, with their innumerable variations. The formation of the palatine membrane, which shows plainly on each impression, likewise constitutes a feature which is distinctive in each individual, never being alike in any two

cases, and remaining unchanged all through life. The circumstance that each individual jaw impression presents so many characteristics insures that, even though one or more lines may be obliterated or rendered unrecognizable during life, either by the

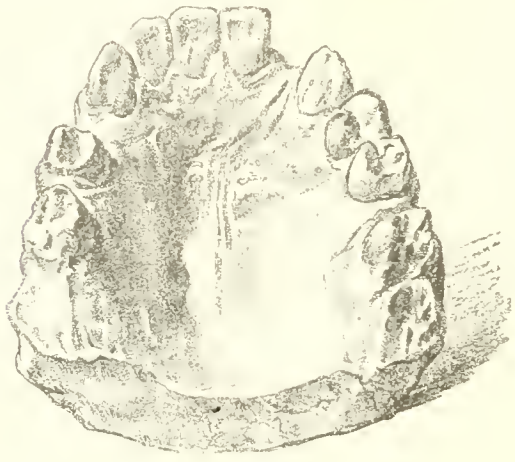

Fig. 5.

action of time or through pathological changes, there will always remain a sufficient number of ineffaceable characteristics to render absolute identification possible.

I have in my possession impressions taken from the jaws of the same persons at intervals of about

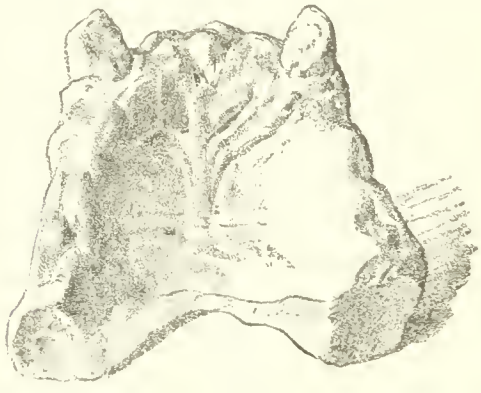

Fig. 6

ten years (see Figs. 1 and 2) and they present absolutely no divergences. The following illustrations show different jaw impressions as they appear at daily observations. What enormous differences in general aspect, form, and size! And this fact I

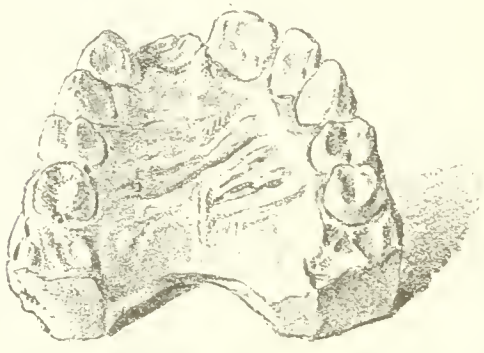

Fig. 7

have demonstrated repeatedly, day in and day out. Never yet have I seen two impressions which were even approximately alike.

To take the impression is a very simple matter. Every physician can attend to it, and every layman can readily learn the manipulation. By taking a plaster cast of such an impression, inscribing it with the necessary data, and keeping it on record, one obtains an incomparable identification mark of a human being.

Fig. 8.

If the system were introduced so that people who follow dangerous callings should put by an impression of the upper jaw, it would undoubtedly be feasible, even in the skeleton, to establish the identity of a person who had met death by drowning, or by falling from a height, or by a mine accident, etc. While I was engaged upon this study I received from a colleague the information that a Paris dentist had succeeded in identifying the corpse of a female patient by means of a jaw impression which he had kept, although her body was almost entirely burned to coal.

DIAGNOSIS AND TREATMENT OF GASTRIC ULCER.*

By WM. A. DICKEY, A.M., M.D.,

TOLEDO, OHIO.

PROFESSOR OF THE PRACTICE OF MEDICINE AND CLINICAL MEDICINE, TOLEDO MEDICAL COLLEGE.

THERE are many inherent difficulties and perplexities to contend with in the treatment of gastric ulcer. They are so numerous, indeed, as often to enshroud the physician in a maze of doubt and uncertainty as to what is the proper course to pursue. The anatomy and physiology of the stomach are of such a character as to make this true. We cannot change the one nor materially modify the other, hence we have no specific for the disease and in the very nature of things cannot have. However, within recent years our knowledge of how to meet these morbid conditions has given us a more comprehensive idea of the best means of placing the stomach in such a condition as to bring about a reparative process. The time is not yet far removed when the physician looked upon the treatment of gastric ulcer as falling wholly within his sphere of action, but in an iconoclastic age like the present, when old ideas are rudely cast aside and new ones put in their places, we must now look at this subject from an entirely different and broader viewpoint. With the rapid advances of modern surgery and the certain conviction that physiological rest is to be obtained as soon as possible, and as far as possible, the clinician must now concede the fact that the surgeon is at times to take his place.

Just when a peptic ulcer should pass from the hands of the one to the other is a matter about which there may be room for an honest difference

*Read at a meeting of the Northern Tri-State Medical Association of Ohio, Indiana, and Michigan, at Elkhart, Indiana, January 8, 1907.

of opinion. When a perforation has occurred, or marked dilatation has taken place as a result of stenosis, or the motility of the stomach is markedly interfered with as the result of adhesions, or possibly, though exceedingly rarely, in certain cases of severe and persistent hemorrhage, then of course there would not be a dissenting voice as to what was the wise thing to do. As physicians, I fear, we are too prone to treat the ulcer too much and the patient too little; that we lose sight of the important fact that an individual who is anemic, whose nutrition is much below par, as a consequence of lack of good and properly cooked food, or of the inordinate consumption of alcoholic beverages, or who lives in damp, illy ventilated quarters, is in poor condition to respond to direct treatment of the ulcer, no matter how canonically done, nor how thoroughly his environments may be changed, for ulcer of the stomach does not differ essentially from ulcer in any other part of the body. These cases should be viewed in the concrete, not in the abstract; should be individualized, not classified, and if this important fact is borne in mind I think the percentage of recoveries of acute gastric ulcer will be materially augmented. It is in the acute form of the disease that the internest must expect to record his greatest success, because when an ulcer has become chronic the muscularis invaded, with edges more or less indurated, medicine, even if supplemented with as near rest as the stomach can be given, will prove of but little avail.

In a series of 493 cases reported by van Leube 74 per cent were cured by medical means, 21 per cent. were improved, 24 per cent. died, and 2 6-10 per cent. were unimproved. Of the 21 per cent. that were reported as improved the results showed that the pain and discomfort returned as soon as they resumed work and their ordinary diet. The question arises, What are we to do with this 26 per cent. of cases? Shall we allow them to drift along in this uncertain and unsatisfactory condition, or shall we turn them over to the surgeon? The Mayos report an operative mortality of about 2 per cent., so that of the 26 per cent. only 2 per cent. will die from the operation, while the remainder will either be entirely cured or so much improved as to make a return to their former pursuits quite probable.

To my mind our duty toward this latter class of cases is a very plain one, and while a mortality rate of 2 per cent., or indeed even more, is a very small one, still with wider experience and more improved technique the knife may yet show a larger percentage of cures than at present. Then, too, the tendency for chronic ulcer to become carcinomatous must not be lost sight of, for the earlier the cure the less liable is this to occur. Unless my memory is treacherous, the Mayos have demonstrated that the starting point of carcinoma is usually an ulcer. Mouillin claims that this is true in probably 90 per cent. of cases. The early diagnosis of ulcus, then, is of the utmost importance, because the more early the diagnosis is made the more certain will be a permanent cure by medical means. This is not always an easy matter, if indeed not at times impossible, because postmortem findings give positive evidence of a healed ulcer that during life gave no indication of its presence. When there is pain on pressure over the stomach, constantly localized, augmented after a full meal, with lumbar pain and vomiting, the vomitus tinged with blood, no matter how little, or melena, hyperacidity with deficient motor function, the diagnosis is easy, but an ulcer may be present and not a single one of these symptoms manifest. There are those of wide clinical experience who claim that hypersecretion in a stomach not containing food is strongly indicative of an ulcer. If to this you add the deficient motility already spoken of, you have almost positive evidence of gastric ulcer, this deficiency being shown by the stomach not being empty seven hours after a heavy meal (Schmidt). Occult hemorrhage, in a meat-free diet, is another valuable aid to diagnosis, but unfortunately it is sometimes not available, unless all the stools are saved and examined during the time the patient is under observation. Again, the ulcus will not bleed continuously and the stools may be examined during intervals of cessation. Occult hemorrhage is much more frequent in carcinoma than in ulcer; except during the early period it is always present in carcinoma, and only in 51.4 per cent. of the ulcers, according to Rutimeyer of Basel. The hemaglobin in ulcer is reduced to about 80 per cent., although it may be much less in those cases in which the nutrition is low, and in whom there is more or less bleeding. Saloman's test, which was originally proposed and primarily used as a diagnosis for carcinoma, may prove to be of inestimable value as an aid in the early recognition, if not the earliest symptom, of gastric ulcer, as it is a strong indicator of a defect in the mucous membrane of the stomach. This test consists of the demonstration of albuminous bodies in the rinsing water after washing out the empty stomach. Gastric ulcer may be mistaken for renal or biliary colic as well as inflammation of the appendix. With the former a careful microscopical examination of the urine for blood, lime crystals, etc., to say nothing of nausea, vomiting, and constipation, will make a diagnosis reasonably sure. With the two latter we have tenderness, disturbances of the stomach, much pain, more or less fever, and usually a history of former attacks. I am in thorough accord with the statement of Hemmeter, made at a recent meeting of the American Medical Association, when he said there was no symptom of gallstone colic that might not be present in gastric ulcer. A diagnosis of ulcus ventricula by the *x*-ray after the deposit of bismuth subnitrate in the ulcer is extremely difficult and would be of little practical value except in the hands of an expert. A differential diagnosis between peptic and duodenal ulcer is not always possible nor indeed necessary, for the treatment of one is essentially the treatment of the other. A positive diagnosis having been made, the best means of treatment at once becomes a subject of grave consideration. The results obtained will depend entirely upon the thoroughness with which the treatment is carried out, and the length of time in which it is persisted in, as well as the subsequent mode of living of the individual. These are all important factors in determining the permanency of the cure. The patient should be put to bed at once and kept there for at least ten days, and much longer in not a few cases. This alone, according to van Leube, will often stop the pain, which in very many cases is such a prominent symptom, and so intense at times as to require morphine subcutaneously to relieve it. Just how rest in bed will stop the pain of gastric ulcer is not easy to explain. Agéron considers that the absence of food pressure on the larger curve of the stomach, and particularly the antrum pyloricum, is one factor and possibly the first one. The recumbent position also does away in a large measure with the pulling and pressing influence of other organs, such as the liver, spleen, and intestines, and possibly the kidneys, as these organs possess in cer-

tain individuals a wonderful degree of motility. But no matter how accomplished, the fact remains that rest in bed has a beneficial influence on ulcer of the stomach, therefore everyone must be put to bed and kept there from ten days to three weeks. If there is a tendency to hemorrhage, as indicated by hematemesis or melena, the patient must not be allowed to assume the upright position, nor, indeed, any position that requires exertion. If there is vomiting, particularly if it is accompanied by particles of food, the stomach should be washed out by means of a tube with a weak alkaline solution, until the water comes away perfectly clear. No food should be allowed for five days, except in rare instances. Thirst may be allayed by rinsing out the mouth with cold water or pellets of ice may be held in the mouth. The hyperchlorhydria, which is such a well-nigh constant accompaniment of ulcus ventriculi, and which not only prevents its healing, but possibly causes an extension of the ulcer, should be arrested by the administration of such alkalies as sodium bicarbonate and subnitrate of bismuth. Kussmaul recommends that the bismuth be given at first daily and then every other day in doses of ten to twenty grains in 200 c.c. of water through a stomach tube. The stomach is first washed out, and then the patient is placed on the side in which the ulcer is suspected in order that the bismuth may settle in the bottom of the ulcer, and the tube is closed by a clamp. When sufficient time has elapsed for the bismuth to settle, the water is allowed to run out, and the tube is removed. This method has a serious drawback in the constant retching to which the patient will be subjected by the presence of the tube, particularly in those in which there is a tendency to hemorrhage. Half-teaspoonful doses of subnitrate of bismuth suspended in water may be given daily, or twice daily with practically, I think, as good results. The bismuth settles in the ulcer and thus protects it from the irritating influence of the gastric juice and any food that may be administered, and is also an antacid and antiseptic. Nitrate of silver is another remedy of much potency according to the statement of clinicians of wide experience, and yet it is difficult to say just how it acts, because only a small amount of the salt can be used. It is most efficacious in those cases in which pain is a prominent symptom. It probably acts either as an antacid or as an antiseptic or both. It may be given in tablespoonful doses of a 1-10 of 1 per cent. solution. It is particularly valuable during the period of convalescence, or in the mild or ambulatory forms. Schmidt and van Leube lay much stress upon the administration of Carlsbad salt in the morning on an empty stomach. Composed as it is largely of alkalies, it probably acts as an antacid as well as a cathartic. Other remedies of greater or less potency are used, but time will not permit me to discuss them in this paper. The best method of treating the hemorrhage of gastric ulcer is sometimes difficult to decide. Local application of ice to the epigastrium in the form of an ice bag or Leiter's coil is often beneficial and is to be used, and pellets of ice may be swallowed if they do not cause vomiting when melted. Just how local applications, either cold or hot, to the epigastrium can influence the blood supply to an internal organ with which the blood-vessels of the skin have no direct connection is difficult to understand. Indeed, I have always been skeptical as to their influencing it at all, and yet such men as Schmidt and van Leube not only use them, but speak well of their results; van Leube alternates them without intermission, while Schmidt so far modifies this process as to make hourly intermissions. The Priessnitz alone are used at night. Schmidt maintains that the physiological action of the blood-vessels is better preserved by hourly intervals. In those cases in which the patient is weak and anemic, and strenuous objections are raised to the use of cold, equal parts of water and alcohol may be used instead. This line of treatment is available not only for the bleeding but in those cases also which give evidences of the presence of some inflammatory condition. The use of such drugs as opium, acetate of lead, ergot, and adrenalin in the treatment of gastric hemorrhage is of questionable utility. What influence they can have on the severed end of a blood-vessel is not clear to my mind, nor can I see how they can in any way hasten clot formation. Too much reliance then must not be placed on these remedies in the treatment of the severe forms of bleeding. It is in this class of cases that the services of a surgeon may be demanded, and yet I have seen the most alarming hemorrhages cease without operation and the patient finally recover. As I have said elsewhere, the one great object to be attained in the treatment of all forms of ulcus ventriculi is rest. Theoretically, the only way to accomplish this is to put nothing into the stomach. Cases will arise, however, from time to time, in which the nutrition of the individual will be at such low ebb that the rectal feeding will not be sufficient. Say what we will, and theorize as much as we like, the patient must receive a requisite number of calories each day to maintain a fair degree of nutrition, or we cannot hope for good results, if indeed the patient does not reach the danger point. In cases of this kind it will be well to risk a small amount of food by the stomach after the original five days' fasting. Years ago Da Costa recommended, if my memory is not at fault, a tentative amount of icecream, which if no bad results follow may be supplemented by other food. However, our principal reliance must be on rectal feeding. I hardly need more than mention the fact, that before giving the nutrient clysma the bowel should be well washed out with warm soap suds, so that the material injected may be the better absorbed. Just what shall be used as a nutrient enema will depend largely upon the teaching or peculiar belief of the physician. I doubt, however, if any will be found more efficacious than milk and eggs, and occasionally meat powder, and if a stimulant is wanted, wine or brandy, to all of which should be added a pinch of salt. Nor is it absolutely necessary to predigest the clyster, as it is not proven that the predigested albumins are more readily absorbed than the native. If there is a tendency for the bowel to expel the enema, which there often is after the method has been used for a time, fifteen or twenty drops of tincture of opium may be added. The temperature of the clysma should not be less than that of the body. It should be given through a tube inserted as far up the colon as possible. The patient should not be disturbed during the night, hence the last clysma should be given not later than eight or nine o'clock. Each morning the bowel should be washed out with a liter of warm salt solution that any remnants of the previous day's feeding may be removed, thus securing better absorption and preventing bowel distention as a result of decomposition. The intense thirst that is sometimes, indeed usually, met with in these cases may be allayed by injecting into the rectum one-half liter of physiological salt solution. Rectal injections should not be given more than three times a day,

at equal intervals, because if they are too often repeated the bowel becomes irritable and expels its contents. Moreover, the constant irritation of the intestine causes stomach secretion, the very thing we are anxious to avoid. On return to stomach feeding, much care will be necessary for a time, that this organ be not distended and that the food taken is properly digested. Small quantities of ice-cold milk, a tablespoonful of milk and lime water (three parts milk and one part lime water) may be given at two-hour intervals. The addition of the lime water will often prevent vomiting that might otherwise occur, and at the same time prevent the formation of curds. At this early period, enough milk cannot be given by the mouth to maintain nutrition, without disturbing and overtaxing the stomach. Hence, the addition of something bland becomes necessary. Meat jelly as recommended by van Leube and Fleiner may be added. This is made by boiling beef with calf's foot until it is thoroughly done, when a gelatinous mass is formed. While cooking, an egg is added, stirring the whole meanwhile, and the mixture strained. Salt is added to suit the taste and the food is given cold. Of this a teaspoonful may be administered at three-hour intervals. As time goes by, other easily digested and nonirritating foods may be added. The more food that is given by the stomach, the less will be necessary by the rectum. As one of the objects to be attained during the early feeding is to diminish as far as possible hyperacidity, care must be taken in the adminstration of the albumins. It may be necessary to administer some carbohydrates. Senator gives gluten, fat, and sugar with small quantities of albuminoids and decoction of gelatin. For the fats he uses, in addition to cream, small bits of frozen butter. His theory is that gelatin prevents hemorrhage and at the same time replaces in a degree the albumin. It would be impossible in the time allotted to this paper to give in detail the various articles of diet that may be used. Suffice it to say that the return to a mixed diet must be slow and gradual, reserving the meats for the last; and yet so good authority as Lenhartz allows a more liberal diet of the albuminoids such as milk, eggs, rice, scraped raw beef, ham, butter, zwiebach, and the like, claiming that they combine with the acids of the stomach, and thus hasten cure better than the somewhat strict diet of van Leube. And yet a glance at the diet list of van Leube shows it to be sufficiently protean in character. He divides the feeding into four periods or sections which I believe he strictly adheres to. The first section comprises a period of ten days, the second seven days, third six, fourth seven. *First period*, boiled milk; meat solution; beef tea, two zwiebach soaked, four cakes. *Second period*, in addition to number one, slimy soups, rice and sago in milk cooked soft with the whites of four eggs; raw and soft-boiled eggs, cooked calf's brain or sweetbread, boiled chicken and pigeon (without skin or fat). *Third period*, in addition to number two, boiled calf's feet, scraped raw ham, scraped beefsteak (half done), mashed potatoes, boiled rice in bouillon, a little coffee and tea. *Fourth period*, added to number three, tender roast beef (half done), roasted chicken or pigeon (without gravy), venison or partridge which has been killed some time, macaroni, noodles (sieved through), and a little white bread. From the fifth week on, slow return to solid and heavier food. He advises that the patient take his daily food in five meals, thus not getting too much at a time. During the rest in bed period the patient must have daily sponge baths and muscular massage, avoiding of course the abdomen.

On getting out of the bed, the individual is to be instructed as to his daily mode of living and particularly his eating and drinking. He should eat slowly, masticate his food thoroughly, and avoid completely all articles of diet that will in any way bruise or lacerate the stomach mucosa. He must also avoid all forms of alcoholic beverages. If there should be relapses, which there sometimes will be, or if the patient goes from bad to worse and complications arise, the services of a surgeon must be invoked. We can, in these latter days, survey this entire field with a calmer and more unbiased judgment and readily concede the fact that the treatment of ulcus ventriculi has a surgical as well as a medical side. A discussion of the former I leave to those who do that work, realizing that it is both interesting and instructive to the purely medical man.

ASTHMA: OBSERVATIONS ON 300 CASES.

By EMMET L. SMITH, M.D.,
CHICAGO, ILL.

Asthma is a spasmodic affection of the involuntary muscular fibers of the small bronchial tubes, caused by a reflex irritation of the pneumogastric nerve which contracts these muscular fibers and gives rise to dyspnea of a paroxysmal character. This definition will harmonize the different theories on this subject, explain the action of various remedies and conditions, and prove out in the clinical test and in the permanent cure of this disease.

By the contraction of the bronchial muscles it is not intended to mean that part called the extrapulmonary bronchi, but the intrapulmonary bronchi or bronchioles, of which the physiologists estimate there are seven hundred and fifty millions in the lungs. In the extrapulmonary bronchi the cartilage and glands exist, but in the small bronchi and bronchioles, the involuntary circular muscles are well developed, and are controlled by the pneumogastric nerve. Of this nerve Ranney wrote: "Owing to the numerous connections of the pneumogastric with other nerves, its varied and extensive distribution, and the important character of its functions, this may properly be regarded as one of the most remarkable nerves of the whole body. It has been often known by the name of the 'par vagum,' from the wandering course of its fibers, which are distributed to five different vital organs, *viz.*, the heart, lungs, stomach, liver, and intestines, as well as to many other parts of secondary importance."

Cases of asthma have vasomotor disturbances, but to claim that true asthma is due to a vascular distention in the bronchial mucosa does not appear to harmonize with the classical physiological experiments or to prove out in the clinical tests. Spasms of the blood-vessels or even a turgescence of the mucosa of the bronchial tubes could not produce the phenomena of true asthma. Again, if turgescence of the bronchial mucosa was the cause of the asthma, then the use of atropine would be noneffective.

Acute bronchitis, fibrinous bronchitis, or angioneurotic edema of the bronchial mucosa may obstruct the bronchial tubes, but in these cases the râles indicate the obstruction is in a fixed locality, while in true asthma the obstruction is rapidly changing its location.

While it is evident that even in true asthma there is vasomotor disturbances, it is not the vasomotor

distention in the bronchial mucosa, but the asthma is due to the pressure on the asthmatogenous points (Brugelmann) in the nasal fossæ. This acts on the pneumogastric nerve and explains the various phenomena of true asthma. This pressure irritation may be on the nasal septum or rarely there may be no occlusion of the nares, and it may be due to a closed empyema of the ethmoid cells or sinusitis. This is the pathology of true asthma and it is confirmed by physiological experiments. It also can be confirmed in every case of true asthma by relieving the pressure on these areas, which gives almost instant relief to the spasm. The relief is made permanent by such treatment as will prevent such pressure.

Among the exciting causes given are inhalation of dust, certain powdered drugs, flowers, hay, and emanations from feather beds or pillows, horses, cats, and parrots. These, as well as others of similar character, cause or aggravate asthma by irritation, congestion, and pressure on the asthmatogenic areas in the nasal cavities. By wearing plugs of cotton in the anterior part of the nostrils or mechanical air filters, these exciting causes are noneffective. However, if these asthmatogenic areas are treated so that pressure cannot take place, then these exciting causes cannot cause asthma.

The following observations are common to asthmatic patients and are easily explained on this theory. If a person is chilled, or has cold, wet feet, or if the air is cold, or cold water is applied to the entire bodily surface, the result is vasoconstriction of the skin, and as the blood leaves the skin it causes internal congestion and increases the nasal pressure, which aggravates the asthma. However, if the skin circulation is normal, the effect of inhaling cold, dry air is to contract the nasal mucous membrane and to relieve the dyspnea in proportion as the nasal engorgement is relieved. Moist heat to the skin surface produces vasodilatation and as the skin reddens the nasal engorgement is relieved.

Cold, damp days aggravate most asthmatic conditions, and, conversely, dry weather, or the dry climate of Arizona, gives temporary relief in some cases. This is because the nasal membranes swell in damp weather—a condition which is observed not only in asthmatics, but in the great majority of people. Localities having dry air reduce the nasal swelling and give relief in proportion as the swelling (or pressure) is relieved. Not all persons get relief by change of climate, but upon examination of such as do not it will be found that there is a local reason.

The inhalation of chloroform for asthma may act (1) by local anesthesia on nasal turgescence, (2) by lowering arterial pressure (English Chloroform Commission), or (3) by the inhibition of the heart (Wood).

The action of iodine in asthma, when favorable, I believe is due to its well known action in reducing glandular (bronchial) swelling and pressure, and to its specific action on the nasal tissues. In cases of arteriosclerosis there are attacks of dyspnea simulating asthma, and the action of iodine in these cases has often been credited as helping asthma. According to M. Huchard "iodine medication is indicated when there is confirmed sclerosis, in which case the resolvent action of iodine on the sclerosed tissues may be obtained by phagocytosis." He also states that "in the period preceding sclerosis iodine medication for high arterial tension is useless, and it is better to have recourse to essential vasodilators (nitrites)."

The nitrites are general vasodilators, and amyl nitrite nitroglycerin, sodium nitrite, and erythrol tetranitrate act as such for from one minue to six hours. Any relief from the use of these in true asthma comes from their action in equalizing the entire vascular system and relieving the pressure on the asthmatogenic areas.

The use of adrenalin in asthma acts only as a local vasoconstrictor, and gives temporary relief in proportion as the turgescence in the nose is relieved. The internal or hypodermic use of adrenalin in asthma has been entirely unsatisfactory in my observation. Sprays or nebulized solutions in the nasal cavities act by relieving the pressure on the asthmatogenous areas.

Atropine in maximum doses, as advocated by von Noorden, Riegel, Campanella, and Rossbach, diminish the reflex excitability of the pneumogastric nerve. This not only gives temporary relief in asthma, but is useful in other conditions controlled by the pneumogastric nerve. During the paroxysm as much as one-eighth of a grain is given in twenty-four hours. The study of the solonaceous alkaloids is very interesting, but the trouble is that the chemists are unable to label these different alkaloids properly, as they generally all revert to atropine. I have used over 100 grains of the different German solonaceous alkaloids in the treatment of asthma. Daturine and hyoscyamine acted best, but their action was not uniform. Thus some observers may get better results than others, if their atropine should contain some daturine or hyoscyamine.

Berkart in his book on "Bronchial Asthma" says: "The fumes of burning nitre paper and smoke of cigarettes or powder, of which strammonium and nitre are the chief ingredients, act merely by the forcible cough which they excite when inhaled.' Then again, according to a recent paper by Francis Hare, these inhalations act by producing bronchial vasoconstriction. I have observed acute attacks in which the nasal cavities had been so completely stopped up with the accompanying acute rhinitis that the usual inhaling of smoke was without benefit. I have also plugged up the anterior part of the nasal cavities so that no smoke could be inhaled through the nose and the result was the same. I believe the temporary relief obtained by the use of these inhalations is due to the local vasoconstriction on the asthmatogenic areas. This explains why in some cases the use of the inhalations "wear out"—that is, that after a time they do not constrict, and consequently do not give the relief they did at first. Berkart says of these inhalations that they irritate the mucous membranes of the nose, pharynx, and bronchi, prolong the disease indefinitely, and paralyze the action of the heart.

If when asthma is treated as an uric acid condition there are favorable results, I believe the same are due to the giving up of sweets and other articles upon the antiuric acid diet list, as these have the tendency as well to engorge the nasal tissues and aggravate the asthma. In the so-called peptic asthma the stomach disturbance is a secondary cause. These peptic cases do not act directly through the pneumogastric nerve, but by engorging the nasal areas. These peptic cases and uric acid conditions aggravate asthma in proportion to the nasal engorgement they produce. The uric acid condition in the one and the disturbance of the stomach in the other may be the starting point, but neither is the real cause. The real cause is in the nasal fossæ, and this can be easily proven; and it can also be proven that the uric acid condition and

the stomach disturbance may be allowed to exist and yet there will be no asthma, if the nasal pressure is relieved. In any case of true asthma, where the nasal treatment has been to relieve all pressure on the asthmatogenic areas, I have found that articles of diet may be taken with no bad effect which formerly were certain to cause asthma. This I have proven time and again, and in cases where this treatment has been carried out I have even advised that the patients take such articles as had formerly caused their asthma, in order that they might test the result of treatment. In the treatment of these asthma cases I formerly used a special diet list, but now I give no dietary directions, and after the treatment has been started and the case is getting along satisfactorily I recommend the eating of different articles of food and the doing of those things that formerly brought on an attack. Patients are even advised to take a cold in the head, which is the crucial test for any line of treatment.

MENTAL SYMPTOMS IN NASAL AFFECTIONS.

By PERCY FRIDENBERG, M.D.,

NEW YORK.

ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY, ETC.

"The exhilaration which comes from pure and refreshing air has a marked influence on our appreciations. To it is largely due the beauty of the morning, and the entirely different charm it has from the evening. It would be curious and probably surprising to discover how much the pleasure of breathing has to do with our highest and most transcendental ideas. It is not merely a metaphor that makes us couple airiness with exquisiteness, and breathlessness with awe; it is the actual recurrence of a sensation in the throat and lungs that gives those impressions an immediate power, prior to all reflection upon their significance. It is, therefore, to this vital sensation of deep or of arrested breathing that the impressiveness of those objects is immediately due."

In his charming essay on "The Sense of Beauty," from which the preceding paragraph is quoted, Santayana has touched on the physiological aspect of an interesting theme. The converse, it seems to me, offers phenomena of at least as great practical importance, and has been studied but little. The effect on mental processes and attitude, of deficient breathing or of vitiated air, offers a wide field for observation, and one from which it may be possible to glean some points in the treatment and prophylaxis of neuroses on the one hand and of nasal disease, on the other.

Nervous disturbances and psychical symptoms may have a two-fold bearing on nasal disease, according as they are in the nature of cause or of effect. The former are of subordinate importance from the practical side, although clinically at least as interesting. It is sometimes difficult to decide whether a patient is neurasthenic or hypochondriacal on account of old nasal trouble, or whether his vitiated nervous system has lowered resistance and increased irritability, so that there is morbid reaction to slight discomfort stimuli originating in the nose. However it may be, many rhinopathics, to coin a term, are also neurotic. Even the cocaine habit, which not infrequently becomes established in the effort to relieve nasal obstruction, may be considered as an indirect result of nasal disease or as a symptoms of a neurosis underlying both manifestations. In actual insanity the hallucinations of smell are much less frequent than those of sight and hearing, as might be expected from the comparative unimportance of the former function in soul life and cerebration. The relations of the sexual sense to that of smell have been studied by a number of scientists, and sexual osphresiology offers many interesting phenomena. In the lower animals the sense of smell is of great importance, not only in this connection, but in relation to perception of objects in the external world, self-protection, taste, nutrition, and other functions, and is, as we know, much more highly developed than in man. It would be as interesting as it is probably difficult to determine the influence of mental disturbances in these animals on the sense of smell and on the functions dominated by it.

Local symptoms are the most common manifestation of nervous disturbances in nasal disease. Neuralgic pain and headache are frequent accompaniments of obstructive forms, and more particularly of accessory sinus involvement. Face ache of a pronounced type, radiating to the teeth, ears, and brow, is common in acute antral suppuration, and even in serous effusion with increased tension. Retention of secretion and chronic hypertrophic inflammation with the production of granulations and polypoid growths, particularly those of the frontal sinus, may produce a dull, intermittent frontal or supraorbital ache which simulates malarial hemicrania closely, particularly as it is temporarily relieved by quinine. A diagnosis, *ex juvantibus*, is ambiguous here, as quinine has a marked effect in constricting blood-vessels, lessening secretion from mucous membranes and thus promoting drainage and reducing tumefaction. Many coal tar products, notably antipyrine, have a similar action.

In the field of motor disturbances, the most varied symptoms may be presented. Usually they are slight. Muscular unrest and slight twitching of individual facial muscles, either as an involuntary reflex, or as the expression of an habitual motion, is found in various forms of nasal disease, and produces an almost pathognomonic facies in many cases of adenoid hypertrophy with middle ear involvement. Pronounced facial tic and epileptiform seizures have been observed in cases of pendulous uvula embarrassing respiration, in foreign bodies of the nose or rhinoliths. The most marked mental complication is that observed in young mouth-breathers afflicted with adenoids, and known as aprosexia. The children are inattentive, listless, dull, do not seem to hear well if spoken to, or, if they give heed for a moment, soon relapse into a sort of day-dream.

The children fall behind their classes, and do not seem to be able to concentrate their minds on school work. Although this symptom complex may be partially explained by the diminution of hearing consequent on secondary involvement of the Eustachian tube and middle ear, it is a noteworthy fact that deafness alone does not produce intellectual torpor, nor seriously affect the ability to study or to concentrate attention. It has been said that these children use up all their nerve force, mental energy, and volition in getting air, leaving no reserve for cerebration. I have elsewhere* called attention to the fact that in mouth breathing less effort is actually required to fill the lungs than with nasal respiration. On the contrary it is just the ease of breathing which encourages superficial, lazy breathing which soon be-

*Nasal Obstruction as a Cause of Disorders of Nutrition, *New York Medical Journal*, April 22, 1905.

comes habitual, and later insufficient. When these children are bent over their books the motion of the thorax becomes still more inadequate, and a decided non-aeration is the result. Autointoxication may have something to do with the mental hebetude observed in these cases. That habitual superficial respiration is at fault is shown quite clearly by the after history, when the adenoids have been removed by operation. In many cases, after complete removal of the hypertrophies, mental hebetude, subnormal vitality, and susceptibility to colds and infection have persisted, until the habit of mouth breathing was broken up by exercise.

Stucky claims that acute or chronic disease of the nasal accessory sinuses frequently gives rise to serious forms of mental disturbance, as shown by the numerous cases of melancholia and suicide attributed to grippe. W. Sohier Bryant says that we have not yet determined whether these symptoms and conditions are due to intracranial pressure, direct or indirect meningeal irritation, reflex nervous conditions, disturbed cerebral circulation, or toxemia. The fact remains that in these cases ventilation of the occluded sinuses or cure of the purulent process often cures the psychosis. On the other hand, retention of secretion aggravated the mental defect, or return of the purulent infection in the sinus was accompanied by a return or aggravation of the psychosis.

THE EXPERIMENTAL EFFECTS OF TOBACCO UPON THE NERVOUS SYSTEM.*

By L. PIERCE CLARK, M.D.,

NEW YORK.

VISITING NEUROLOGIST TO THE RANDALL'S ISLAND HOSPITALS AND SCHOOLS; CONSULTING NEUROLOGIST AT THE MANHATTAN STATE HOSPITAL, N. Y.; CONSULTING NEUROLOGIST AT THE CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.; ASSISTANT NEUROLOGIST AT THE VANDERBILT CLINIC (COLUMBIA UNIVERSITY), NEW YORK.

There is great need of careful and exhaustive study of the effects of tobacco upon the nervous system. The general prevalence of the habit, especially in the young, shows that we should have a full and sane knowledge of the effects of tobacco on the nervous system. Observations upon the subject in future should try to parallel the taking of tobacco as in common practice. Much data of older experiments has been found of little use because this fact has not been kept in mind. We hope some modern research laboratory may correct this defect at an early date.

A variety of substances have been found in tobacco aside from nicotine. Some of these are pyridin, picolin, tulidin, parvolin, collodin, rubidin, varidin; also carbolic acid and marsh gas. Krouse states that cyanogen is also present in considerable quantity. None of the above, aside from nicotine and pyridin, have been thoroughly studied. No little of the differences of opinion which observers have held regarding the action of nicotine may be due to the lack of exclusion of the other products in crude tobacco. This statement is particularly pertinent in studying the effects of tobacco on the nervous system. Tobacco only registers a permanent and definite impression in nervous structures when it is used for months or years. Tobacco deprived of nicotine may be made to produce contraction of the pupil, dyspnea, general convulsions, and death in animals. The neural action of pyridin is that of a respiratory paralysant and spinal cord depressor.

Inasmuch as it is fairly well proven that tobacco is a cardiovascular poison, many attempts to make tobacco substitutes have been undertaken, but it may be said that none has been successful. Not a few efforts of late years have been directed toward making a tobacco, nicotine-poor. One of the latest and most interesting experiments is that of the Austrian government, which, it will be remembered, has a monopoly of the tobacco trade. It has manufactured tobacco brands which are made almost entirely free from nicotine, but they did not meet with satisfaction, as the flavor suffered a marked loss; besides, the sedative effects were not obtained as formerly from the consumption of crude tobacco. Nevertheless, the government holds patents for reducing the nicotine and pyridin of tobacco at least fifty per cent. by means of a lime or potash treatment. A still better method has, however, been employed during the past year. It consists in heating ready-made cigars and cigarettes to a temperature of 200° C.; thus twenty to fifty per cent. of the nicotine is driven off at a single treatment. Physiological studies have already proven that this nicotine-poor tobacco is very much less harmful on the nervous and vascular systems. The latter experiments are the more interesting as it has been heretofore held that the intense action of smoking tobacco on the nervous system is due to the presence of the bases of the pyridin series, and not to alkaloid nicotine itself. However, it is not yet proven that all the essential alkaloidal series of tobacco do not suffer loss in this caloric or chemic treatment.

The experimental effects of tobacco on the nervous system may be divided into acute and chronic. It acts both on the peripheral organs and nerve centers. In its action on the cardiovascular apparatus its maximum effects are registered on the aorta and coronary arteries, producing, when taken in habitual excess, arterial sclerosis of these parts.* It induces also a peculiar form of cirrhosis of the liver, which does not immediately concern the main purpose of this paper. Nearly all the experimental work done on tobacco has been done by the use of graduated doses of nicotine.

The alkaloids of tobacco are chiefly absorbed by the mucous membranes, although it may be taken

*Read before the joint meeting of the New York and Philadelphia Neurological Society, March 16, 1907.

*Drs. Adler and Hensel have recently reported some pioneer work (*Jour. Med. Research*, September, 1906) on the ability of nicotine to induce atheroma of the aorta. They appear to have been unaware of the work done in this field by Anstio (Italian) about a year earlier. These American authors seem only to have been aware of some negative results obtained by Josne in this field (*Arch. gen. de Med.*, 1904, November 1). The authors used ⅓ c.cm. of a ½ per cent. of nicotine in water, which was injected daily into the ear vein of the rabbit. Ten minutes after each injection each animal had a violent and typical convulsion, lasting several minutes. But after such convulsion the animal behaved normally until following day, when injection was repeated. There developed neither cumulative action nor tolerance. Some animals received a hundred consecutive injections without any change whatever in the typical effects as detailed above.

The chief aim of the article is to show that by such intravenous injection rabbits, after a very variable interval, may develop lesions of the aorta. These greatly resemble those caused by adrenalin and digitalen. The first lesions appear as calcareous areas, which differ greatly as to size, shape, etc.

With progressive injections the areas continue to spread to the thoracic and abdominal aortas, and even to the iliacs. Naturally these areas tend to become the seat of aneurysms. The nicotine lesions are primarily necrotic in character. While closely resembling the lesions of human arteriosclerosis, there are many differences.

us by the skin. Animals have been killed by the latter method of administration.

The acute effects from toxic doses of nicotine administration are fairly well known to all; they embrace horrible nausea, vomiting, giddiness, intense malaise, with weakness, followed, if the dose has been sufficient, by burning pains in the stomach, purging, free urination, extreme giddiness passing into delirium, a rapid running and finally imperceptible pulse, cramps in the limbs, absolute loss of strength, a cold, clammy skin, and finally complete collapse and death. In the lower animals, especially in the frog—aside from the symptoms just enumerated, which have been encountered in man—violent convulsions of spinal origin are superadded, followed after a time by spinal paresis.

Tobacco is a powerful depressant to the motor or efferent nerves, acting primarily upon their peripheral filaments. The afferent or sensory nerves are much less affected, but are probably also depressed. The sympathetic ganglia are first stimulated and then depressed by nicotine. To these actions are probably due the increase of saliva and other secretions caused by small doses, and the lessened gland activity produced by large doses. The acuter effect of nicotine upon the nervous mechanism of the heart and circulation is very pronounced. While the initial rise in blood pressure is certainly due in part to direct stimulation of the heart muscle and a stimulating contraction of the peripheral vessels, the heart ganglia receive the greater part of the excitation. As is well known, the contrary holds good for alcohol. It is further probable that the final paralysis of the heart in nicotine poisoning is due to a double depressing influence upon the heart and arterial walls.

The acute toxic effects of tobacco upon the pupil induce a myosis, probably paralyzing the peripheral ends of the sympathetic; and it almost certainly stimulates the oculomotor nerve.

It first excites, then paralyzes the respiratory center. Prag states that retardation is universal in the animal kingdom, while among mammals acceleration is found. Traube teaches that the lungs always give out before the heart in acute nicotine poisoning; this he ascribes to paralysis of the respiratory center. Rosenthal has induced inspiratory cramp and death by sufficient doses of nicotine. However, no little difference of opinion exists among experimentors as to whether the final paralysis of the nervous mechanism of respiration is central or peripheral. Probably both are right. According to Mittenberg's experiments upon dogs, nicotine acts in accordance with the dose, either as a pure excitant to the respiration or as a first excitant and then paralysant, or as a primary paralysant. Excitation of the center in general means accelerated respiration, and paralysis means retardation of respiration, with long expiratory pauses. Death occurs through primary arrest of respiration.

In feeding the animals either crude tobacco mixed with food or the alkaloid nicotine, tolerance is easily and early established, requiring but two or three days. The animals lose neither flesh nor appetite. Adler fed four cigars daily to a female rabbit for six months; everything proceeded as in health; the rabbit became pregnant, giving birth to seven young, which she nursed successfully.

Cats are the most susceptible to nicotine of all mammalia. Birds are also easily affected. One drop of nicotine given to a pigeon will cause collapse, tetanic convulsions, and death in a minute. A sort of tobacco chorea has been induced in some horses. However, the toxic coefficient or the amount necessary to produce death has never been definitely determined.

In chronic poisoning there is more or less gastroenteritis of a hemorrhagic character. Ecchymosis occurs in the pleura and peritoneum. Hyperemia of the lungs, brain, and cord is found. There is a lowering of the hemoglobin content of the blood, which has been reported as low as forty per cent.; there is also a diminution of red corpuscles. Coarse lesions have been found in the brain and spinal cord. Walicka claims to have seen peripheral neuritis in animals which on autopsy showed the same changes in the peripheral nerves as that noted for the optic nerve in tobacco amblyopia. In Australia the horses which eat a variety of tobacco known as *Nicotiana anavcolens* develop severe chronic ocular disturbances analogous to tobacco amblyopia in man, and in extreme cases, at autopsy, the optic nerve is found degenerated. Virginia deer eat this tobacco plant without harm. Possibly they grow immune. Horses are more affected than cattle and sheep, to which latter class deer belong. Vas has shown that in the rabbit there are well defined abnormalities in the chromatin distribution and swelling of the cell body in the ganglion cells of the spinal cord. This change was uniformly found in all the spinal and large sympathetic ganglia. Parsons and Pandi claim to have seen degeneration of nerve fibers similar to that noted by Walicka.

In the experimental induction of nicotine poisoning in rabbits Papow and Modeston have frequently seen distinct pathological alterations in the retina of rabbits. Curiously enough no systematic study of the ocular lesions of tobacco poisoning has ever been undertaken. It is an interesting fact that tobacco abstinence in animals, previously made tolerant of toxic doses, is attended by symptoms analogous to those seen in man. The animals are extremely restless, irritable, insomnic, apprehensive, and subject to violent fits of anger.

A study of Kobert's work leads one back to our original view that the subject of tobacco poisoning on the nervous system, especially in its chronic (although also in acute) phases, is fraught with contradictions. An attempt to schematize the subject matter has been foiled by the facts. Why should one pharmacological authority class nicotine with muscatine, another with conine, and a third with pilocarpine? This alone teaches us the status of the action of tobacco. At the same time these incompatibilities give an independent observer some certain light and a chance to find facts suited to his individual views— a study in pragmatic philosophy.

From the animal experiments upon tobacco poisoning the following conclusions may be drawn:

1. It is fairly proven that tobacco is primarily a cardiovascular poison.

2. Its acute toxic effects on the neuromuscular apparatus are, first, as an excitant and mild convulsant; second, motor nerve depressant, and finally a paralysant of the central and peripheral nerves of the heart and lungs.

3. Its chronic toxic effect on the nervous system (as yet so inaccurately studied) is to induce toxic congestion of the brain, spinal cord, and peripheral nerves; inducing finally in the latter, a mild type of degenerative neuritis.

4. The toxic coefficient, even in animals, under strict test, is so very variable as to vitiate much of the attempt to derive any definite conclusions of its effects on the nervous system in man.

DIET IN PULMONARY TUBERCULOSIS.

By HERBERT C. CLAPP, M.D.,
BOSTON.
VISITING PHYSICIAN TO THE MASSACHUSETTS STATE SANATORIUM FOR INCIPIENT CONSUMPTIVES, AT RUTLAND, MASS.

Diet is an extremely important factor in the treatment of tuberculosis. Nothing is so discouraging to the physician as a persistently rebellious stomach or bowels, and nothing so decidedly interferes with the recovery of the patient. Thanks, however, to the modern fresh air treatment, which stimulates the appetite and digestion, these difficulties are as nothing to what they were formerly. Nevertheless, it often requires much tact, patience, and good generalship to make a patient eat properly.

The big difference between the new system of feeding and the old is in the amount of food to be taken. Now we resolutely insist that the patient who is under weight shall eat large quantities of food up to the limit of his digestive powers; and if fresh air and rest do not enable him to assimilate of this enough to gain steadily up to his normal point or a little above, we must invoke special medicinal aid. Overfeeding, as it is often called, is so important that some in their eagerness to succeed overdo the matter, and from their results seem to aim to produce fat folks instead of well folks. While the gaining of flesh is generally an indication of an improvement in lung condition, it is not necessarily so, as some hopeless cases may become quite fat for awhile; and even when the lungs are getting into good condition, if the stuffing process is carried to the extreme, we may be confronted by the dangers (as in overfeeding well people) of inducing dyspepsia, gastric dilatation, lithemia, or the uric acid condition with its pseudorheumatism, intestinal putrefaction, etc., with gout, gravel, hepatic congestion, arterial and kidney degeneration, diabetes, obesity, etc. Besides, the carrying around of an excessive amount of fat brings too great a strain on the already weakened heart. These dangers, however, although real and occasionally met with, less often confront us than that of insufficient nourishment. The great problem generally is to make people eat *enough*. Appetite is no guide. It is almost invariably found that a consumptive can digest far more food than his appetite demands, and it is the physician's duty to show him how he can do this. Some patients think they cannot take milk, others that they cannot digest eggs, others meat, etc. In a few rare cases this may be so, but with the vast majority it can be done in one way or another, if the right methods are employed. If a patient can eat at a table where others are eating heartily, he will generally do better than if he eats alone. If on the day in each week when he is weighed he shows an increase, this will encourage him anew. The palatability of food is important in gaining weight, as is also the attractiveness of its serving. A cheerful dining room, a clean tablecloth and napkins, pretty dishes and thin glass tumblers are almost necessities as well as luxuries. Small, steady gains are better than large, irregular ones. When the patient weighs enough, he should be instructed to eat less.

When the overweighted patient who has been discharged with his disease arrested goes to work, he is apt to lose his superfluous flesh. If not, he should reduce his diet for the good of his general health. It is too much tax on his digestive and assimilative power to maintain this increased weight. In some cases where, from a variety of causes it is difficult for the patient to take sufficient food, the employment of a tactful trained nurse, if it can be afforded, will be a great help, even if she is not otherwise needed. Meals should be served with the greatest regularity. Only the pleasantest conversation should be allowed at the table. The patient should particularly avoid worry. He should eat slowly and masticate thoroughly, remembering that by doing so he ought to secrete and utilize for important digestive purposes a large amount (one quart, perhaps) of saliva each day. Gladstone used to chew each mouthful thirty-two times, once for each tooth in his head. The patient should not eat when very tired, nor exercise on a full stomach; and therefore, if necessary, he should rest both before and after eating. He should surely lie down for the quiet hour after his noon meal. If the symptoms of overeating come on, such as great fulness of the stomach, sleepiness after meals, flatulence, vomiting, diarrhea, muddy urine, intestinal fermentation, etc., and do not yield to medicines, the diet should be lessened in amount.

As to just what the food should be there is no invariable rule. Patients differ, and the physician should individualize. One man may do well on the coarse fare of a Western ranch or of the Maine woods, while another may need the most tempting viands prepared with the greatest skill and delicacy.

The diet should be mixed. No exclusive fads should be indulged, like the grape cure, the milk cure, the raw-meat cure. No one article of food contains the proteids, fats, and carbohydrates in proper proportion to be sufficient alone. Besides, a single food becomes after a while painfully monotonous and repulsive. Rubner estimates that a person of average weight (150 pounds) in health needs differing amounts of food according to his occupation. Twenty-five hundred calories would do for a clerk at the desk, while a blacksmith might need 5,200. The average man without much exercise might need about 3,000, and the average consumptive would need much more, especially if his disease were active and he were much under weight. A calorie (we must not forget) is the amount of heat required to raise one kilo of water one degree centigrade. Theoretically we ought to be able to figure out first for the healthy man and then for the consumptive in different stages and conditions just the amount and the relative proportions of proteids, fats and carbohydrates, mineral salts, and water which he needs. Practically, this theoretical diet often fails because we never know just how much of each of these classes of foods a defective alimentary tract may assimilate. Many experiments have been tried and are being tried along these lines, but so far without much success. Perhaps some time we may learn enough for a good working basis, but hitherto most of our good results have been empirical rather than derived from scientific deductions. In general, a consumptive's diet may for the present be considered fairly correct, if he regains flesh and strength after having lost both.

Except when we are making experiments there is no need to weigh the food eaten. It is easier, pleasanter, and better to weigh the patient once a week. Thus we can estimate the amount really assimilated, which is far more important than the amount ingested. He often gains for a while two or three pounds a week.

All of the necessary nutritive elements are in milk and in certain other foods, but their proportions vary. The proteids predominate in eggs, meat,

cheese and fish, the carbohydrates in sugars and starches. The fats are found in the flesh of animals and fishes, in cream and butter, in olive and cotton-seed oil and in nuts, and the mineral salts in vegetables. Fats are especially needed by consumptives, and they seem to be assimilated easily, if well chosen. The following proportion has been suggested, subject to further experimentation: Proteids 120 grams, fat 140, and carbohydrates 300. In caloric value a glass of milk is said to be equal to one ounce of cheese or to two eggs or to two ounces of bread, three ounces of lean meat, or sixteen ounces of oysters. We depend upon the proteids to build up the tissues, and these can be helped out by the fats and carbohydrates, the latter being better proteid sparers than the fats, and also being cheaper, but unfortunately being too bulky and hard to digest, if used in sufficient quantities without much fat.

In establishing a dietary there is no one routine advisable for all cases. In actual practice great variation occurs. But on one point there seems to be a wonderful unanimity of opinion among those who have helped the largest number of tuberculosis cases to recovery. The constant and extensive use of milk and eggs is deemed by all well-nigh essential. After one has got well started in the right way, he can be expected to take from two to three quarts of milk and from four to six eggs a day in addition to his regular meals of solid food. If he is not able at first to take these with his solid food, it may be wise to leave out the latter for a while and confine himself entirely to the milk and eggs. If he has a great repugnance to these, he can begin with very small quantities, an ounce or even less of milk and one egg, for example, to be taken at more frequent intervals. The milk should be taken in sips, very slowly, and the eggs should be tossed off whole, perhaps adding a little lemon juice or salt for a relish. The eggs should be as fresh as possible and the milk pure, unboiled, hot or cold, clean, rich, and daintily served. Cream may be added if desirable. Small quantities of milk may be constipating to some extent, but the large amounts which consumptives require, on account of the fat and water contained, are slightly laxative. Milk and eggs are usually taken for lunches between meals and before bed. Some who claim to be familiar with them think that the milks from asses and mares are more digestible and the best; but most of us, I fancy, even if we could get them easily, would be quite content with good cows' milk.

If necessary, the milk can be peptonized. Kumyss and buttermilk may help out our menu. Milk will sometimes digest better if a little salt is added. It will relieve the tediousness of raw eggs if the flavor is changed now and then.

Some physicians advocate three square meals a day with three lunches interspersed, and some only one hearty meal at noon; in the latter case more milk and eggs being taken at other times. A few advocate leaving out the lunches and eating only three times a day, including the milk and eggs at these meals. Most, however, believe in eating five or six times a day. Although milk and eggs come nearer to the ideal diet for consumptives than anything else, yet it is certainly unwise to use them exclusively. Even in fever up to 102° a solid diet is better, giving way to milk, malted milk, gruels, and broths if the temperature is higher. If for any reason we have to leave the solid and mixed diet, we like to get back to it as soon as possible.

The very best way to get in the necessary amount of fat required is by means of milk, cream, and butter. Every consumptive should eat large quantities of butter, preferably not cooked. Cod-liver oil, until lately so much used, is so nauseating to most that it should not be thought of. A little olive oil on salads or on other foods or alone is better, and many enjoy it or learn to like it. Cotton-seed oil is much the same and is cheaper. Bacon for breakfast is very appetizing, and sardines and salmon also contain much fat.

Most consumptives need a great deal of fresh meat, and should have it two or three times a day. It is much better rare than well-done, and should not be twice cooked. Raw beef would be better still if people would be willing to eat it. Some do and grow to like it after a while. It is more digestible and is often good for diarrhea. When scraped it may be rolled into balls easy to swallow, or put into sandwiches with anchovy paste or salt herring to give it a flavor. The yolk of raw eggs may be added. To tempt children it may be mixed with sweets, or when made into balls the outside of it may be cooked just enough over a quick fire to take away the raw taste of the whole. Thin soups or meat extracts do not contain much nourishment, but are appetizing and excite the flow of the gastric juice. Meat juice, on the contrary, is nourishing. It is pressed out of raw or slightly browned beef cut into small pieces after it has steeped for a while in an equal weight of warm water (a little salt being added), and should be freshly prepared. To make a good raw meat soup mix half a pint of finely minced fresh meat with enough milk to make a thick paste. When ready to serve add half a pint of hot milk or chicken or veal stock. Mutton, lamb, chicken and other poultry, game and venison are also to be included, and even veal and fresh pork are allowable if the patient has a very strong digestion. Pastry, candy, fried foods, and cabbage should very seldom be eaten.

Tea, coffee, cocoa, and chocolate may be allowed in moderation if they seem to agree. Excessive smoking should be discouraged, but a moderate amount out of doors may be allowed to those who have long been used to it and feel dependent on it. Alcoholic stimulants should be positively forbidden. Alcohol is now universally recognized as a very frequent cause of tuberculosis, and the treatment of the disease can surely be conducted far better without it.

The following dietary, subject to modifications, will convey some idea of how consumptives with good digestion should be fed, if under weight:

Breakfast.—7:30 A.M. Fruit, cereal, coffee, toast or muffins, one raw egg, two glasses of milk.

Lunch.—10 A.M. Two raw eggs, two glasses of milk, crackers.

Dinner.—12:30 P.M. Soup: rare roast beef, or lamb, mutton, chicken, turkey, steak, chops, sweetbreads, or raw chopped beef; potatoes, two vegetables chosen from among stewed tomatoes, corn, peas, beans, squash, spinach, beets, onions, turnips, asparagus, cauliflower, celery etc.; salad; baked or stewed apples or a simple pudding, custard, cornstarch, farina, rice, junket, or bread pudding.

Lunch.—4 P.M. Two raw eggs, two glasses of milk, bread or cheese sandwich.

Supper.—6:30 P.M. Hot or cold meat, bread, milk-toast, fruit or sauce, tea, one raw egg, and two glasses of milk.

Lunch.—9 P.M. Two glasses of milk.

THE CANCER PROBLEM.

It must be confessed that in spite of the time, brains, energy, and money which have been expended during the past few years in the attempt to solve the problem of cancer, in almost all parts of the civilized world, little or no apparent progress has been made. Of course, this is not to say that the research work which has been carried on so earnestly by skilled investigators in America and elsewhere has been in vain, for many important and new facts relating to malignant tumors have been unearthed. But insofar as a final elucidation of the many obscure points which still wrap the mysterious disease known as cancer is concerned, the end is not yet even in sight. Theories in regard to its etiology have been abundant within the decade just gone by, some of which have been extravagant, some plausible, and one or two have been almost accepted as clinching the matter once and for all. However, a closer analysis of every theory as to the causation of malignant tumor has revealed a weak link in the chain of argument, and one after the other each theory has been rejected.

At the present time, the situation is this: In the United States, in Great Britain, and in Germany, research work having as its object the discovery of the nature and cause of the malignant growths, is being eagerly prosecuted by bands of skilled and energetic investigators; and now and then from one or other of these laboratories comes the news that a forward step has been made in the direction of the goal. It must not be forgotten also that there are in the field many independent investigators, and many scientific men, both surgeons and physicians, who, while they do not make a special study of cancer, at the same time miss no opportunity that may come in their way of increasing their knowledge of the disease.

To this latter class belongs Mr. Bland-Sutton, one of the best known of English surgeons, and who recently delivered an illuminative address on "The Cancer Problem" at the Institute of Hygiene in London. Mr. Sutton began his address by pointing out that while the public is persistently asking the profession to explain the nature and cause of the tumor diseases, grouped together for clinical convenience under the general term cancer, some observations have been made which tend to show that physicians and surgeons have failed to grasp the subject in its full meaning. Mr. Sutton is of the opinion that investigators would do well not to rely on histological methods alone for distinguishing between the various groups of malignant tumors, but to consider the larger structural details which serve for the identification of these neoplasms.

There are five distinct groups of malignant tumors, and Mr. Sutton draws attention to the fact that in dealing with these tumors the position is such that we are unable to point to any absolute histological indication of malignancy, and that clinical and histological characters must be considered together. Microscopical examination, even when conducted by the most expert microscopist, cannot determine with precise certainty whether a tumor be malignant or not. "The true character of such tumors can only be determined by careful observation of the patient." In the course of his address Mr. Sutton gave examples drawn from his own wide experience of the futility of relying wholly on histological methods to determine the nature of a tumor.

Perhaps the most interesting part of Mr. Sutton's lecture was that which related to the permeation of the cancer poison through the body. The old idea was that such dissemination depended on the invasion of the blood, but Mr. W. S. Handley showed that cancer was spread by way of the lymphatics. Mr. Sutton himself has always been puzzled by the fact that although, when cancer arises in organs such as the breast, eyeball, testicle, tongue, or lip, it is invariably unilateral, yet in the case of the ovary carcinoma is usually bilateral. This led him to suspect that in many instances bilateral cancer of the ovaries might be secondary, and further experience and observation have so strengthened his belief that it practically amounts now to conviction.

The point, however, of Mr. Sutton's address was that histological methods alone are not sufficient or accurate enough to determine clearly the nature of a tumor, but that these must be supplemented by careful observation of the patient in order to gain a correct diagnosis. In a few words this means that laboratory methods are not by themselves to be relied upon in order to determine the nature of tumors, but that practical bedside observation in this connection has a very important part to play.

BLOOD-PRESSURE APPARATUS.

Now that the determination of the blood pressure has established itself as an indispensable routine procedure in a very great variety of conditions it is natural that efforts should be made to improve the existing apparatus, both in accuracy and simplicity. While instruments of the Riva-Rocci type, particularly the Janeway sphygmomanometer, apparently leave but little to be desired in the way of accuracy, the records obtained with them when properly used probably not being more open to criticism than those furnished by the clinical thermometer, they suffer to some extent from structural disadvantages that justify efforts to produce a nearer approach to the ideal. Two new forms of apparatus for measuring the blood pressure are described in a recent issue of the *Berliner klinische Wochenschrift* (June 3, 1907), one of which is presented by its originator as being an advance in the direction of exactness, while the other has been devised as an improvement in mechanical construction.

Bing considers that it is preferable if possible to determine the end pressure in the axillary artery rather than the lateral pressure, which is the one usually measured by instruments in which an armlet is employed, since the latter is, theoretically at least, susceptible of modification by the degree of contraction of the vessels peripheral to the constricted district. In order to gauge this pressure, he employs two armlets, which are applied side by side above the elbow. The upper of these corresponds to the one in ordinary use, while the lower and narrower one is intended for the purpose of securing complete closure of the artery immediately below the point at which the pressure is being measured. The tubes from these two armlets enter a two-way stop cock, by means of which either one can be put in communication with the ordinary manometer and inflating bulb. Communicating with the lower armlet is a tube terminating in a U-shaped capillary tube containing a droplet of petroleum colored red. In order to use the apparatus the lower armlet is inflated to a point 20-30 mm. higher than that required to secure obliteration of the radial pulse. The stop cock is then adjusted in such a way as to permit inflation of the upper armlet. This is carried to a point at which the fluctuations of the red index in the capillary tube caused by the end impact against the upper border of the lower armlet disappear. The pressure is slowly lowered, and the point at which the pulsation as evidenced by the fluctuations of the index reappears is read as the systolic pressure. Systematic comparisons between this apparatus and the Riva-Rocci instrument gave readings that were consistently higher for the former; the difference usually being in the neighborhood of 10 mm.

Stillmark claims as the chief advantage of his instrument that no rubber is used in its construction, and that it is therefore practically indestructible under ordinary use, and that inaccuracies due to variations in the elasticity of the rubber components of the usual sphygmomanometer are eliminated. The instrument consists of a lever with unequal arms, the shorter of which is provided with a weight of 500 g. and has projecting from its lower surface a short vertical arm bearing a conical knob intended to serve for the compression of the vessel. The long arm of the lever is provided with a graduated scale and a sliding weight. At its extremity is a concave mirror having a focus of about 3 m. The instrument is used by placing a weight at the short end of the lever sufficiently great to cause complete obliteration of the patient's radial pulse. As an index of this the image of a lamp reflected by the concave mirror remains motionless. The sliding weight is now moved along the long arm until the blood wave just overcomes the compressing force, as is shown by a sudden oscillation of the light image. By means of a formula, the result in grams obtained in this way can be transposed into millimeters of mercury.

In regard to the first instrument, it may be said that it is somewhat questionable whether the advantage of measuring the end pressure instead of the lateral pressure is sufficiently great to offset the increased complexity of apparatus which it entails. Stillmark's instrument also does not appear to offer very decided advantages since it is open to serious criticism on the score of the fundamental principle of its construction, and certainly it is not adapted for use at the bedside.

OPERATIVE TREATMENT OF CARCINOMA OF THE STOMACH.

The operative treatment of carcinoma of the stomach may be radical or palliative, but unfortunately the mode of procedure can be decided upon only when the abdomen is opened, for only then can we see whether there are metastatic nodules in the liver or peritoneum. An exploratory laparotomy is indicated in almost all cases, but the only successful treatment is radical removal of the new growth. Of late the indications for radical removal have certainly become more numerous, as a few statistics go to show. From 1881 to 1898 Broquet operated in 52 cases; from 1898 to 1904 Matti made 45 resections of the stomach; and now Kocher, in an article in the *Correspondenz-Blatt für Schweizer Aerzte*, No. 9, 1907, reports 25 cases covering a period of only 2½ years. As regards the mortality, Broquet's was 34.6 per cent., Matti's 17.7 per cent., while Kocher had only four deaths, or a mortality of 16 per cent. In three of the latter's cases, the transverse colon was involved and required resection; in the fourth fatal case an abscess of the pancreas existed as a complication. Two advanced cases, with resection of the transverse colon, and the remaining nineteen uncomplicated cases of Kocher all terminated in recovery. As regards radical cure, much depends upon the possibility of making an early diagnosis. Makkas, in a series of 130 cases, reported a radical cure (*i.e.* freedom from recurrence three years after operation) in 18.4 per cent.; Matti reported 19.3 per cent. cured out of 95 patients operated upon, or 26 per cent. of those who survived the operation.

Kocher believes that the method of operation is of importance as regards both mortality and radical cure. Guinard collected statistics of 291 pylorus resections, of which 148 were performed according to the Billroth method No. 1, with a mortality of 35.3 per cent., and 64 according to Kocher, with a mortality of only 15.6 per cent.

Matti reported 97 resections (1881 to 1904), of which 71 were done according to Kocher, with a mortality of 16.9 per cent. Of the 25 cases reported by Kocher himself, 21 were operated upon according to his own method, with a mortality of 9.5 per cent. Of the patients reported radically cured by Matti, all but three were operated on by the Kocher method, *i.e.* a gastroduodenostomy was done each time when the pylorus was involved, a sure sign that recurrences do not appear in the duodenum, in spite of the arguments of the opponents of this method, who claim that enough tissue cannot be removed. According to Kocher the duodenum can be made more movable by cutting the parietal peritoneum on its right side. Furthermore, if a gastrojejunostomy is performed, the duodenum and stomach must first be closed separately, and through poor closure numerous patients have

died. Resection with gastroduodenostomy brings about more natural conditions than the other operative procedures, which explains the fact that patients feel well soon after the operation, and remain in good health for some time, even though recurrences take place.

Lead Poisoning from Encapsulated Projectiles.

It is ordinarily considered that aside from the possible mechanical disturbances they may induce, projectiles encapsulated in the tissues are more or less harmless. The possibility of systemic lead poisoning from this source is hardly thought of, though it is a rare, but still occasionally occurring, contingency. Braatz (*Münchener medizinische Wochenschrift*, May 28, 1907) has discovered records of six such cases, from a study of which it appears that neither the length of time that the tissues have harbored the foreign body nor the amount of metallic lead present is of importance in regard to the development of symptoms of plumbism. In making the diagnosis the blood examination is of the greatest value, and the detection of basophilic granules in the red cells, as described by Grawitz, affords a valuable diagnostic hint, providing that the few other conditions leading to this appearance, such as malignant disease, pernicious anemia, sepsis, and malaria, can be excluded. While the remote danger of plumbism will probably not cause any modification in the surgical maxim not to resort to extreme measures in endeavors to remove more or less inaccessible projectiles, it is evidently the part of wisdom to examine the blood with this idea in view in cases of obscure illness occurring in those known to be the carriers of such foreign bodies, and if indications of lead absorption are present to proceed at once to operation for removal of the offending body.

The Public Attitude Toward Consumptives.

An editorial in the *Lancet* of June 8, 1907, calls attention to a timely article in the *Westminster Gazette* by Mr. A. K. McClure, who, writing under the heading "Panic and Prejudice," says that a wider recognition of the fact that infection is chiefly conveyed by careless expectoration, would "do far more to prevent the spread of consumption than the callous ignorance which brands all consumptives as outcasts." This callous ignorance is already working hardships on many patients who are intelligent, fully understand their potential danger to the community, and most carefully observe every sanitary precaution. Many health resorts are already closed to them. Mere pleasure seekers appear to have ordained that all sufferers from tuberculosis who leave home must go to some sanatorium, whether they want to or ought to, or not. Persons who have the disease in a slight degree, and are careful, are discharged from their positions, forced to leave the wage-earners' ranks, and thus become dependent. The profession has labored long and earnestly to inform the laity of the dangers of the disease, but as so frequently happens the latter have misinterpreted the advice and drawn conclusions which are working an injustice to many worthy persons. How to adjust the balance is a very urgent problem before the numerous agencies now engaged in combating tuberculosis. We feel that much of the present unreasoning alarm is due to loose statements in some of the daily journals, and might be corrected by a more temperate and careful treatment of the subject in these organs of public opinion.

An Operation for Prolapsus Uteri.

At a recent meeting of the British Gynecological Society, Dr. Macnaughton-Jones presented for Prof. Jacobs of Brussels a paper (*British Medical Journal*, April 20, 1907) describing a radical treatment for prolapsus uteri as tried in seventy-seven cases, the ages of the patients averaging from forty-three to seventy-one years. The operation was named abdominal colpopexy, and consisted in exposing the uterus by a median incision and then exercising strong traction on it in an upward direction. The uterus was then carefully released from its attachments until held only by the vagina. Section of the latter was then made at a point lower or higher, according as the prolapse was pronounced, by V-shaped anterior and posterior incisions with widely separated limbs above at the junction of the vagina and the uterus. The margins of the incisions were then united by sutures, the knots turned into the vagina, and the pelvic floor reconstructed by whipping together the cut surfaces of the broad and round ligaments on each side so as to unite them above the newly formed vaginal vault. To prevent any return of prolapse the round and uterosacral ligaments on both sides were united to the vaginal stump, which was thus raised up in the middle of the pelvic cavity. The results in the small number of cases in which the operation was tried do not seem to have been very encouraging, as a perfect mass was obtained in but one case out of seven. In five cases there was a slight relapse consisting in cystocele with prolapse of the anterior vaginal wall, and one patient died from stomachic causes.

Exploratory Puncture of the Brain.

Operations for the relief of cerebral tumors are very often unsuccessful because the operation is not undertaken until the growth has extended beyond all hope of complete removal. Had a diagnosis been made earlier the result might have been different, but statistics show that in from twenty to thirty per cent. of all the cases a mistake is made in the diagnosis of the locality in which the tumor is situated. The successful surgical treatment of cerebral neoplasms depends principally on the perfection of diagnostic methods. Pfeiffer (*Archiv für Psychiatrie und Nervenkrankheiten*, Vol. 42, No. 2) considers that exploratory puncture of the brain affords the best means of determining the status of the case. He reports five instances in which a satisfactory early diagnosis was made, the exact locality of the lesion being determined. Naturally the results obtained by this procedure must be supported by a careful neurological examination and a clinical localization of the growth. In such cases cerebral puncture is practically without danger and affords a means of differentiating a tumor from other conditions present in the cranium, particularly hydrocephalus, whether external or internal. The fluid from a cyst or distended ventricle may also be evacuated by this means, and thus the latter becomes in effect a therapeutic as well as a diagnostic measure.

Low Arterial Tension as a Diagnostic Sign of Renal Tuberculosis.

Many investigators have found a lowered arterial tension in patients affected with tuberculosis of the lungs, and there seems to be no reason why the same condition should not be present in patients with

tuberculosis of other organs. K. Reitter (*Zeitschrift für klinische Medizin*, Vol. 62) found a constantly lowered arterial tension in a patient who showed all the symptoms of a chronic parenchymatous nephritis, but later turned out to have a tuberculous kidney. After this experience he tested the blood pressure in ten undisputed cases of tuberculous kidney, and found the arterial tension diminished in all. Control tests in cases of nontuberculous pyuria showed no such diminished tension. His examinations led him to conclude that the urine of all patients suffering from kidney disease, whose arterial tension is at the same time lowered, should be examined for tubercle bacilli.

News of the Week.

Quiet for the Hospitals.—At the instance of the Society for the Suppression of Unnecessary Noises, of which Mrs. Isaac L. Rice is president, Alderman Sullivan recently introduced an ordinance providing that signs, reading "Hospital Street," be placed at the corners of all streets on which hospitals are situated. The areas bounded by these signs will be known as hospital zones, and within them drivers will be compelled to walk their horses, motormen must send their cars as slowly and quietly as possible and refrain from clanging the gongs or suddenly applying the brakes except in case of absolute necessity, hucksters will not be allowed to cry their wares, the hurdy-gurdy and the hand-organ will be silenced, newsboys must refrain from calling their extras, and children and hoodlums will be kept away. The plan has the indorsement of Police Commissioner Bingham, who will see that the law is enforced, and of Health Commissioner Darlington. Fourteen hospital superintendents signed a petition urging the passage of the ordinance, which went through without serious opposition. Anyone making unnecessary noises within these areas of silence will be liable to a fine of $10.

Institute of Pathology for the City Hospital.—Mrs. Russell Sage has given the sum of $300,000 to found an adjunct to the City Hospital on Blackwell's Island to be known as the Russell Sage Institute of Pathology. It was largely through the efforts of Dr. T. C. Janeway that the desirability of establishing such fund was brought before Mrs. Sage, and the new institute is to be organized according to the plans and under the direction of Drs. E. G. and T. C. Janeway, with whom are to be associated on the Board of Trustees, as *ex-officio* members, the Commissioner of Public Charities of the City of New York and the President of the Medical Board of the City Hospital, and as individual members Dr. D. Bryson Delavan, Dr. Simon Flexner, and Prof. Graham Lusk. One of the objects of the institute will be to make use of the unexampled material of the city institutions on Blackwell's Island for the purpose of investigating heart and kidney diseases and the other morbid conditions attendant on advanced age.

Pasteurization of Milk.—In a report recently issued with the indorsement of the Secretary of Agriculture, the pasteurization of all milk is strongly advocated. The advantages and disadvantages have been studied by Dr. M. J. Rosenau, Director of the Hygienic Laboratory of the Public Health and Marine Hospital Service, and in his opinion the advantages so far outweigh the disadvantages that he "unhesitatingly recommends compulsory pasteurization of all milk not certified." Even in the case of certified milk home pasteurization is urged in order to guard against the slight risk of occasional contamination.

Health in the Canal Zone.—According to the latest report of Col. Gorgas to the Canal Commission, the health conditions in the Zone are better than ever before. The largest percentage of malaria for any week in the month of May was 65-100 of 1 per cent., and it has been as low as 52-100 of 1 per cent. The percentage of all disease has ranged from a minimum of 96-100 of 1 per cent. to 1 1-10 per cent. The prolonged dry season and the late beginning of the general summer rains have been productive of conditions unusually favorable to the rapid breeding of mosquitos, so that it has been necessary to carry out the work of mosquito extermination with greater activity than ever before.

New York City's New Water Supply.—On June 20 the work of excavation for the Catskill Aqueduct of the city's new water supply system was formally begun by Mayor McClellan at a point about two miles from the town of Cold Spring. The water is to come from the three reservoirs up in the Catskills in aqueducts which will pass under the Hudson at Storm King at a depth of about 700 feet and come up at Breakneck on the other side of the river. From here they will cross gullies and pierce hills in three conduits which enter the ground at the spot where the formal excavation was started. The new system is designed to deliver 600,000,000 gallons daily, and its estimated cost is $161,000,000.

Ambulance Accidents.—A Lebanon Hospital ambulance, in charge of Dr. Rottnoss, was run into by a junk wagon at the corner of Brook avenue and Westchester avenue and overturned, and wrecked. The patient, a child with meningitis, and the surgeon were thrown into the street, and the child died a few minutes later. An ambulance of the Hudson Street Hospital, in charge of Dr. Elliott C. Burrowes, was smashed at West Broadway and Worth street by a collision with a trolley car. The surgeon and driver were badly bruised and cut and the horse was killed.

St. John's Guild Ship and Hospital.—The St. John's Guild floating hospital, the *Helen C. Juilliard*, has been thoroughly renovated since last year, and will begin its regular work on July 5. The Guild's Seaside Hospital at New Dorp, Staten Island, is also ready for the summer season.

Civil Service Examinations.—The State Civil Service Commission will hold examinations July 13, 1907, for the following positions: Assistant in Clinical Laboratory, Manhattan State Hospital, $900 and maintenance; Medical Inspector of Factories, $2,400; Trained Nurse, State Institutions (men and women), $420 to $600 and maintenance; Woman Physician, State Hospitals and Institutions, $1,000 and maintenance. The last day for filing applications for these positions is July 6. Full information and application forms may be obtained by addressing Mr. Charles S. Fowler, Chief Examiner of the Commission in Albany.

St. Vincent de Paul Fresh Air Farm.—The children's free summer vacation season at the St. Vincent de Paul Fresh Air Farm at Spring Valley was opened on June 18 with a party of about 200 younger children from the day nurseries. The first party of school children will go on July 5, and the season will close late in September, when another party of children will be sent.

Automobile Accidents in Germany.—The Imperial German Statistical Bureau has published figures showing that on January 1 there were 27,926

automobiles in the country. According to these figures in the half year ended September 30 last there were 2,290 automobile accidents in Germany, of which 673 caused injury to persons. The number of persons killed and injured amounted to 1,570, including 51 killed. Of the latter, 9 were chauffeurs, 9 passengers of automobiles, and 33 other persons. In 1,024 cases the cause of the accident was determined, and in 478 of these too rapid running or failure to give the alarm signal was given as the cause, while 220 were caused by unskillful steering, 26 through disregard of stop signals, 53 through failure of brakes, 174 through lack of proper precaution on the part of persons in the streets or roads, 48 through slippery pavements, 20 through breakage of parts of the machine, and 5 through explosions. Suits were brought in the courts in 695 cases, and of these 625 were against chauffeurs.

Optometry Bill.—At the hearing on this bill before Governor Hughes last week, the measure was strongly opposed by the State Medical Society through Dr. H. L. Shaw of Albany, and others. The Governor reserved decision on the bill.

Opium Restriction in Shanghai.—In accordance with the recent imperial decree against the consumption, sale, or cultivation of opium, the opium shops in the native quarter of Shanghai were closed on June 22, and similar action is soon to be taken in the surrounding districts. Contrary to expectation, no trouble was encountered from the populace.

To Quarantine Consumptives.—Dr. W. H. Brumby, State Health Officer of Texas, has announced his intention of issuing a proclamation quarantining all persons suffering from advanced tuberculosis.

Commencement Exercises of the Chicago College of Physicians and Surgeons.—These were held June 4, when a class of 165 was graduated, the degrees having been conferred by President Edmund J. James of the University of Illinois. The doctorate address was delivered by Rev. Rufus A. White.

A Medical Night School.—Under the title of the Hippocratean College of Medicine a night school for the study of medicine has been opened in St. Louis.

Dedication of Michael Reese Hospital.—This new hospital, recently built at a cost of more than $700,000, was dedicated and opened for the care of patients June 16. It is said that the new hospital will accommodate 300 patients and 100 nurses. It is six stories in height, fireproof throughout, and is fitted with every modern equipment.

A Hospital in Dover, N. J.—A number of the residents of Dover, N. J., are planning to establish a hospital in that place, and a committee has been appointed to devise ways and means of carrying out the project.

Sanatorium for Hebrew Children.—The sanatorium for Hebrew children at Rockaway Park, L. I., has been opened, and now has more than 200 inmates.

Dr. **James Packard Mann** has been elected professor of orthopedic surgery in the Medico-Chirurgical College of Philadelphia. He has held the position of clinical professor in the same branch for ten years.

Dr. **Harmon Smith** has been appointed Surgeon to the Throat Department of the Manhattan Eye, Ear, and Throat Hospital.

Ambulance for Beth Israel Hospital.—An ambulance costing $700 was presented to this hospital last week by an organization of young women and girls who had raised the necessary sum of money.

Greenport Hospital Opened.—The new hospital of the Eastern Long Island Hospital Association has been opened at Greenport and is ready for patients.

Chicago Medical Society.—The annual meeting of this Society was held June 19, 1907, with Dr. George W. Webster in the chair. Reports were received and read of the work done by the thirteen branches of the Society. Dr. Harold N. Moyer reported that the Medico-Legal Committee had considered seventy-nine items. He used the word items advisedly because they could not be dignified as suits. These items varied all the way from complaints to threats and suits of malpractice. In four cases the committee won after legal battles. The committee had disposed definitely of eight cases, and he thought that nine-tenths of the others would not be heard of again. No judgment had been rendered against a doctor for malpractice in Cook County, and no compromise had been made by the committee in any malpractice case in four years, excepting in three instances. In one of these, clearly a malpractice suit, although trivial, liability was certain. The other two cases were disposed of in an amicable manner. The following officers were elected for the ensuing year: *President,* Dr. H. B. Favill; *Secretary,* Dr. Robert T. Gillmore; *Councillors for three years,* Drs. Adolph Gehrmann, William L. Noble, George Bell, Frank X. Walls, and William L. Baum; *Alternates for three years,* Drs. Heman Spalding, Charles E. Paddock, A. B. Keyes, W. E. Pickard, and E. C. Riebel.

Franklin County (Vt.) Medical Society.—At the annual meeting of this society, held in St. Albans on June 5, the election of officers resulted as follows: *President,* Dr. F. S. Hutchinson of Enosburg Falls; *Vice-President,* Dr. A. L. Cross of Swanton; *Secretary and Treasurer,* Dr. E. A. Hyatt of St. Albans.

Maine State Medical Association.—At the annual meeting of this organization held on June 13 in Portland these officers were elected: *President,* Dr. B. B. Fuller of Portland; *Vice-President,* Dr. Albert D. Sawyer of Fort Fairfield and Dr. O. C. S. Davies of Portland; *Secretary,* Dr. Walter L. Tobie of Portland; *Treasurer,* Dr. Arthur S. Gillson of Portland.

Rhode Island State Medical Association.—The ninety-sixth annual meeting of this association was held in Providence on June 13. The officers elected for the ensuing year were as follows: *President,* Dr. C. V. Chapin; *Vice-Presidents,* Dr. F. B. Fuller and Dr. Eugene Kingman; *Secretary,* Dr. S. A. Welch; *Treasurer,* Dr. G. S. Mathews.

Chattahoochee Valley Medical and Surgical Association.—The semi-annual meeting of this organization will be held at Opelika, Ala., July 9 and 10, 1907. Dr. J. A. Goggans of Alexander City is the *President* and Dr. W. J. Love of Opelika is the *Secretary.*

New Haven County (Conn.) Anti-Tuberculosis Association.—At a meeting of this society, held in New Haven on June 13, the following were elected officers for the ensuing year: *President,* Dr. Francis Bacon; *Vice-Presidents,* Professor Henry W. Farnam, Dr. C. W. Gaylord, and Dr. H. L. Swain; *Recording Secretary,* Professor Irving Fisher; *Financial Secretary,* E. L. Chapman; *Treasurer,* W. Perry Curtiss.

Obituary Notes.—Dr. Charles L. Mullholland of Brooklyn died on June 18 at his home in that city. He had practised for many years in the lower section of Brooklyn and was a graduate of St. John's College and the University of New York.

Dr. Willard Parker died at his home in this city on June 24. He was a graduate in arts of Columbia College in 1866, and in medicine of the College of Physicians and Surgeons in 1870. He was a son of the late Dr. Willard Parker, who was for years a leader of the profession in this city, one of the first American surgeons to operate for appendicitis, and the organizer of the first college clinic in this country. Dr. Parker was buried at New Canaan, Conn., on Thursday of this week.

Dr. Thomas Hill of Brooklyn died on June 20, at the age of sixty-two years. He was born in Ireland and was a graduate of Niagara University.

Dr. S. H. Frazier of Crescent, Mo., died suddenly at Lilbourn on June 8. He was graduated from a St. Louis college seven years ago.

Dr. George J. Bucknall of San Francisco died on June 11 at the age of seventy-one years. He was a native of New York State and had practised in San Francisco since 1856.

Dr. Edward H. Birckhead of Albemarle County, Va., died on June 14, at the age of forty-eight years. He was born in Proffit, Va., and received his medical education at the University of Virginia and the Bellevue Medical College, from which he was graduated in 1883.

Dr. Charles B. Gilbert of Washington, D. C., died on June 13, at the age of sixty years. He was born in Bath, Me., and received his medical education in Philadelphia. He had practised in Washington for over thirty years.

Dr. R. D. Wilkin of Cass County, Ia., died on June 6 after an illness of several weeks. He was sixty-nine years of age and had practised in the county since 1875.

Dr. C. L. Lewis of Nashville, Tenn., died suddenly on June 12, at the age of seventy-five years. He received his degree from the University of Virginia and had practised for many years in Nashville. A few years ago he retired from active work.

Dr. Arthur D. Hayes of Hartford, Conn., died on June 17 of tuberculosis, at the age of forty-one years. Dr. Hayes was born in Evansville, N. Y., and received his medical degree from the Dartmouth Medical College.

Dr. Henry E. Muhlenberg died at Lancaster, Pa., on June 17, at the age of fifty-seven years. He was descended from a long line of distinguished physicians and ministers. As a young man he entered the U. S. Naval Academy as a cadet, but he resigned before he had fully completed the course of study. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1871 and entered the U. S. Marine Hospital Service, from which, however, he resigned after four years to enter upon the practice of medicine in his native city of Lancaster. He was in time elected to City Councils and in 1900 Mayor of Lancaster.

Dr. Charles J. Schulze, the oldest practising physician in Bucks County, died at Reading, Pa., on June 16, at the age of eighty-nine years. He was a native of Germany and was a graduate of the University of Greifswald in 1846.

Dr. Israel Hart of Pennington, N. J., died on June 23, at the age of seventy-nine years. He practised medicine in Pennington until 1863, when he was appointed assistant surgeon in the army, where he remained until the close of the war. He then returned home and continued in practice until a few years ago.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent

GENERAL MEDICAL COUNCIL — HOSPITAL ABUSE — CHARITY ORGANIZATIONS' CONFERENCE — MYELOPATHIC TRICHOSIS — PERSISTENT URINARY FISTULA—PROLONGED PYREXIA—HEART-BLOCK—ITEMS—OBITUARY.

London, June 7, 1907.

The session of the General Medical Council was concluded within the week. The proceedings, subsequent to those I mentioned in my last, comprised a good deal of penal business, a discussion on the teachings of midwifery and gynecology, examination on these subjects, the presentation of reports of committees, and the usual closing formalities.

The question of medical and dental practice by companies has passed from the Council to Parliament, and on Monday the select committee of the House of Lords began to take evidence upon the bill. The president of the Council and Mr. Tomes gave evidence, and the committee examined some other witnesses yesterday and adjourned.

Last night the Metropolitan Branch of the B. M. A. held a meeting respecting hospital abuse. By dint of an urgent whip a fair attendance was obtained, and a resolution passed that a Central Hospital Authority for London should be constituted, on which the profession should be adequately represented. Drs. Knowsley Sibley, Lewiston Shaw, Forbes Ross, Southcombe, McCann, Heslip, F. J. Smith, Roche, Surgeon-Colonel Myers, and Mr. D'Arcy Power took part in the proceedings. Some other meetings have taken place in support of this view, but what will be the result is very uncertain. The British Medical Association will, no doubt, make every effort to dominate any representation the profession may obtain. That may not be much, considering how the lay element has hitherto monopolized all power.

The Charity Organization Societies have been holding a conference at Norwich, when the abuse of hospitals, the work of provident dispensaries, and kindred topics were discussed. In a paper, read by Lieutenant-Colonel Montefiore in place of Dr. Gray, who was detained in London, the cooperation between hospitals and dispensaries was held to be most important, but to attain the object many more provident dispensaries are required. The plan of appointing almoners, or inquiry officers, was commended. It was, however, said that at present many patients, finding such an officer at a hospital, left it and went to another where inconvenient inquiries were not made. When almoners are appointed at all hospitals their value will be realized. It was further said that cooperation between dispensaries should be general, so that a member having to move to another district could be transferred without loss of benefit. Dr. Beverley of Norwich said the working classes had for so many years had recourse to hospitals that they had ceased to regard themselves as objects of charity, to which the present rates of wages did not entitle them. He had had abundant opportunity of seeing the abuse of hospitals, both in London and the provinces.

Dr. Ballance gave the particulars of the working of the Norwich Public Medical Service, a society instituted to provide the working classes with attendance in sickness. The class they desired to aid was that just below the one that could pay minimum medical fees. Such people would be thrust on charity in illness, unless they had provided by contract for the help they needed in illness. The society was entirely provident—had no contributions from outside. There was no wish to impose a wage limit on entrance, but it found that some who benefited from the society when poor, and afterward became better off, would go on obtaining medical attendance at the trivial contribution when they could afford to pay a general practitioner.

Mr. Henderson raised the socialist issue, asserting that the whole thing should be put on the basis of citizenship, and every citizen who liked be able to avail himself of a public medical service. He was supported by a clergyman, when Mr. Loch protested that such a thing would be an extended poor law and the antithesis of the history of medical relief in this country. Mr. Day said if charity was bad so was the work of the provincial medical societies. This part of the discussion was, on further protest, ruled out of order; but on another day Mr. Henderson returned to the attack and said that Mr. Loch and the organization society only persecuted the shabby, begging-letter imposters, while landowners did the same thing in a wholesale way.

Sir Wm. Gowers has contributed to the Medico-Chirurgical a rare case of cervical myelopathic trichosis in a man of 41. Unequivocal symptoms of syringomyelia were associated with a growth of hair, which occupied a triangle, of which the inner side was along the middle line of the spine from the sixth cervical to the third dorsal vertebra. It

extended at one point nearly two inches from the spine. The condition, he said, pointed to a disproportion between the inner and outer layers of the epiblast in the lower cervical region. A notable feature was that the growth of hair was of greatest vertical extent at the middle line, corresponding to the edge of the neural ridge of the epiblast. Had the other side been affected also the area of trichosis would have presented a lozenge-shape, which was strikingly present in some of the recorded cases of lumbar trichosis in spina bifida occulta.

Mr. Haward, president, mentioned a case in which no defect in the vertebræ was detected, but the patient had loss of power and talipes, loss of sensation, and a great tendency to ulceration of the toes, leading to exposure of bone, requiring removal of the toes. The patient, now a young man, is still troubled with ulceration and discomfort of the foot.

Mr. Pernst thought the case must be unique. There were however, cases of artificial hypertrichosis recorded—one in which it followed an injury to a nerve in one upper limb.

Dr. Grainger Stewart had seen a similar case, under Dr. Ormerod, in a miner who had wasting and weakness of the right arm, with spasticity of that and both lower limbs. He had also dissociated sensibility. The seventh cervical spine was suspiciously prominent, and when a baby he had had a growth of hair in the cervical region, with a bag-like formation. It was thought the seventh spine was bifid. There was a scar in the middle line, or slightly to the right 1½ inches broad.

Sir William Gowers remarked that he doubted whether a bag connected with the spinal canal could fail to prevent closure of the arches.

A paper was then read by Major M. P. Holt on a case of persistent urinary renal fistula. Rupture of the kidney had been followed by extensive suppurations, and attempts to perform nephrectomy had had to be abandoned on account of furious hemorrhage. Supposing the secretion of urine in the abscess to be the sole hindrance to healing, Major Holt ligated all the renal vessels on that side through the transperitoneal route. Within five days urine ceased to be present in the discharge, and by the fifty-seventh day the sinus was completely healed—after two and three-fourth years' persistence. The patient has remained quite well up to the present time, nearly two years since the operation.

The concluding annual meeting of the Clinical Society was held on the 24th ult., prior to a special general meeting, when the final arrangements will be made for its becoming the Clinical Section of the Royal Society of Medicine.

Dr. de Haviland Hall read notes of two cases of prolonged pyrexia, one connected with tuberculosis, the other with ulcerative endocarditis. It was remarked that these were the most frequent causes, and in arriving at a diagnosis the family history was important. On the one hand hemoptysis, enlarged glands, and other suspicious symptoms in near relatives suggested tubercle, while a rheumatic family history pointed to the possibility of endocarditis. This would be more likely if the patient had been attacked with acute rheumatism, followed by cardiac trouble.

Dr. Sidney Phillips had turned to the list prepared by Murchison of conditions accompanied by continuous pyrexia; he found syphilis named. So, in a doubtful case, he had given mercury and the temperature at once fell. Ulcerative arteritis without endocarditis was another cause; so was ulcerative colitis.

Dr. Walter Carr mentioned a case in which no cause could be assigned, when insensibility suddenly supervened, and death in four days. A mass of vegetation was found at the post mortem on the mitral valve, which had caused no murmur during life. Dr. Box cited a case connected with basic meningitis, and Dr. Glover one of rheumatic origin.

Dr. A. M. Gossage read a paper on heart-block, and illustrated it by sphygmographic tracings on the screen. He pointed out that conductivity might be affected separately from other functions of cardiac muscle and that depression of conductivity showed itself in the fibers which connect the auricles and ventricles. Such depression was illustrated by tracings showing a lengthening of the normal interval between the contraction of the auricles and ventricles. Still further depression was shown by the dropping out of ventricular beats. This might occur as an effect of digitalis or be due to the action of the vagus. Tracings were exhibited where there were three auricular beats to every two ventricular, two auricular to one ventricular, and three auricular to one ventricular.

A new medical scholarship at Oxford, of the value of £100 a year, tenable for four years, has been founded by Dr. C. Theodore Williams.

The late Lady Kortright has left to the London Hospital £10,000, and also a share in her residuary estate.

Sir T. Barlow presided on Wednesday evening at a meeting on behalf of the Medical Missions of the Wesleyan Methodist Society. He announced a gift of £500 from a friend of the society toward a new hospital in Central China. Mr. Pearce Gould said nothing broke down the prejudice and superstition of heathen races so much as medical skill, combined with Christian charity and kindness. Dr. J. B. Hellier maintained that it was the presence of medical missionaries in lands like China that made it possible for other missionaries to be there.

Dr. Maxwell Tylden Masters, whose death has occurred at the age of 74 from heart failure, although he practised medicine for some years, was best known as a botanist. For forty-one years he edited the *Gardeners' Chronicle*, in which his most important contributions to botany appeared. From 1865 to 1868 he lectured on the subject at St. George's Hospital. He also served as an examiner at the London University. He was a fellow of a number of learned societies, including the Royal and the Linnean, an officer of the Leopold Order, and a corresponding member of the Institute of France. He took L.S.A., 1854; M.R.C.S., 1856, and M.D.St.And., 1862.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

SURGERY OF THE HEART—SURGERY OF THE VESSELS—PULMONARY SURGERY—SURGERY OF THE LIVER—FRACTURES OF THE THIGH—HYPERTROPHY OF THE PROSTATE—CONGRESS OF THE ROENTGEN RAY SOCIETY.

BERLIN, May 15, 1907.

A FEW notes relative to the Surgical Congress held last month may be of interest.

A review of the subject of surgery of the heart was given by Rehn of Frankfurt, who was the first to perform suture of this organ, and was able to report 124 cases. In regard to the operative technique, he said that any tendency to stereotyped methods was to be deprecated, and the main object was to avoid injury to the pleura and to make the incision in such a way as to render satisfactory drainage possible. If the hemorrhage was abundant compression of the venous trunks leading to the right auricle might be tried. Interrupted sutures of fine silk and cylindrical needles were most satisfactory. Sauerbruch of Greifswald explained that pneumothorax in cases of heart injury at first had a hemostatic effect, but later induced cardiac weakness, and he therefore recommended the use of the pneumatic cabinet for such operations. Numerous speakers recommended resort to cardiac massage through a laparotomy wound in cases of chloroform syncope.

To the subject of surgery of the vascular system, Lexer of Königsberg contributed reports of two cases, in one of which after extirpating an aneurysmal sac he had been able to do an end-to-end anastomosis of the popliteal artery, and in the other he had restored the continuity of the subclavian artery through implantation of a piece of the patient's saphenous vein. Küttner of Marburg reported two cases of splenectomy, one of which was for a gunshot wound, while the other was one of extirpation of a greatly enlarged spleen in myelogenous leukemia. In the first case polycythemia resulted, but in the other there was no effect on the blood picture.

Friedrich of Greifswald discussed the surgery of the lungs, and said that echinococcus, pulmonary abscess, and gangrene afforded the best opportunities for operative interference. The operation should be performed at one session and the incision should be made with a knife rather than with the cautery. As the prognosis is good in acute cases, the results should be satisfactory in about 70 per cent. Injuries should be treated expectantly. Several speakers spoke in favor of the Brauer method of hyperpressure for use in operations on the lung. Gluck of Berlin presented a patient from whom ten years previously he had resected the entire lower lobe of one lung. Sinuses after pulmonary operations or injuries were discussed by Garré of Breslau, who said that, like bronchiectases, they were often very difficult to cure. In chronic cases extensive resection was often necessary. Lenhartz of Hamburg reported eighty-five cases of gangrene with fifty-three cures, and five abscesses with four cures. The presence of globules of fat in the sputum in 05 per cent. of the cases points to the presence of a new growth. Brauer of Marburg reported good results from the induction of artificial pneumothorax in cases of contraction of the pleura such as accompanies pulmonary tuberculosis. Schlange of Hanover has treated severe hemorrhage from tuberculous cavities by resecting the third rib and packing the resulting opening.

In discussing surgery of the liver and bile passages, Sprengel of Braunschweig described the formation of a

retroperitoneal abscess secondary to perforation of the cystic duct by a stone, and expressed the opinion that such an occurrence was not uncommon. Anschutz of Breslau reported twenty cases of resection of the liver and said that the danger of hemorrhage was not very great, for the operation itself had never caused death in his experience. In resecting small portions the vessels are ligated, but if larger areas are to be removed the tissues must be tied off *en masse*, the ligatures being slowly tightened. By incising the triangular ligament and resecting the costal arch the operative field is rendered much more accessible.

The treatment of fractures of the thigh was discussed by Bardenheuer of Cologne, who recommended his method of multiple extension with heavy weights. In 179 cases of this sort, union was secured without shortening in 159. König of Altona was in favor of operative interference, especially in dealing with younger patients. In the discussion it was stated that results like those of Bardenheuer could be obtained only by the closest attention to the details of the method, which preferably should be learned in Bardenheuer's own clinic.

Kümmell of Hamburg stated that in hypertrophy of the prostate operation was indicated only in the severest cases that required frequent catheterization, in which the bladder was infected, or stones were present. Prostatectomy was to be preferred to all other methods on account of the freedom from relapses. In most cases the vesical route was preferable to the perineal operation. His mortality was 22 per cent. Most of the speakers were in favor of suprapubic prostatectomy and recommended local and lumbar anesthesia. Pulmonary emboli from the prostatic plexus were a frequent cause of death. Rovsing of Copenhagen resorts to prostatectomy only after resection of the vas or the formation of a vesical fistula has been without result. This speaker has also performed total extirpation of the bladder in three cases of carcinoma, the urine being collected in a satisfactory manner in a suitable apparatus.

The third Congress of the German Roentgen Ray Society expressed the official opinion that the use of the Roentgen rays for diagnostic and therapeutic purposes by individuals not qualified as physicians was an infraction of the laws regulating medical practice. It was also decided that in therapeutic radiations the degree of hardness of the tubes used should be noted, and one of the approved direct or indirect methods of measurement of the rays should be employed. A case of death after insufflation of oxygen into the knee joint was reported by Jacobsohn of Breslau. A few hours after the procedure cyanosis and death occurred. No gas emboli could be discovered, though it is possible that the oxygen might have been absorbed before the autopsy, which was not performed until twenty-four hours after death. Holzknecht of Vienna reported a similar case in which a considerable amount of gas was found in the heart. In regard to the value of the Roentgen rays in the diagnosis of brain tumors, it was concluded that in this direction there was but little to be hoped for from their use. Krause of Breslau stated that metabolism was modified through the Roentgen rays and that healthy persons when exposed to them acquired a hyperleucocytosis followed by a leucopenia. Forsterling found that the limbs of young animals exposed to the rays were backward in growth. By exposing the head to the rays the development of the entire body of the animal was impaired. Hahn of Hamburg had treated two boys for lupus, and found, as a result, that one-half of the face remained smaller than the other and that the development of the teeth was defective. Köhler of Wiesbaden presented cinematographic presentations of the act of respiration; these pictures had been obtained by taking separate views of the phases of the respiratory act and then combining these in the cinematograph.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

COLLECTING THE PHILIPPINE LEPERS—CHOLERA CASES TREATED AT THE SAN LAZARO HOSPITALS — LOCO-WEED DISEASE — QUARANTINE AGAINST CHINA—EXAMINATION OF THE MILK SUPPLY OF MANILA—A NAVAL HOSPITAL AT BAGUIO.

MANILA, P. I., May 1, 1907.

THE work which was recently undertaken by the Bureau of Health in concentrating the lepers upon the islands of Samar and Leyte for the purpose of transferring them to the Culion leper colony, located on the island of Culion, afforded considerable additional evidence that the number of lepers in the Philippines is probably not as high as has been thought heretofore to have been the case. In order that the matter might be placed on a definite, scientific basis, the steamer which was sent out for the purpose of collecting the lepers was fully equipped with a bacteriological outfit, and several competent microscopists accompanied it for the purpose of making microscopical examinations of all cases before they were taken aboard, and also for the purpose of studying some of the skin lesions which are so frequently encountered, and many of which have no doubt been erroneously classed as leprous. In this way the mistake of taking nonleprous persons from their homes and segregating them in the Culion colony was avoided, while at the same time none of those actually infected with the lepra bacillus were left behind to serve as centers of infection.

In order to aid this work as much as possible, and with the hope of having an opportunity to see as many of the skin lesions as possible, instructions were sent out in advance to the local officials to have all present themselves for microscopical examination who showed any evidence, even though slight, of being afflicted with leprosy, or who had any ulcers or contractions of any sort. In this way several hundred persons were brought, who, in many cases presented a most repulsive appearance, but who, on careful examination, were found to be afflicted with tropical ulcers, phagedenas, or syphilis. Quite a number of cases of the latter were found, particularly on the island of Samar, at places where troops had been stationed heretofore. The spirochete was demonstrated in quite a number of cases.

In concentrating the lepers no serious difficulty was encountered, and so far this feature of the work has given rise to less friction than would ordinarily be expected to be the case. This attitude of the people is, however, no doubt largely brought about by the excellent accommodations and care that is given the lepers at Culion. In the great majority of cases they, no doubt, have better houses, better clothing, and more food than they enjoyed before their incarceration, and this, coupled with the fact that they are not compelled to work, has a strong tendency to make them contented. In this connection it is interesting to observe that the steady decrease in the number of lepers in the islands still seems to continue. For the quarter ended December 31, 1906, there were 3,225, and for the quarter ended March 31, 1907, there were 3,151 as against 3,580 reported August 31, 1905.

A review of the record of the cholera cases treated at the San Lazaro hospitals during the past year shows that of 100 cases in which the diagnosis was actually verified by laboratory methods, 46 had a temperature of normal or above, several reaching 103°, and 54 had a subnormal temperature. These figures would indicate that, while a subnormal temperature is an excellent symptom in making a diagnosis, yet it is not so certain as the average textbook would have it appear.

The regular monthly meeting of the Manila Medical Society was held at the St. Paul's Hospital on the evening of April 8. A case of Weil's disease was reported upon by Dr. Thornburg. Dr. H. T. Marshall, Pathologist of the Bureau of Science, read a paper on "The Loco-weed Disease in Sheep," from which he concluded that no such disease existed as a specific entity; that the term "loco-weed disease" was a name given to a number of different kinds of disorders that occurred in animals.

The United States Quarantine Service, on account of the appearance of plague in different places of China, and in accordance with the usual annual custom which has been observed since 1900, has declared a seven days' quarantine against vessels arriving from that country, which is to date from the time the disinfection is completed in the Philippines. It is provided, however, that vessels coming from ports in China at which regular officers of that Service are stationed, and when proper facilities for disinfection exist, that the quarantine will be waived. The quarantine became effective May 10, 1907.

About ten days ago the Bureau of Health started to make a systematic laboratory examination of the milk sold in the city of Manila. Reports of the analyses are being awaited with much interest.

Dr. H. G. Beyer, Medical Inspector and Fleet Surgeon, Asiatic Fleet, has proceeded to Baguio, Benguet, upon instructions of the Admiral of the Pacific Squadron, with a view to reporting upon the desirability of establishing a Naval Hospital or sanatorium at that Philippine health resort. It will be remembered that the Army and the Civil Government have already established hospitals at that place, and reports have been made from both these independent sources, which indicate that Baguio possesses great advantages for the cure of certain forms of tropical disease, and more particularly amebic dysentery.

The report of the committee which was named for the purpose of investigating the deaths which occurred at Bilibid prison among some prisoners who were inoculated by Dr. R. P. Strong is now in the hands of the Governor-General. It is generally understood that at least one report is favorable to Dr. Strong.

Progress of Medical Science.

New York Medical Journal, June 15, 1907.

Traumatism as an Etiological Factor in Appendicitis—This subject is considered at length by J. B. Deaver, whose conclusions are thus summarized: (1) From personal experience and from a study of the cases found in the literature the author does not consider that trauma is ever the direct exciting cause of acute appendicitis in a perfectly normal appendix. (2) He believes that an acute attack of appendicitis can follow a severe blow upon the abdomen or fall upon the abdomen, or be due to muscular contractions of the ileopsoas muscle in an appendix which has been previously inflamed only under the following conditions: (*a*) In a latent or residual abscess or extensive pathological lesion of the appendix, where the appendix does not occupy a deep pelvic position, but is in close proximity to the anterior abdominal wall, severe direct traumatism may precipitate an acute attack. (*b*) Strong contractions of the ileopsoas muscle cannot in my opinion be the immediate cause of an acute attack of appendicitis, where the appendix is chronically diseased or where it has extensive pathological lesions, unless it is firmly adherent to and not simply in apposition to the peritoneum overlying this muscle. (*c*) The degree of traumatism to be a factor in the causation of appendicitis must be direct and of considerable force; such force applied to the right iliac fossa may tear the underlying parietal peritoneum and so simulate an acute attack of appendicitis that only opening the abdomen and exposing the appendix could definitely settle the matter. (3) The acute attack of appendicitis of traumatic origin is observed more frequently in males than in females on account of their more active life and greater liability to injury and strains, and between the ages of ten and twenty-five years. (4) In an appendix previously diseased the liability to an acute attack of appendicitis supervening upon injury is in direct ratio to the degree of injury, and depends entirely upon the pathological changes present in the appendix at the time of injury. (5) He maintains that it is exceedingly rare to find a case of acute appendicitis in which it can be definitely stated that traumatism is the direct exciting factor. This statement is borne out by a review of 1,400 cases. (6) The mortality is very high in these cases, on account of (*a*) the failure to recognize the condition until the disease is well advanced, (*b*) the rapid gangrene and perforation which come on, and (*c*) the delay in operation. (7) The author strongly urges a more careful study of this class of cases, and insists as soon as a diagnosis has been made, upon an immediate operation if the best results are to be attained.

The Bubonic Plague As Seen in Siam.—Some notes are presented by C. S. Braddock, Jr., who was formerly the chief medical inspector of the Siamese Government. The disease presents no peculiarities in the locality named. The author considers that the best work done in checking its ravages in the Far East has been done by the American physicians in the Philippines. In his own attendance on plague cases he always used plenty of coal oil on his shoes, stockings, and leggings, as this kept the infecting fleas away. He also noted that the coolie employees of the oil companies did not contract the disease. The fleas leave an infected scab as soon as the animal dies, and are apt to settle on the pariah dogs. These are fed and petted by children, and among the latter the disease was especially common. One of the most effective measures to stop the disease after all disinfection and sanitation was accomplished was to wash all floors and furniture with crude coal oil, and sprinkle it with a watering pot in large quantities under the houses and over the ground in the vicinity. He never found medicine to be of any use. In the detention camps on his daily morning and evening rounds he always used quinine as a diagnostic agent. On examining suspects and finding any one with fever, either with or without pain or soreness in groin or axilla, he was at once given twenty to thirty grains of quinine at one dose. Six hours later if the fever was less in the slightest degree it was not plague. If the fever was higher it was plague, and the patient was at once sent to the detention hospital. In all of his patients this proved an infallible test.

The X-ray, Ultraviolet-ray, and High Frequency Currents in Diagnosis and Treatment.—S. Tousey gives a general description of these remedial agents from both the physical and therapeutic points of view. He calls attention among other matters to the importance of the proper quality of *x*-ray in therapeutics. He states that the least penetrating rays are arrested and absorbed by the skin. They produce a therapeutical or a pathological effect dependent upon the condition of the skin and the distance, intensity, duration, and frequency of the application. These soft rays, as they are called, are useful in treating eczema, psoriasis, ringworm of the scalp, and some cases of lupus and epithelioma. In some cases the tube may advantageously be regulated so as to produce only soft rays. They are the rays which produce *x*-ray burns, if the exposure is too great. These rays, which would be absorbed by the skin and would cause an *x*-ray burn in case of over exposure, may be arrested by interposing a piece of sole leather between the *x*-ray tube and the patient. Such a shield should always be used when making *x*-ray examinations and in *x*-ray treatment, especially about the face. This has reference to cases in which the tube has a medium degree of vacuum and is giving out rays of various degrees of penetration and in which the rays which are desired are those which will penetrate the flesh and produce a picture or an effect upon the deep tissues. Rays of medium penetration are beneficial in cancer, tuberculosis, leukemia, colitis, rheumatism, neuralgia, glandular swellings, and similar conditions. Rays of very great penetration are of little or no use for therapeutic or radiographic purposes, but overexposure to these will produce a dermatitis or even a periostitis.

Journal of the American Medical Association, June 22, 1907.

Sodium Cacodylate.—S. L. Dawes and H. C. Jackson found that sodium cacodylate could be detected in the urine after hypodermic injection of daily doses of from .050 to .200 gm. within periods ranging from ten to thirty-six days or more, and that organic arsenic was eliminated in two cases under observation in twenty-two and forty-four days respectively. The amount eliminated was small, and personal idiosyncrasy seemed to play a considerable part. The authors feel sure that cacodylic acid is deposited in the tissues. That such large doses are required to produce effects is undoubtedly due to the fact that the drug is only partially decomposed to inorganic arsenic, and the beneficial effects are to be ascribed to a self-regulation and automatic immunity which the organism acquires by the constant presence and new formation of arsenic of the inorganic type in the body. The production of arsenious or arsenic acid in a nascent state is probably not an unimportant factor, as in this condition smaller amounts of the ions become more active and give better results than arsenic given as such per os. It is not impossible, however, that cacodyl or its oxide, which is also produced, may have an action of its own, and not unlike that of the inorganic arsenic compounds. The blood picture when the drug is given is a very constant one. In anemic cases there is always an increase of hemoglobin, usually a small increase of red cells, but little variation in the number of whites; an increase in the percentage of polymorphonuclears and large mononuclears, with a corresponding decrease in the small mononuclears. In nonanemic cases there seems to be no special effect on the hemoglobin or red cells, but there is usually an increase of the polymorphonuclears. Therapeutic results in forty-five cases, including eczema, psoriasis, anemia of different types, Hodgkin's disease, gastralgia, and various neuroses, are reported. Thirty-four patients were cured or very much benefited, eleven were not helped, and two were apparently made worse. In several of the second class the dose used was probably too small and the technique faulty, they being among the first treated with the remedy. The authors' present practice is to dissolve the drug in the syringe with hot water just before injecting, as solutions do not seem to keep well. The effective dose in the reported cases seems to average between 0.05 and 0.15 gm., though very much larger ones were employed in one case of anemia reported.

Typhoid Perforations.—C. D. Selby remarks on the almost uniform fatality of typhoid perforation as compared with the better results obtained in the similar surgical condition of bowel perforation in appendicitis. Of the 400 cases of operation reported in the literature, recovery took place in 25 per cent. Nevertheless, it has been statistically demonstrated that the mortality from typhoid perforation runs from 8,000 to 16,000 annually in the United States. The conclusion inevitably follows that the vast majority of cases are either not diagnosed or diagnosed so late that operation is hopeless. The mitigating circumstances for the physician are that the text-books are not sufficiently definite on the subject; that the accident occurs in a disease with infinite variations in its symptoms, severely testing the diagnostic ability of the medical attendant, the blunted sensibility of the patient rendering subjective symptoms unavailable and frequently also masking, to a great extent, the early objective ones, on which a timely diagnosis depends. Selby points out the various indications and

their value in some detail, but says that, unfortunately, there is no one symptom, nor syndrome, indicating with certainty the existence of perforation. The diagnosis must be based largely on the judgment of the physician, who has watched the case and its variations so attentively that he subconsciously recognizes the changes brought about by the perforation, and the surgeon, seeing the case for the first time, must be guided by the opinion of the physician. But when the three cardinal symptoms—suddenly appearing abdominal pain, rigidity of the muscle wall, and tenderness on pressure—appear in any case of typhoid fever, the assumption is warranted that perforation has occurred, and operation is not only indicated, but demanded.

The "Open Method" Treatment of Cancer.—W. D. Witherbee advocates the treatment of cancer by first enucleating the growth and involved glands, and then, instead of closing the wound, leaving it open to heal by granulation and giving daily *x*-ray treatments until the wound has healed. He claims for this method the advantages of perfect drainage of the whole infected region and the changing of a deep or subcutaneous cancer into a superficial one, which can be more directly attacked by the rays, the value of which in superficial growths has been demonstrated. He has had very favorable results with this method in a number of cases, four of which are reported. The same has been the case in one case of tuberculous ulceration of the skin.

The Lancet, June 8, 1907.

The Nature of Infectivity in Relation to Tumor Growth.—D. A. Welsh says the essence of infection is that bacterial cells have entered the tissues and there begun to multiply. As regards cancer, it may be said that its cells become differentiated at a very early stage and sharply marked off from all other cells of the organism. The growth of cancer cells proceeds independently of and at variance with the requirements of the organism and orderly growth in parent tissue is replaced by the unregulated and disorderly growth of the tumor. Cancer cells grow also independently of one another, particularly at the margin of a cancerous deposit. They are essentially parasites and have the attribute of infectivity. The author declares that all growths are essentially malignant and that the so-called benign tumors represent merely a difference in degree and not in kind. Clinically, malignant growths are made up of cells whose infective capacity is high, whereas benign growths are made up of cells of low infective capacity. Cancer cells are endowed with great vitality and longevity. They appear to possess a reserve of vital energy in excess of that retained by the natural tissues of the body. In their growth they appear to be free from the laws governing the growth of tissues in general. Certain forms of nuclear division appear early in cancer cells. Such nuclear divisions are found only in cells of reproduction tissues preliminary to maturation (and in leucocytes) and nuclear exchanges take place between wandering leucocytes and developing cancer cells. Is there any condition, asks the author, which might predispose a group of tissue cells to assume the character of reproductive cells? As a matter of fact, there is evidence that two conditions are commonly present—one general and the other local—both of which may possibly influence this transformation. The general condition is a chemical change in the reaction of the body fluids. It has been shown that developing cells may be induced to undergo increased and abnormal nuclear divisions when the chemical reaction of their environment is altered and when, in particular, the alkalinity of the medium is increased, and there is evidence that the body fluids of a cancer patient commonly exhibit this increased alkalinity. Hence it may at least be said that the body fluids of a cancerous subject are commonly in a condition which independent biological research has shown to be favorable to abnormal nuclear transformations.

Two Cases of Infection by the Paratyphoid B. Bacillus.—The cases are reported by E. A. Gates. In case 1, that of a woman of 54 years, there was a continued fever with four relapses, venous thrombosis, acute bronchitis, cholecystitis, lentigines, and agglutinative reaction, with paratyphoid *B. bacillus*. Recovery followed. Case 2, a young woman of 21 years, the daughter of the foregoing patient, presented catarrhal jaundice, slight fever, and the agglutinative reaction. This patient also recovered.

Ligature of the Renal Vessels by the Transperitoneal Method for the Cure of Persistent Urinary Fistula.—One case is reported by M. P. Holt. His patient was a sturdy young man who nine months previously had sustained a rupture of the left kidney from a kick at football. His very short subcostal space was filled with scar tissue and a sinus through which pus and urine were freely discharged. Concerning the technical feature of the operation, the author notes the necessity of a careful search for accessory or abdominal renal afferent vessels. Asepsis can be secured only by avoiding the suppurating area at all costs; this is effected by keeping as far from the kidney as possible and as close to the aorta and vena cava as is safe to apply a ligature. Access to the renal pedicle in abdominal nephrectomy is claimed to be safer when made through the outer layer of the mesocolon by reason of less danger to the colic blood supply; to follow this route, however, would almost certainly open up the septic area, and, moreover, the colon may be found inseparably united to the kidney. In his case no evil resulted from approaching the renal vessels through the inner mesocolic layer, and this notwithstanding that a search was made for possible renal afferent vessels. The advantages claimed for this method are that if it is properly carried out there is little or no risk from hemorrhage, shock, or sepsis. As regards (a) hemorrhage, this method is in great contrast to any form of piecemeal nephrectomy; (b) it is an aseptic operation which nephrectomy would certainly not be; and (c) subcapsular or piecemeal nephrectomy is at best a very severe operation; ligature is not so and shock should not occur; there is inappreciable risk as regards possible damage to the colon or other surrounding organs and serous cavities (septic infection). The author concludes by saying that he would not hesitate to employ renal vessel ligation as a substitute for nephrectomy where this latter operation promised great difficulty and the likelihood of such severe hemorrhage as would suffice to turn the scale between life and death in an exhausted patient. Moreover, as a preliminary to a subsequent nephrectomy (a septic operation) an aseptic ligation of the renal vessels would be sound surgery, though the author claims that nephrectomy would then be unnecessary, as the ligature would be followed by rapid and permanent cure. Ligature of the renal vessels is surely a great improvement on any form of subcapsular piecemeal nephrectomy or morcellement. The former is a simple and the latter a very serious, procedure, and both effect the same result.

British Medical Journal, June 8, 1907.

Asthma Caused by Impacted Tooth.—A. J. Rice Oxley reports the case of a housemaid who went to have some teeth extracted, and took gas rather badly. Directly after she began to have the typical symptoms of asthma, which were relieved by belladonna tincture and the iodides. They continued, however, in varying degrees for nearly eighteen months, when, in a paroxysm of cough, the patient expectorated a fairly large portion of tooth, with immediate relief and permanent cure of the asthmatic attacks.

Treatment of Birth Asphyxia.—J. W. Malini relates that in a recent case the child was born in a state of white asphyxia. He tried the Sylvester and Schultze methods of recuscitation without avail, and then mouth-to-mouth inflation. The child was pale and limp; there was no attempt at respiration, and apparently the heart was not beating; but a little dark blood oozed from the child's untied cord. The baby being wrapped in a warm blanket, he breathed into the mouth and inflated the lungs, and at the same time attempted to compress the heart externally by placing the right thumb parallel to and below the left costal arch, with the fingers extended over the precordia; simultaneously the left hand was applied to the right side of the chest in order to express the air from the lungs. No air appeared to pass into the stomach, but perhaps his hand prevented it. After a few minutes the child's skin flushed and the untied cord had to be secured owing to the commencement of hemorrhage. Natural respiration started after about a quarter of an hour.

Aortic Pressure in Post-Partum Homorrhage.—In a recent case under the care of M. Henry, he relates that after the head had been for one hour on the perineum without making any progress he gave chloroform, applied forceps, and delivered easily. The body followed shortly after. There was very little hemorrhage before the third stage was completed, but the uterus remained flabby and did not contract for about twenty minutes after the second stage. He held it firmly all the time. An enormous gush of blood came away with the placenta, and was followed by a very copious flow. The handy woman who was assisting, and who is accustomed to attend labor cases among the working classes, fainted when she saw such an amount of blood, and he was left to his own resources, as there was no one else in the house. He turned the patient on her back and pressed on the abdominal aorta, which at once controlled the hemorrhage. In about half an hour the

uterus began to contract, and in one hour it was firm and hard. He gave her two or three grains of ergot, when the placenta, which came away entire, was born. The puerperium was satisfactory and the patient is now well, though somewhat anemic.

Complete Vocal Rest During the Sanatorium Treatment of Laryngeal Tuberculosis.—The paper of N. Bardswell and B. Adams is based mainly on six personal cases, the symptoms of which are preserved in tabulated form. Patients on the silent treatment are allowed to take their walks with other patients and to eat at the common table. Care should be taken in choosing companions for silence cases, as on the commonsense of these companions is largely conditioned the ability of the silence patients to maintain the observance of the restrictions under which they are placed. The silence treatment, carried out under the circumstances above referred to, is much less irksome than when the patients are isolated, for by signs and scribbling pads the patients can, to a considerable degree, take part in the conversation and amusements around them. In the cases referred to, the silence treatment carried on for a period of five months, the laryngeal disease immensely improved. Four of the six patients had ulceration of the cords in addition to their congestion. The remaining two had swelling and congestion of the cords, and of the arytenoid mucosa or interarytenoid region. The ulcers all cicatrized in the first group, while the swelling and congestion very much diminshed or greatly cleared up. In the fifth case normal voice was restored after previous hoarseness, while in the sixth case the hoarseness was greatly lessened. In all the cases the laryngeal improvement was associated with great improvement in the lungs and in general health.

Münchener medizinische Wochenschrift, May 28, 1907.

Phimosis as a Cause of General Disturbances.—Witzenhausen says that while attention has already been directed to phimosis as a possible etiological factor in the causation of urinary disturbances and nervous symptoms in children, it has not been recognized to a sufficient degree that other conditions may also be referable to this abnormality of the prepuce. He reports a number of cases in which constipation in infants was relieved by the operation of circumcision, and explains the beneficial effect of the procedure as follows. As a result of the stenosis of the preputial opening the act of urination is rendered difficult and ultimately the bladder is imperfectly emptied, becomes dilated, and a more or less serious state of overflow incontinence results. As a consequence of this the pelvic organs are crowded by the enlarged bladder, the rectum is pressed upon and constipation results. In consequence of this early perversion of function more or less serious and persistent disturbances are caused which may require a long time to subside even after the initial source of the trouble has been relieved by circumcision.

Examinations of the Urine in Practice.—Grube says that the habit of having urinary examinations carried out by others than the attending physician is one that is to be seriously deprecated. It is open to numerous objections, among which are the facts that the patient loses confidence in a physician who does not carry out the examination himself, and then it is not always wise to have the patient know the results of the analysis, as is the case when he is told to take the specimen to a laboratory himself. The author takes the stand that it is not necessary to carry out the elaborate analyses that chemists are in the habit of supplying and states that in practice the most important substances for determination are sugar, albumin, diacetic acid, bile pigment, and indican. Of these the only one that requires quantitative estimation with any great degree of accuracy is the sugar. For this the Pavy method is excellent, but the author describes a still simpler procedure by means of which sufficiently exact results for practice may be obtained. For the albumin determination the rough method of estimating the amount of precipitate resulting from the heat and acid test is practically as satisfactory as the more elaborate analytical methods.

Deutsche medizinische Wochenschrift, May 30, 1907.

The Technique of Symphyseotomy and Hebosteotomy.—Sellheim, under the latter terms, designates what is usually spoken of as hebotomy or pubiotomy. He describes the various misadventures that may assail the operator in performing the operation, such as snapping of the saw, uncontrollable hemorrhage, cutting through only one ramus of the pubis, omission to cut through the ligaments, etc. He emphasizes the fact that the inexperienced operator is likely to encounter many difficulties and suggests that theoretical instruction, watching others operate, and operating on the cadaver, be supplemented by operations on the living body of an animal. For this purpose the sheep is particularly suitable, as the dimensions of the anterior part of its pelvis and other anatomical considerations render it in this regard particularly similar to the human female. The inguinal region is not excessively fatty and the vagina is sufficiently spacious to allow the necessary control of the steps of the operation from this direction. The time during which the animal lies unconscious as the result of the violent blow on the head given it by the butcher before slaughtering may be utilized for the performance of the operation, and the condition of the parts may be accurately studied at the subsequent dismemberment of the animal.

The Use of the Murphy Button in the Large Intestine.—Vogel says that while the Murphy button may safely be employed in operations about the stomach and small intestine, its use in dealing with conditions in the large intestine, particularly its lower part, should be avoided. He describes two cases of resection of the splenic flexure in which the Murphy button was used, but in which a fatal termination was caused through the formation of a fecal abscess about the anastomosis. In the one case the intestinal stumps were united end to end and in the other a lateral anastomosis was done. In each instance the perforation was found in the same relative position, viz., just at the point where the intestine passed over the rounded shoulder of the proximal half of the button. The lumen of the button was completely occluded by a plug of feces. The author considers that as a result of this obstruction the proximal intestine becomes much distended and the pressure of the gut against the button leads to necrosis and perforation.

French and Italian Journals.

Therapeutic Indications in Cancer of the Uterus Complicating Pregnancy.—Oui considers the influence of cancer of the uterus on the course of pregnancy and the life of the fetus, as well as the effect of pregnancy on the development of the cancer. The author considers it very doubtful whether pregnancy does in reality cause a more rapid development of the cancer. The mortality of the mothers after labor is not from the presence of a rapidly developed cancer, but from puerperal infection. The infant is sacrificed in about one-quarter of the cases, but this might in many cases be prevented by a cesarean section done before the child had been exhausted by prolonged labor. In inoperable cases we should not undertake any but palliative treatment, giving to the child the chance of delivery. In operable cases, during the first two months it is justifiable to perform hysterectomy in small cancers that are distinctly limited. Induction of premature labor is useless to the mother and deleterious to the child. Curettage of fungosities with cauterization will in all probability sacrifice the child by producing interruption of the pregnancy. If the pregnancy has reached term and the cervix is little involved it may dilate, and delivery take place normally. If the cervix is rigid a cesarean section should be done early enough to save the child, and in inoperable cases a Porro operation done at once will prolong the life of the mother. In operable cases an immediate hysterectomy should be done, thus removing at once the growth and the source of infection.—*Annales de Gynécologie et d'Obstetrique*, April, 1907.

Prolonged Retention of the Ovum after Abortion.—R. Garipuy states that complete or partial retention of the ovum after abortion has been threatened forms a condition that is exceedingly difficult of diagnosis. The placenta alone may be retained, and hemorrhage and infection may both be absent. The placenta not being separated, the circulation is maintained and no changes may go on, or there may be a gradual transformation into a malignant growth. Again, the placenta may be eliminated in pieces at stool without the knowledge of the patient. If the entire ovum is retained it will be expelled intact without any transformation. The uterus will close on the ovum as if it were alive, there being absolutely no symptoms to guide the diagnostician. If pregnancy has been previously diagnosticated, this is an aid in diagnosis, but if there has never been any examination made previously the diagnosis is still more obscure. There is no hemorrhage and no pain or contractions. The cervix may be closed, and there may be little modification in form of the uterus. The only reliable sign is the consistency of the uterus, which an experienced touch will reveal. It is neither of the peculiar softness of pregnancy nor of the normal hardness, but of a consistency between the two. Metritis and subinvolution must be differentiated, but in them there is generally some tenderness. It is justifiable, having excluded pregnancy, to dilate the cervix and remove all that is found in the uterus.—*La Presse Médicale*, April 24, 1907.

Twenty-second Annual Meeting, Held in Washington, D.C., May 7, 8 and 9, 1907, in Conjunction With the Congress of American Physicians and Surgeons.

FRANCIS P. KINNICUTT, M.D., NEW YORK, PRESIDENT, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 837.)

Thursday, May 9—Third Day.

Pathological Anatomy of Lymphosarcoma; Its Status with Relation to Hodgkin's Disease.—Dr. W. G. MACCALLUM of Baltimore, Md., discussed in this paper the status of lymphosarcoma in relation to Hodgkin's disease. A fairly constant and characteristic histological picture had been shown by the study of a series of cases of lymphosarcoma. This had been described by Kundrat and others. This histological picture, together with the mode of origin and distribution of the new tissue, and with the examination of the blood, made it possible to arrive at a definite diagnosis of the condition. It might be distinguished from true sarcomata on the one hand, and from lymphatic leukemia and the lymphosarcomatosis of Sternberg on the other. The histological description of the lesions of Hodgkin's disease given by Dr. Reed rendered it easy to differentiate lymphosarcoma from that condition. Of six cases studied at Johns Hopkins Hospital three agreed fully with what Dr. Reed had said in his paper. He detailed briefly the histories of these cases.

Dr. H. A. CHRISTIAN of Boston thought the distinction which Dr. MacCallum, Dr. Reed, and others had drawn between lymphosarcoma and Hodgkin's disease was rather sharper than could be applied clinically. Hodgkin's disease, as described by Reed, was a perfectly definite entity, but from the clinical point of view this distinction could not be borne out. In 1895, at the Boston General Hospital, he saw a number of cases which clinically were Hodgkin's disease, but none of these had the cytological characters described by Reed and others. There were border-line cases and others which were closely related to the leukemia group.

Dr. MACCALLUM, in closing the discussion, said that he had hardly seen a case in which the appearance and distribution of the lesion resembled that of Hodgkin's disease which did not, upon microscopic examination, differ materially from it, and he had no hesitation in making the distinction. He had not seen a case in which the cytological features were like those of Hodgkin's disease which did not resemble it clinically. Lymphosarcoma, as he had seen it, was always sharply differentiated.

Chylous Ascites and Chylous Pleurisy in a Case of Lymphocytoma Involving the Thoracic Duct.—Dr. GEORGE DOCK of Ann Arbor, Mich, read this paper, in which he detailed briefly the history of a case, under observation only for a short time, in which there were chylous exudates in the peritoneum and pleural cavities. There was moderate enlargement of the superficial lymphatic glands. A tumor mass, resembling an enlarged spleen, filled half the abdomen, and there were other smaller abdominal tumors. There was a relative increase of lymphocytes in the blood. Autopsy revealed the following: Lymphocytoma ("lymphosarcoma"), causing enormous thickening of the thoracic duct; a large mass in the abdomen of similar tissue, filling the mesentery; lymphocytomatous change in numerous abdominal and superficial glands.

Dr. W. G. MACCALLUM of Baltimore, Md., said this case fell very well into the class of leukosarcoma. He cited two cases and emphasized the importance of systematic classification of these cases.

Dr. ALFRED S. WARTHIN of Ann Arbor, Mich, had seen four cases of lymphosarcoma which, followed out several years, became leukemic. He took issue with Dr. MacCallum in his attempt to differentiate between cases of the large-celled type and those of the lymphoid type, citing a list of thirty-seven cases. He had also had interesting cases of the myeloid type.

The Histological Lesions in Experimental Glanders. Dr. C. W. DUVAL of Montreal, Canada, in this paper reviewed the opinions held by different authors as to the cytogenesis of glanders, and presented a series of lantern-slide sections from the pathological and bacteriological laboratories of McGill University showing the various lesions produced by the glanders bacillus. He called attention to the analogy between the proliferative changes produced by the glanders bacillus and miliary tubercle.

Dr. W. G. MACCALLUM of Baltimore, Md., cited a case which died of pneumonia in which the cytological study showed the glanders bacillus, and showed that the lesions in the lungs were those of bronchopneumonia.

Multiple Myeloma; the Histological Comparison of Six Cases.—Dr. HENRY A. CHRISTIAN of Boston presented this paper, illustrating it with lantern slides. He said the cells in myelomata are premyelocytes, myelocytes, lymphocytes, plasma cells, or erythroblasts according to the interpretation of the individual observer. Almost all agreed that myelomata form a distinct class of tumor and have their origin from the bone marrow. These differences of opinion as to the nature of the tumor cells must have arisen either from the fact that a variety of tumors are included under the term myeloma, or from the fact that different observers have assigned different origins to cells possessing similar histological characteristics. The latter explanation seemed preferable. Few observers had studied as many as two cases. He had compared six cases, finding that they possessed many characteristics in common, and that there were minor individual differences, which, however, were no greater than occur in individnal examples of other tumor groups. The tumor originated from cells of the bone marrow. In normal bone marrow a few cells occurred which bore close resemblance to the cells of these six myelomata, and could be regarded as the ancestral cell from which the tumor cells originated. It did not seem possible to exactly determine the nature of this cell type. It bore a strong resemblance to a plasma cell, but presented certain differences. The latter were prominent in some of the tumors. There was no evidence of an erythroblastic origin.

Typhoid Endaortitis.—Dr. ALFRED S. WARTHIN of Ann Arbor, Mich., in this paper, detailed two cases which he had carefully studied. The gross lesion was what is usually called fatty degeneration, and in each case these areas corresponded to the axis of the vessel. The changes in the aorta showed the various stages of arteriosclerosis. In many of the areas it was possible to demonstrate bacilli corresponding to typhoid bacilli. A number of lantern slides were shown, and in only a few of the sections did the lesion extend through the intima and involve the media.

The Antagonistic Action of Alcohol and Carbolic Acid.—Dr. ALONZO ENGLEHART TAYLOR of Berkeley, Cal., said, in this communication, that the statement commonly made, to the effect that alcohol exerts an antagonistic action upon carbolic acid, might be tested directly by the following procedure: The antiseptic action of carbolic acid is employed as the medium of measurement. A yeast, known to be tolerant to alcohol up to a concentration of nearly fifteen per cent., serves as the object of the experiment. By the froth of this yeast upon a standard solution of sugar, with relative and varying quantities of carbolic acid and alcohol, the measurement

of the carbonic acid evolved in the fermentation will be the index of the activity of the yeast and, conversely, of the action of the carbolic acid upon the yeast, and of the effect of the alcohol upon the antiseptic influence of the carbolic acid. The experiment indicated that alcohol has no direct antagonistic action to carbolic acid; it does not lessen the antiseptic action of carbolic acid.

Dr. T. Sollmon of Cleveland, Ohio, said that alcohol favored absorption, its action being not physical, but physiological, and that carbolic acid was slightly more toxic in the presence of alcohol.

Demonstration of Large Phagocytic Cells from the Circulating Blood.—Dr. H. A. Christian, for Dr. F. Van Nuys of Boston, Mass., presented pictures of these cells. The patient from whom the blood was taken was a Russian Jew, who was suffering from aortic insufficiency, bronchitis, and a tumor. It was not known whether the cells originated from the tumor or from some leukemic condition. The cells were interesting in that they varied from ten thousand to ninety-eight thousand in twenty-four hours.

Dr. Richard C. Cabot of Boston, Mass., cited another case which Dr. Van Nuys will report later. This patient was a Russian Jew, suffering from aortic regurgitation, but with no evidence of tumor. The variation in the blood count was the result of technique. The high counts were from the ear, not from the finger or toe, being eighty thousand from the ear and ten thousand from the finger. Just why there should be such an enormous difference between the ear and any other part of the body was not known. The ear itself was perfectly normal.

Unclassifiable Fevers.—Dr. James Tyson of Philadelphia, Pa., presented short reports of a few typical cases, illustrating the difficulty in classification which grows out of the occurrence of certain cases of fever which do not meet the requirements of a diagnosis for typhoid fever, influenza, malarial fever, or other fever due to discoverable irritative causes.

A Contribution to the Study of Long Continued Fevers.—Dr. Herbert C. Moffitt of San Francisco, Cal., detailed in this paper the history of a woman, forty-seven years of age, in whom recurrent fever had been the chief symptom over a period of ten months. The attacks at first were of a few days' duration, separated by an interval of ten to fourteen days of apparent perfect health. Subsequently the periods of fever lasted for twenty-two days, with an interval of seven days, and finally fever of remittent-intermittent type lasted for twenty-seven days. There were occasional chills and frequent sweats. A history of lues thirteen years before was obtained, of cough every winter for ten years, of an appendix operation eight years before, of several attacks of abdominal pain in the last two years, suggesting cholelithiasis. The patient had traveled extensively during the past three years. During the first attacks there was aching in the muscles and bones, but later no symptoms were manifest other than fever and weakness. The temperature was chiefly remittent, occasionally intermittent, 103° or 104° in the afternoon hours. There was evidence of an old process, slight, at both apices. Extreme myosis was evident, the pupils were irregular, reaction to light very slow. No other signs of lues. The heart was markedly dilated, and a systolic murmur was heard over the precordia. No glands palpable; spleen never palpated. Abdomen distended; no tenderness. No pigmentation. There was a peculiar enlargement of the liver upward; the edge not felt. Dullness at fourth rib, and at angle of scapula behind. Moderate secondary anemia; leukopenia 2,600 to 5,500; large mononuclears 9 to 18 per cent.; blood culture negative. Mercury, iodide, and later arsenic, were employed in the treatment. Autopsy revealed the following: Lymphosarcoma of one retroperitoneal gland near the right kidney, multiple nodules in the liver.

Dr. Richard C. Cabot of Boston, Mass., said he had recently gone over the records of the Massachusetts General Hospital with reference to long continued fevers, and had found that over ninety per cent. of fevers of over two weeks' duration fell under one of three heads, viz., typhoid, sepsis, and tuberculosis in one form or another.

Dr. Alfred Stengel of Philadelphia, Pa., cited the case of a young man who had had typhoid fever of several months' almost continuous duration, with slight fluctuations. He had lost fifty or sixty pounds. Previously he had been in perfect health apparently, with no indication for the development of the disease so far as was known. He had emaciated sufficiently for Dr. Stengel to follow up a mass in the abdomen which he thought to be a tumor at the head of the pancreas. The abdomen was opened and a mass of retroperitoneal glands the size of the fist were found. A small nodule was taken, the rest of the mass left, and the abdomen closed. The patient improved, and was seen again two weeks before, having gained sixty pounds in weight. This tumor was slightly palpable at that time. This was a case of retroperitoneal tuberculosis. Dr. Stengel cited a number of other cases.

Dr. S. Weir Mitchell of Philadelphia, Pa., asked if there were not individuals in whom the temperature normally was higher than what is usually attributed as normal to man. He cited a number of cases in which the temperature normal to the individual was higher or lower than the generally accepted normal.

Dr. George Dock of Ann Arbor, Mich, cited a case of a man operated upon for gallstones. The gall-bladder was found to be perfectly normal, but over the surface of the liver were found tumors, thought to be secondary carcinomatous masses. One of the masses was removed and the wound closed. The diagnosis of tuberculosis was made by a pathologist. The man subsequently consulted Dr. Dock, who asked to see the pathological specimens. There was absolutely no obtainable history of syphilis, but upon examination of the specimens Dr. Dock found not tuberculosis and not cancer, but a large gumma. He subsequently obtained from the family physician a history of syphilis eleven years before, when he had treated the patient for a primary sore. Antisyphilitic treatment brought about complete recovery. The case emphasized the importance of old syphilitic lesions, which should be thought of in connection with these cases of long continued fever. He called attention to the still continued use of quinine in long continued recurring fever, which he deprecated.

Dr. W. S. Thayer of Baltimore, Md., cited two cases of recurrent fever diagnosed as typhoid which subsequently proved to be carcinoma of the liver.

Dr. Reginald H. Fitz of Boston, Mass., cited the case of a man, under observation for the last two months, who had recurring attacks of fever. Examination revealed an enormous enlargement of the spleen, moderate abdominal distention, and somewhat symmetrical enlargement of the liver. There was a deficiency in hemoglobin. He had been treated with large doses of quinine and arsenic. During the greater part of the time he had shown no diminution of nutrition, and for the past six months had been at work. The temperature was high and irregular. The diagnosis of splenic pseudoleukemia was suggested.

Dr. Joseph Sailer of Philadelphia, Pa., cited a case in which a woman, thirty years of age, had had chronic relapsing fever for over a year. The causal factor in this instance was a dermoid cyst. The patient made a complete recovery.

Further Studies on the Spirilla of Relapsing Fever.—Dr. F. G. Novy of Ann Arbor, Mich., presented this paper. Since the preparation of the paper at the last meeting of this association, showing the existence of two and possibly three distinct relapsing fevers, several foreign work-

ers had confirmed the specific differences between the *Spirillum Obermeier* and the *Spirillum Duttoni*. The eastern relapsing fever, as met with in Russia and India, was probably equally distinct. The cultivation *in vitro* had not been accomplished, but it was now possible to grow both of these organisms in collodion sacs in the peritoneal cavity of certain animals. Some immunity experiments and further facts relating to the nature of the spirochetes were detailed.

The Measurement of Functional Heart Power.—Dr. Richard C. Cabot of Boston, Mass., presented in this paper the results of his attempts to measure the functional heart power by the methods of Graupner, Herz, and Levy. Direct examination of the heart, that is, by auscultation and percussion, even when supplemented by radioscopy, the study of the pulse and blood pressure movements, revealed but little as to the amount of power possessed by the heart. The evidence of peripheral congestion (lungs, liver, kidneys, stomach, extremities) came relatively late, after the damage which it was desired to prevent had already occurred. The strength of the heart muscle and of the whole circulatory apparatus should be measured early in the course of both functional and organic diseases.

The paper was discussed by Dr. W. S. Thayer of Baltimore, Dr. Charles G. Stockton of Buffalo, N. Y.; Dr. Henry Sewell of Ann Arbor, Mich, and Dr. Cabot closing the discussion.

Observations Upon Certain Reflexes, Lowering Blood Pressure, which Arise from Stimulation of the Inflamed Pleura.—Dr. Joseph A. Capps and Dr. Dean D. Lewis of Chicago detailed in this paper, which was read by Dr. Capps, the results of their experiments along the line indicated by the title of the paper. In healthy dogs it was found that irritation of the pleura by mechanical, chemical, thermal, and electrical stimuli caused very little change in blood pressure. In dogs with artificially produced pleurisy, stimulation of the pleura sometimes gave rise to a marked or even fatal fall in blood pressure. Analogous conditions were seen in man during operation upon the thorax.

Clinical and Pathological Studies of Arteriosclerosis. Dr. W. S. Thayer and Dr. Marshall Fabyan of Baltimore, Md., presented in this communication, read by Dr. Thayer, a study, clinical and pathological, of the radial arteries in forty cases. The distribution of the arteriosclerotic changes in the various cases was given in detail.

Cerebral Types of Arteriosclerosis.—Dr. Alfred Stengel of Philadelphia, Pa., read this paper, in which he discussed the subject under the following heads: (1) Convulsive attacks, local or general, due to cerebral arteriosclerosis with or without thrombosis. (2) Stupor and coma. (3) Psychic manifestations. (4) Differential diagnosis from brain disorders, toxic conditions, and various neuroses. He emphasized the fact that the diagnosis of uremia is exceedingly difficult, and that undoubtedly many cases of supposed uremia, particularly those treated in large hospitals, are not uremia at all, or if uremia the uremia is a terminal condition rather than the principal condition. He believed it to be not uncommon that persons dying slowly from any cause may become uremic at the end. This would apply to persons with arteriosclerosis. Just before death uremia might develop, in proportion, of course, as the kidneys had been affected by the preceding disease. The same might be said of gastrointestinal troubles.

Further Studies on Experimental Arteriosclerosis.—Dr. I. Adler and Dr. O. Hensel presented in this paper, which was read by Dr. Adler, the results of further experiments with nicotine, alone and in combination with other substances. The total material employed in these experiments consisted of ninety rabbits, which were treated with nicotine in various combinations; of these there were only twelve which showed macroscopic lesions.

Dr. Henry Sewall of Ann Arbor, Mich., in discussing the three papers on arteriosclerosis, asked what part of the arterial system was involved specifically, if there was a specific local involvement in producing the functional changes which depend upon arterial elasticity and its loss —in other words, what is arteriosclerosis?

Dr. A. Jacobi of New York City said just what it meant could not be decided in every case. Arteriosclerosis might be in the brain, it might be renal; it would never be a uniform process. He called attention to one symptom of senility which he had long noted, and which was perhaps less intellectual than moral, viz., a sudden change of temperament. In a person of advanced age a sudden, marked change of temperament was certainly indicative of arteriosclerosis of the brain, and meant approaching death.

The three papers were further discussed by Dr. Joseph Weaver and Dr. Joseph Sailer, and the discussion closed by the readers thereof.

Motor Insufficiency Due to Perigastric and Duodenal Adhesions.—Dr. Frank Billings of Chicago presented this contribution. Among the causes of perigastric and duodenal adhesions might be mentioned infection of the stomach, duodenum, or some neighboring organ or organs, most frequently the gall-bladder; chronic ulcer of the stomach; surgical procedure, etc. Of these the most important might be said to be the gall-bladder, second, surgical procedure, third, ulcer of the stomach. He outlined the methods of detecting disturbed motility resulting from these conditions, and suggested that the indications for treatment pointed to processes underlying the condition.

Dr. J. H. Musser of Philadelphia, Pa., cited three cases of pyloric and duodenal obstruction, with vomiting, occurring in early convalescence from typhoid fever.

Gastric Disturbances Associated with the Presence of an Excess of Acid.—Dr. Joseph Sailer of Philadelphia, Pa., in this paper outlined the methods of determining approximately the total quantity of hydrochloric acid secreted by the stomach, and the distinction between actual and relative excess. He also spoke of the irritability of the secretory apparatus of the stomach; excessive secretion, associated with hypermotility, approximately normal motility, and retention; and the apparent excess of hydrochloric acid, found in cases of retention of the stomach contents.

On the Lenhartz Treatment of Gastric Ulcer and Hyperchlorhydria.—Dr. S. W. Lambert of New York City gave in this paper some of the practical objections to the older methods of treatment, and the principles upon which the Lenhartz treatment is founded. He detailed briefly the method of Lenhartz, discussing some of the special points of interest in cases reported, and the conclusions to be drawn therefrom, the claims advanced by Lenhartz in favor of his method and the relation of the method to surgical treatment.

The Effect on Blood Pressure of Nauheim Baths in Various Types of Heart Disease.—Dr. Philip King Brown of San Francisco, Cal., presented statistical results showing that, contrary to the accepted view at Bad Nauheim, blood pressure is raised by the baths, except in cases of very advanced myocarditis, arteriosclerosis, and the arteriosclerotic renal conditions. The conditions under which the blood pressure may be increased or lowered by the treatment were detailed.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 22, 1907.

The President, Dr. Walter Lester Carr, in the Chair.

Cardiac Hydrothorax. Report of a Case Aspirated 311 Times.—Dr. W. Travis Gibb reported this case, which was interesting on account of the large number of times the man's chest was aspirated and the enormous quantity

of serum withdrawn in a comparatively short space of time. The patient was a physician, forty-six years old, not in active practice, and who had always led a fairly active, more or less outdoor life, and, while not in robust health, had never had any serious illness. At the age of twenty he discovered that his urine contained a small percentage of albumin. At twenty-five years of age he contracted syphilis. His family history was excellent. When Dr. Gibb first examined him in 1903 he found the heart greatly hypertrophied with obstructive murmurs at both mitral and aortic valves. There was no fluid in the chest or abdomen at that time. The urine contained .5 per cent. of albumin and a few hyaline casts. During the summer of 1903 and 1904 he sailed a small yacht, and on several occasions, especially in 1904, he was in considerable danger and compelled to overexert himself. Shortly after a particularly severe exertion, when his boat went ashore in a storm, dyspnea on the slightest exertion began to develop, his feet and legs became edematous, and he found a small amount of fluid in both pleural cavities. His condition became rapidly worse, the fluid in his chest increased, ascites appeared, and the edema reached his buttocks. He aspirated the chest for the first time October 15, 1904, and from that time until he died on May 19, 1906 (580 days), he aspirated his chest 311 times, averaging one aspiration every 1.9 days for the entire nineteen months. The total amount of fluid withdrawn was 10,690 ounces, or about 83 gallons, weighing nearly 700 pounds. The amount of fluid withdrawn at each aspiration varied from 12 to 110 ounces, averaging 34 ounces. There was an average daily loss through this channel of about 19½ ounces. As he averaged less than 16 ounces of urine each day, he passed more fluid through the aspirating needle than through his kidneys. The patient's average weight throughout his illness was about 140 pounds, and as he withdrew about 700 pounds of fluid from his chest in nineteen months, there was a loss through this channel of an amount equal to his body weight every 118 days. Of the last 200 tappings, 103 were on the left and 97 on the right side. The 103 left side tappings yielded about 3,100 ounces, an average of 30 ounces, and the 97 right side tapping yielded about 2,700 ounces, an average of almost 28 ounces for each tapping. These frequent operations were of necessity a great tax upon his time, but he found that by simplifying and systematizing the procedure he could sterilize the instruments, his hands, and the site of puncture, and complete the tapping in about twenty-five minutes, at the same time doing the operation aseptically. Although the chest wall was punctured more than 400 times there never was the slightest evidence of infection. So far as he could ascertain from the medical literature at his disposal, this record of 311 aspirations of the pleural cavities, with the withdrawal of 10,690 ounces of serum in nineteen months, was one which had never been surpassed.

Heart Disease Complicating the Infectious Diseases of Infancy and Childhood.—Dr. Henry Koplik read this paper. He said that it should be recognized at the outset that in infancy and childhood the peculiar conditions, anatomical and dynamic, made the heart a favorite object of attack in any infectious conditions. That organ was working under a constant physiological strain; its larger size, as compared to the body weight, seemed one of the provisions of nature to meet the great excess of energy put forth with every bodily movement at this period of life. The greater activity of this organ in a normal state was still greater in conditions of disease. The very anatomical and dynamic conditions peculiar to the heart in infants and childhood made a diagnosis of lesions much more difficult than at a later period of life, especially in young infants the differentiation of certain rare murmurs as to their congenital or acquired origin. The myocardium was peculiarly open to attack in the acute infectious diseases, and in a much more dangerous manner than either the peri- or endocardium. In preparing his paper Dr. Koplik studied a group of 100 cases of cardiac disease, valvular in character, occurring in his hospital service. Sixty-two per cent. of the cases were rheumatic; with these rheumatic cases there was concomitant chorea in four. Thus the exanthemata could not be considered as a potent factor in the causation of valvulitis in children. In passing through the latest report of the scarlet fever hospital, the absence of valvular cardiac affection in some 300 cases was striking. On the other hand, affections of the heart muscle in conditions of profound sepsis was frequent. Even in mild or moderately severe cases of the exanthemata, it was quite common to obtain murmurs over the pulmonic and at the apex, which subsequently disappeared, and which might partly have been due to a relative insufficiency, as well as hemic in origin. These murmurs were also frequent in other infectious diseases, such as typhoid fever. In the severe states of toxemia, as in a complicating peritonitis of typhoid fever, the myocardial infection was quite marked. Valvulitis or pericarditis were uncommon in typhoid fever as they were in the exanthemata. The grippal or catarrhal infections of the tonsils and nasopharynx were often the starting point of the severer affections of the heart. Of the 100 cases of cardiac disease a distinct history of a tonsillitis preceding the invasion of the joint and endocardial disease was found in 13; in many others there was a history in the past of repeated attacks of tonsillitis. Among the infectious diseases pneumonia had attracted most unexpected attention as a causative agent in endocardial affections. Cases of endocarditis occurring in the course of pneumonia had been published and had been said to originate in a pneumococcus, or a strepto- or staphylococcus infection, originating from the brachial nodes. It was quite common in children to find, after a pneumonia had run its course, an affection of the myocardium manifested in cardiac weakness. The innervation of the myocardium was affected, and cases of so-called infectious or toxic bradycardia were not infrequent. He had never seen attacks of syncope or tachycardia or cardiac paralysis similar to what was so much feared in diphtheria. Many cases in infants failed to rally at the lysis or crisis because the heart muscle had become overwhelmed with the poison of the disease, and failed the patient at the most needed period. Of all the diseases pneumonia placed the greatest tax upon the heart. A pneumonic endocarditis was infrequent in children. That the malignant forms of endocarditis, with all the septic and pyemic symptoms described by Litten in the adult, did occur in children, he showed by citing a case. It followed and complicated an unresolved pneumonia. In closing, he said that it was striking that in the exanthemata the fevers, such as typhoid fever, the endocardium, and thus the valvular apparatus, should escape injury, whereas the myocardium bore most of the burden of the toxemic infections. The explanation of this was that, with the exception of scarlet fever, bacteriemia was uncommon in these diseases, and the endo- and pericardium was not as susceptible to infections as in other conditions, such as grippe and pneumonia.

The Heart in Infectious Diseases; Adult Life.—Dr. C. H. B. Camac presented this communication. He said that Dr. Koplik, in treating this subject in its relation to childhood, with his extensive clinical experience, had given them much information applicable to the adult life, as well as that of childhood. In the brief time in which it was possible to speak, Dr. Camac said it would be practical to treat of but one aspect of this broad subject. The child, having passed through a cardiac complication in an infectious disease under the care of a pediatrician, came to the internist in adult or early adult life. The questions which were of paramount importance were the mechanism of *compensation* and the integrity of those structures by which this was accomplished. Compensation was, therefore, the part of the subject Dr. Camac selected for consideration.

The Vascular System as a Factor in Compensation.—In analyzing 799 autopsy records at the New

York Foundling Asylum (the opportunity having been afforded by the courtesy of Drs. Bishop, Bovaird, and Mathias Nicoll), the writer found not a single case of vascular disease in children under ten years of age. In childhood the healthy vascular system, together with a greater reserve force in the heart muscle, was a great factor in aiding compensation. The vascular and cardiac systems should be considered *as one*. In adult life the condition of the vascular system in the question of compensation *should be our first consideration*.

Part of the Heart Involved; Power of Compensation Varied According to Part Involved.—While the vascular system and heart should be considered as one, the pericardium, myocardium, and endocardium should be considered separately owing to the great diversity of compensating power, as one or the other of these was the seat of disease. Dr. Camac here reviewed the anatomical arrangement of these structures, showing the relation of the diaphragm and pleura with the *pericardium*, and therefore the greater tendency of the latter to become infected in pleurisy and pneumonia. The *endocardium*, including the valves, being continuous with the intima of the blood-vessels, was more exposed to bacterial infection circulating in the blood. He showed preparations of the sheep's heart, demonstrating the complete separation between auricles and ventricles, except for the bundle of His, and the continuous "S"-shaped arrangement of the ventricular muscles. This unity of the right and left side of the heart was a very important feature of the *myocardium*, which if involved proved the most incapable of compensation.

Diseases Which Show a Selective Power Over These Portions of the Heart.—Dr. Camac here gave a clinical subdivision of the infectious diseases in accordance with their present knowledge of their etiology. These were grouped under the three following main headings:

(1) Rheumatic group; (2) septic group; (3) infectious diseases not included in (1) and (2), keeping in mind that (a) power of compensation differed according to the part of heart involved, and that (b) diseases showed tendency to select various parts of heart. Clinical experience gave the following:

Pericardium—Rheumatic group. Pneumonia—relative to extent of lung involved, and whether right or left lobes. Scarlet fever.

Endocardium—Including valves, benign, malignant. Common—Septic group, scarlet fever, rheumatic group. Uncommon—Diphtheria, typhoid, tuberculosis. Rare—Smallpox, measles, chickenpox.

Myocardium—Typhoid, diphtheria, tuberculosis, scarlet fever.

It was this last group which compensated least thoroughly. In the pericardial and endocardial group, compensation was usually good and of long standing. Fatal cases in these latter, as a rule, were due to the severity of the infection, and not to heart failure. Dr. Camac then illustrated on the blackboard the histological changes which took place in the myocardium. These in the fatal cases were usually diffuse, in those which reach adult life they were focal and militated against compensation, being often the direct cause of fatal heart failure.

The Rate, Rhythm, and Intensity as Index of Compensatory Power.—These were considered and Professor Wenckeback's admirable work on "Arhythmia" referred to.

Relation of Right Heart to Left in Compensation.—The work of McCallum at Johns Hopkins and Haven Emerson at the College of Physicians and Surgeons, New York, was referred to as experimental evidence that the right heart promptly aided the left in establishing equilibrium. Dr. Camac reported six cases followed by him during the past winter, in which this "safety valve action" of the tricuspid valve was directly concerned in maintaining the compensation. Five of these were walking about during this right heart involvement, without detriment. He gave the signs by which tricuspid regurgitation could early be detected. From the anatomical facts demonstrated earlier in this communication, together with the experimental evidence just given, it was clear that we should no longer regard the right and the left heart as separate, but as essentially one structure.

The following summary was then given: In weighing the ability and means of the heart to compensate, (1) heart and vascular system should be considered as one; (2) the pericardium, the endocardium, and the myocardium should be considered as separate structures; (3) the selective power of the infectious diseases for these structures, especially those attacking the myocardium, should be remembered; (4) the unity of the right and left heart should be recognized and the "safety-valve action" of the tricuspid early detected, and nature cooperated with in this effort to establish compensation.

The Treatment of Cardiac Conditions of the Acute Infectious Diseases.—Dr. David Bovaird, Jr., read this paper. He confined his remarks to a consideration of the conditions resulting from changes in the cardiac walls, the condition which they grouped under the heading of myocarditis, including the degenerative or inflammatory changes in the cardiac muscle and in the interstitial tissue of the heart walls. It seemed best to limit himself to the more common diseases, such as measles, scarlet fever, diphtheria, pneumonia, typhoid, and septicemia. The discussion of the subject was taken up under the following heads: (1) Circulatory failure at the height of the acute infectious diseases; (2) cardiac dilatation (acute); (3) bradycardia irregular or intermittent heart action; (4) asystole.

Circulatory Failure at the Height of Infectious Diseases.—Certain observers had studied the effects of infections with pneumococci, diphtheria bacilli, and the *Bacillus pyocyaneus* in various animals. Of these only the diphtheria bacillus produced definite changes in the myocardium, and their careful experiments demonstrated fully that the circulatory failures seen in fatal cases of such infections was the result, not of cardiac failure properly speaking, but of a vasomotor paralysis produced by the effect of the toxins on the vasomotor center in the medulla. The vasomotor paralysis affected especially the vessels of the splanchnic area; the animal, as it were, bled into his own veins, thus depriving the vital parts of an adequate blood supply. The heart failed because of a lack of blood to act upon. To strengthen cardiac action, therefore, one must restore the tone of the vessels, particularly the splanchnics. According to experimental investigations, the remedies most efficient were caffein, camphor, infusion of normal salt solution, and abdominal massage. Although neither caffein nor camphor was readily soluble, both could be given hypodermatically, as was usually required, camphor in the form of a 10 per cent. solution in olive oil, and caffein as a sodiosalicylate made according to Tanret's formula. Dr. Bovaird's own experience with these two remedies had not led him to put great confidence in them. Especially in children were they likely to fail. Theoretically, adrenalin chloride met the indications better than any of the drugs named but its action was very transient and uncertain. H. C. Wood said that he had seen patients who he thought were being killed by trusting to the powers of adrenalin as a circulatory stimulant. Dr. Bovaird had never seen the beneficial effects claimed for adrenalin. The remote dangers, however, of producing atheromatous changes in the arteries should not prevent its use in the crisis of infectious diseases if it had real benefit. All were convinced of the value of normal saline solutions to help the failing circulation but there was good reason for caution in its use in pneumonia else they only added to the burden of an overtaxed right heart. Despite the apparent failure in experimental work the best clinicians still relied upon alcohol, strychnine, and digitalis to meet this circulatory failure of the acute infections. With the value of abdominal massage to improve the tone of the splanchnic

vessels he said he had had no experience. As a substitute for this Forchheimer advised the application of two or three icebags to the abdomen to act upon the abdominal reflexes, increase the blood pressure, and reduce the frequency of systole.

Acute Dilatation of the Heart.—This, resulting from myocardial changes directly, might occur at the height of any of the acute infectious diseases, but it was more frequently seen during the period of convalescence. In most cases it might be avoided by proper care of the patient after the subsidence of the fever, such cases requiring rest in bed until the pulse had been normal for some days. The danger of acute dilatation was greatest from diphtheria. It might come on independently of exertion of any kind. It might occur suddenly with intense symptoms of cardiac failure, increased rapidity of the pulse, but with no marked systemic disturbance. The treatment of this emergency demanded the most rapid and vigorous stimulation of the heart. For this purpose they employed first camphor and ether, and whiskey, given hypodermatically, then strychnine and digitalis. Caffein might also be given, or strong black coffee. Once the crisis of the onset had passed they relied upon the systematic use of strychnine and digitalis. On account of the liability to vomiting in these cases, it was desirable to avoid the administration of any medicine by mouth for some days. As a substitute for the tincture of digitalis, they had used with satisfaction a soluble preparation of digitoxin. The general care of these patients was of the utmost importance. If there was restlessness or pain, morphine or opium was of great help, especially in children. This aided the laboring heart. The convalescence of these patients often presented difficult problems. Often a point was reached where progress ceased. The safest plan was to keep these patients quiet until the heart and pulse returned to normal, and then to gradually allow the patient to get up and about. So long as there were signs of cardiac weakness there was a risk in allowing any liberty, especially in children. After getting up they should be cautioned against unusual exertions.

Irregular or Intermittent Heart Action and Bradycardia.—In certain cases of acute infectious disease the heart action was modified in force and rhythm without increase in the size of the heart, or increase in the pulse rate. In some instances there was a notable slowing, with or without irregularity, the pulse dropping to 50, 40, or even 30 beats per minute. This was most commonly seen during convalescence, and perhaps most frequently met with in diphtheria. The gravity of this disturbance varied greatly. Occurring during the height of diphtheria or pneumonia they excited the greatest alarm. In the convalescence from pneumonia or typhoid fever, bradycardia was quite harmless. In diphtheria, however, any disturbance of the pulse must always be viewed with concern, and every effort made to prevent possible serious cardiac failure. These patients should be managed as carefully as those in which acute dilatation had already occurred, and their convalescence should be watched with the same care. Medication was of secondary importance. If there was faintness or prostration associated with any irregularity, give alcohol, caffein, or strychnine. Digitalis or strophanthus were not of service in these conditions.

Asystole.—The sudden stopping of the heart was a rare climax of the myocardial changes in the acute infectious diseases. It might occur in any of them, but was fortunately infrequent except in diphtheria or pneumonia. The possibility of its occurrence was the final argument of a careful observation of the heart in all cases of acute infectious diseases, and for care in the transition from rest in bed to active effort. The responsibility rested with the patients after they had been warned. Once disaster came there was no opportunity to retrieve it, death being instantaneous.

Dr. A. Jacobi said there was no such thing as a hemic murmur in the very young. He had heard a few murmurs in small babies which he had reason to believe were not organic because, a few years after, they had disappeared without any change in the heart muscle. But they were very rare. When one found a murmur in a baby of one or two years it should not be considered functional, but an organic murmur, or valvular murmur. Later in life, when dealing with murmurs, they knew they might be endocardial in type. What had been said regarding the heart changes in infectious diseases he agreed with, and diphtheria was the worst of all; in this disease it was a common thing to find a myocardial murmur which might last a long time. When it lasted one year the case might be considered as hopeless, for the patient was liable to die of pneumonia or some intercurrent disease. In diagnosing a myocardial from an endocardial murmur an important point was that endocardial murmurs were found posteriorly, but not myocardial murmurs. So far as the myocardial changes were concerned, there was a hyaline degeneration, but no fragmentation; the latter was only found in the dead. There were myocardial changes which resulted in embolic deposits in the heart muscle, the changes in the heart being mostly found in those who had the right to atheromatous degeneration. Adrenalin had but little if any effect when given internally. Since he began teaching in the 60's he employed camphor; it was his standby, and he always carried it in his emergency satchel in solution, one part camphor to four parts sweet almond oil. Camphor might be used in emulsion.

Dr. Beverley Robinson said that in many instances of pneumonia, influenza, diphtheria, acute articular rheumatism, etc., unquestionably at times one could learn by physical examination that there was a certain amount of dilatation of the heart. Sometimes it seemed as if it was limited to the left ventricle. Again it seemed as if the right heart was particularly attacked as in pneumonia. These cases were handled differently. There was one agent he relied upon a great deal, strophanthus. If there was a considerable rise of temperature, the icebag applied locally was of value; but, if there was much depression, the hot water bag. He also relied upon the best alcohol, that was the best brandy. This gave the patient the best fighting chance, especially when there was consolidation of pneumonia. He was confident that if they used more local blood letting, but in a moderate way with children, and more aggressively in adults, over the heart or right lobe of the liver, a flip might be given to the heart's contraction which could not be started in any other way.

Dr. Henry Dwight Chapin said that an irregular and intermitting heart was not a bad condition especially, and was improved often by letting the patient out of bed, while another child would present more distress, even though the physical signs were the same in each case. One child would be improved by getting up; the other not. In his opinion the greatest danger was when the heart became slowed. In one of his cases the heart dropped to 25 beats; invariably these cases were followed by death. In some cases the heart might become suddenly very fast, and these were bad cases as well. When the heart and stomach together were affected, a fatal result was apt to follow, *i.e.* if the pulse was quick and weak, and the child vomited. He emphasized the importance of using morphine in small, nonnarcotic doses; this was a sheet anchor in cases of failing heart. It caught hold of the heart like digitalis and strengthened systole. It controlled the restlessness, particularly in children with weak and irregular hearts.

Dr. Charles E. Nammack said that, judging from his clinical experience, his results were the same as Dr. Koplik's, except in reference to the use of digitalis in the pneumonias of children; in view of its unreliability, he thought it better to use other drugs belonging to the same class as digitalis. He heartily agreed with Dr. Robinson when he said he preferred to use strophanthus in those cases where it seemed that digitalis was indicated. The

heart should not only be studied in the acute and general infections, but the condition of the blood-vessels as well, and the blood pressure in particular. They were too apt to regard the blood-vessels as appendages of the heart, when in truth the heart was an appendage of the blood-vessels. At Bellevue Hospital adrenalin was much used in cases of heart failure; it was used in cases of pulmonary edema and collapse in the acute infectious diseases in which it seemed desirable to raise the blood pressure.

Dr. Bovaird closed the discussion.

College of Physicians of Philadelphia.

At a stated meeting, held May 1, Dr. William L. Rodman presented a communication entitled "Complete Excision of the Tongue by Kocher's Latest Method," and he exhibited a man, 46 years old, from whom he had amputated the tongue for carcinoma of four years' standing, attributed to the irritation caused by a jagged tooth. Dr. Rodman recited the several operations that had been proposed and performed successively for the relief of carcinoma of the tongue, referring especially to ligation of the lingual or external carotid arteries for the control of hemorrhage or the purpose of starving out the growth. In some operations the tongue is approached directly through the mouth; in others an opening is made in the cheek; in still others removal is effected through the floor of the mouth, also resection of the inferior maxilla through the symphysis has been practised. A modification of this last method, extensively practised by Kocher, has yielded admirable results, and it is this operation that Dr. Rodman performed. An incision is made to one side of the median line from the mucous margin of the lip down to the hyoid bone, and, after the removal of one or two teeth, the bone is sawed through in this plane with the aid of a Gigli or a Hay saw. The floor of the mouth is incised through the lingual inversion and the tongue is thus rendered accessible, without division of important muscles or nerves, and the hemorrage is inconsiderable. In Dr. Rodman's case the tongue was divided as far back as possible, after a median incision had shown that the growth could not be included in a hemisection, and removal was effected by means of the thermocautery. There was little bleeding except from the bone. The patient was able to swallow on the day after the operation, and he was soon encouraged to sit up. Primary union took place, except at the point where a drainage tube had been introduced, and the alignment of the teeth was perfect. The danger of aspiration pneumonia, so common after other operations on the tongue, is largely obviated by the operation described by reason of the preservation of important muscles and nerves, rendering swallowing possible early and permitting free use of the stump of the tongue left behind. When glands in the neck are enlarged, as in the case reported, they are removed at a secondary operation. The enlarged glands are to be removed within a day or two. Operating in two stages is to be preferred to making so large an incision as would be required in a single operation, with the resulting grave dangers of infection and imperfect union. In the case exhibited union ensued without complication, and the result, in so far as it has gone, has been excellent.

Subinvolution of the Uterus.—Dr. Joseph B. De Lee advises the following to prevent subinvolution of the uterus: Avoid sepsis; conduct the labor with the same antiseptic precautions that one uses in laparotomies. Leave the case to nature as much as possible. Avoid practices to shorten the duration of normal labors. Avoid lacerations of the cervix; repair them if deep or if they bleed; repair the torn perineum accurately. Leave the uterus empty of clots, membrane, and placenta; therefore conduct the third stage of labor properly. If the uterus does not decrease in size rapidly in the early puerperium, give ergot. Don't allow the patient to lie on her back too long. Build up the general system.—*Southern Medicine and Surgery.*

Surgical Suggestions.

Induction of Labor.—Joseph B. Cooke recommends for this purpose in the case of a multigravida with short, softened, and dilated cervix, so-called expansion rings, which the obstetrician can easily make for himself. The appliance consists simply of a soft rubber catheter with the tip cut off, into which is passed a long spiral watch spring of the cheaper grade. This forms a circle when in place, and the approximate ends of the catheter are sewn together. When boiled the instrument is sterile and ready for use. It is then pinched up at one point and tied with bobbin tape, in a bowknot, with short loops and long ends, and grasped with a bullet forceps. The anterior lip of the cervix is now drawn down and held by an assistant or nurse, and the constricted segment of the ring, guided by the fingers of the left hand of the operator, is introduced by means of the bullet forceps into the cervix and just through the internal os. The nurse now pulls on the long end of the tape, unties the knot, and releases the spring. The operator, still holding the bullet forceps firmly in place while the anterior cervical lip is steadied by the nurse, grasps one side of the ring between his thumb and forefinger and pushes it slowly and gently into the uterus, until about half has passed the internal os. This is accomplished without pain or discomfort to the patient and with absolutely no danger of rupturing the membranes. When the ring is in place, in the form of a figure 8, with its greatest constriction at the level of the internal *os uteri* the vagina is packed with gauze and labor may be expected to begin within a few hours or even minutes. It is well to attach a tape to the vaginal portion of the ring, lest it work its way into the uterine cavity.—*American Journal of Obstetrics.*

Turpentine for the Hands.—Pure turpentine is a strong antiseptic and is very useful in cleaning the hands for operation, when one cannot use the permanganate of potassium and oxalic acid method (which ought to be employed when one has recently had the hands in pus and yet must operate). It is generally used improperly. The correct procedure is to scrub the hands with soft soap and warm water—running water if possible; if not, the bowl emptied and refilled at least twice—for at least five minutes; then to dry the hands thoroughly upon a clean, (but not necessarily sterile) towel; and then to cut the finger nails "to the quick." The turpentine is then poured over the hands and rubbed in thoroughly around the roots and ends of the nails and between the fingers, two minutes at least being devoted to this. Finally the hands and fingernails are to be scrubbed in soap and clean warm water and then soaked two minutes (by the watch) in 65 per cent. alcohol. They are then ready for immersion in the 1 to 2,000 sublimate solution.—*American Journal of Clinical Medicine.*

Tracheotomy.—Many valuable lives have been lost by the practice of sucking a tracheotomy wound in cases of emergency; but there can hardly be any case in which a surgeon is justified in resorting to such a dangerous method, which is almost certain to infect him with a very serious disease. The immediate dangers of a tracheotomy always seem greater than they are in reality. Even when the patient has ceased to breathe during the operation, the opening of the trachea with all convenient speed and the subsequent performance of artificial respiration, without attempting to introduce a tube, but merely with the edges of the trachea held apart, nearly always restore the patient to life. Blood can be prevented from entering the trachea by making the opening in it sufficiently large and bringing it up to the edges of the skin incision at once. Blockage of the tube by membrane is more difficult to treat, but it is generally sufficient to remove the membrance with a feather and to pick it out with a pair of laryngeal forceps.—*The Hospital.*

Surgical Observations in Manchuria.—From practical experience in the Russo-Japanese war, von Manteuffel of Dorpat would operate in neck wounds for hemorrhage only. In the thorax await effusion, and then in evacuating do it gradually, as otherwise infection may be sucked from the lung. Wounds of heart, "touch not." Manteuffel has seen seven shot wounds of heart heal smoothly. The spine gives nothing new; only the old, gloomy picture. In transverse palsy do not operate. If the palsy is not exactly transverse but irregular, laminectomy may be done. Improvements were few. Generally one should await possible absorption of blood clot. Shrapnel wounds are generally infected. Bladder wounds heal smoothly. With the extremities, follow the old von Bergmann precept—do not disturb and plaster-of-Paris at once; this is established by both positive and negative trials.—*Annals of Surgery.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

INDEX.

A

Abdominal quadrant, the right upper, 690; suppuration, left sided, 921.
Abortionists, decision regarding, 736.
Abscess, intraabdominal complicating pregnancy, 396; of the liver, 736; puncture and disinfection for, 828; the diagnosis of subphrenic, 914.
Absinthe, to be tabooed in France, 528.
Academy of Medicine, reminiscences of practitioners in New York during the early history of the, 129, 161.
Acetone in the urine, tests for, 619.
Acetonuria in children, 817.
Acid fasts, what are? 1027; intoxications, 289; or acidosis a factor in disease, 895.
Acne keratosa, 415.
Addison's disease, suprarenal extract in, 128.
Adenoids in infancy, 1010.
Adrenalin in renal hematuria, 868; therapeutic applications of, 875.
Aerotherapy in cold weather, 1053.
Air, fresh, treatment in hospital wards, 213, 246; passages, diseases of the upper, in relation to life assurance, 952.
Albuminuria, functional in athletes, 146, 158; juvenile physiological, 367; prostatic and seminal, 112; orthostatic, 654; postural, 188.
Alcohol and carbonic acid, the antagonistic action of, 1087; in the treatment of diabetics, 315; its relation to degeneracy, 241; the physiological action of, 241.
Alcoholism, speed mania and objectless activities, 481.
Alexander-Adam's operation, the, 702.
Alimentary canal, Röntgen ray observations on the, 1012.
Alkaloidal salts, physiological action of, 660.
Alkaloids, the function of in plant life, 733.
Alopecia areata, a case of complete, 455.
Alvarenga prize, 150, 737.
American Academy of Medicine, 994.
American Antituberculosis League, 319, 570.
American Association for the Advancement of Science, 21.
American Association of Medical Examiners, 1038.
American Gastroenterological Association, 946.
American Hospital for Diseases of the Stomach, 67.
American International Congress on Tuberculosis, 109.
American Laryngological Association, 863.
American Medical Association, its aims and interests, 925, 958; management of the, 903; the meeting of the, 991.
American Mosquito Extermination Society, 694.
American National Red Cross, 66.
American Physiotherapeutic Association, 67.
American Society of Sanitary and Moral Prophylaxis, 738.
Amniotic liquid, method of infection of the, 103.
Amputation stump, a new form of, 968.
Amyotrophic lateral sclerosis, 1041.
Anatomy, normal in the first twelve years of life, 834.
Anemia, anomalous cases of pernicious, 198; early symptoms of pernicious, 962; hemolysis in pernicious, 782; the theory of the toxic origin of pernicious, 175; treatment of severe with transfusion, 830.
Anesthesia, an ideal local for submucous resection, 311; concerning local, 352; for nasal and aural operations, 404; infiltration in surgery, 662; lumbar, 796; ocular paralysis after spinal, 702.
Anesthetist, the, 904.
Aneurysm, a case of, 79; multiple, of the aorta, 700; of the aorta, a case of ruptured, 595, 622.
Angioma, of skin, malignant, 1042; the treatment of, 535.
Anguillula intestinalis and chronic diarrhea, 914; observations on, 953.
Annals of Otology, Rhinology, and Laryngology, Festschrift of the, 149.
Anorexia nervosa in children, 874.
Anthracosis, pulmonary, 451; of intestinal origin, 496.
Anthrax, germs, to destroy, 1038; resistance of the spores of the bacillus of, 17; the treatment of, 32, 785.
Antialcoholic Congress, the eleventh, 994.
Antinoise bill favorably reported, 150; passed, 234.
Antismoke League, work of the, 655.
Antitoxin and postdiphtheritic paralysis, 836; for free distribution, 822; from convicts, 486.
Antivaccination in California, 274.
Antivivisection bill killed in Pennsylvania, 777; in this State, 571; petition, 66.
Anuria, calculus, and ureteral catheterism, 75.
Aorta, rupture of the, 494; rupture of dilated, 450; spontaneous rupture of the, 800.
Aphasia, the clinical study of, 792.
Appendectomy, phlebitis of the lower extremity after, 75; the technique of, 1005; and obstruction of the ileocecal orifice, 212; and jaundice, 232; and twisted ovarian pedicle, 29; as a cause of intussusception, 30; cases of, 743; chronic, 870; in infants and children, 759; in nurslings, 252; in pregnancy, 867; in the negro, 165; medical treatment of, 322; nonsurgical treatment of, 271; the pathology of, 367; the state preceding, 732; verminous, 380.
Appendicitis, traumatism in causation of, 1084.
Appendicostomy, 385.
Appendicular pain, acute and chronic, 1000.
Appendix and laparotomy, the, 147; gallstones in the, 197; harmful involution of the, 555; intestinal worms in the, 578; preventive surgery in epithelioma of the, 785; primary carcinoma of the, 20; the etiology of the punctiform hemorrhages in the, 588.
Arequipa, letters from, 112.
Argyria, a case of, 34.
Arizona Medical Association, 995.
Arkansas State Medical Society, 995.
Army medical corps examinations, 356; surgeons, a proposed organization of, 231.
Arsenic, the therapeutic application of, 828.
Arseniuretted hydrogen poisoning, 577.
Arterial pressure, the control of high, 951.
Arteriosclerosis, 395; blood pressure in, 660; experimental, 568, 1089; experimental by adrenalin inoculations, 144; observations on, 673; symposium on, 453; the ocular lesions of, 408, 421, 454.
Arthropathies, syphilitic, 451.
Ascites, operative treatment of, 662.
Association of American Physicians, 1038.
Asthma, a sure cure for, 830; infantile and its treatment, 716; 300 cases of, 1068.
Ataxia, a new type of, 804.
Athletes, the longevity of college, 62.
Atmospheric pressure, the mechanical action on the body of lowering the, 328.
Auditory sclerosis, the treatment of, 317.
Aural affections in relation to mental disturbances, 500, 576; examina-

tions, the importance of, for healthy people, 200.
Auricular extrasystoles, blocking of, 828.
Autointoxication in its medico-legal aspects, 973; in relation to the eye, 281.
Automobile accidents, errors of vision as a factor in, 30; in Germany, 1079.

B

Bacteria, effect of the tropical sun on, 64.
Baginsky, Adolf, treatment of acute cardiac affections in childhood, 589.
Bailey, Pearce, pathological changes in fracture dislocations of the spine, 471.
Baldness, the cause of common, 220.
Ballenger, Edgar G., an unusual nidus for gonoccoccic infection, 142.
Balleray, G. H., unnecessary operations the opprobrium of modern surgery, 238.
Bangs, L. Bolton, a comment on the *x*-ray as applied to prostatic enlargement, 902.
Barlow's disease in the Island of Cuba, 464.
Barringer, Benjamin S., the diagnostic value of the cystoscopic examination in carcinoma cervicis uteri, 805.
Barringer, Theodore B., some unusual results of intrathoracic compression, 637.
Baths, the temperature of Japanese hot, 328.
Beans, a lacteal fluid from, 108.
Beard, John, the interlude of cancer, 109; the scientific criterion of a malignant tumor, 24; the scientific criterion of a malignant tumor and the nature of Jensen's mouse tumor, 403.
Beck, Carl, a new method of operation for epispadias, 505.
Bee stings as a cure for rheumatism, 149.
Behring's tuberculosis cure, 190.
Belfield, W. T., pus tubes in the male, 731.
Bell, Robert, the approaching conquest of cancer, 258.
Bellevue Hospital plans filed, 273.
Benedict, Charles S., retirement of Dr., 20.
Bennett, A. B., symptomless mastoiditis, followed by meningitis and death, 600.
Benzidin test, the, 569.
Berg, A. A., the diagnosis and surgical treatment of gastric and duodenal ulcer and their complications, 85.
Bergmann, death of Prof., 529.
Berlin, declining birth rate in, 945; information bureau in, 442; letters from, 71, 323, 491, 781, 1082; municipal positions in, 442.
Berthelot, death of Prof., 489.
Beth-Israel Hospital, 21.
Bier, appointment of Prof. August, 007.
Bier's Method, amputation of the leg by, 582; method in acute suppurative conditions, 754; treatment, the, 630; treatment in acute otitis, 212; treatment in surgical affections, 966.
Bilharziosis, 313.
Biliary colic, cardiac murmurs during, 827; passages, surgery of the, 940; system, drainage in operations on the, 749, 911.
Bilibid prison inquiry, result of the 906.
Birchmore, Woodbridge H., is an herpetic origin of pleurisy possible? 769; the hyoscine sleep in obstetric practice, 58.
Birth rate, the lowered, among prosperous nations, 482; the relation of to population, 356.
Bishop, William H., a new plan of suturing in perineorrhaphy, 906.
Bladder, air distention of the, 321; distention of the, with oxygen, 188; hernia of the, 582; operation for exstrophy of the, 966; simple ulcer of the, 532; symposium on new growths of the, 665; the treatment of benign tumors of the, 354.
Bleyer, J. Mount, prognosis in the consumptive, 95.
Blind, census of the, 149; magazine for the, 441.
Blindness, legislation and methods for the prevention of, 200.
Blood cells, origin of the red in mammals, 114; clinical observations of the index of refraction of the, 1043; count, the clinical value of the, in otology, 196; cultures in children, 156; examinations in otology, 78; examinations in surgical diseases, 77; examinations in surgery, 280; pressure apparatus, 1070; pressure, a study of, in compressed air workers, 855, 875; pressure determination in man, 115; pressure in arteriosclerosis and Bright's disease, 660; pressure, low as a sign of renal tuberculosis, 1078; pressure study, 204; pressure, the renal origin of increased, 233; serum, animal, in surgery, 868; test, a new, 937; test, the specific solubility, 496.
Blumgart, Leonard, observations on the diagnostic and prognostic value of the eosinophiles in the circulating blood, 560.
Board of Health inspectors, reform urged in the, 667.
Bone lesions, posture as an aid in the diagnosis of, 669; tumors, multiple, 455; tumors, the diagnosis of by examination of the blood, 568.
Book Notices.
Abdominal operations, by G. A. Moynihan, 33.
Ame et le systéme nerveux, by August Forel, 872.
Anamien, die Diagnose und Therapie der, by Josèph Arneth, 1002.

Gynecology, aids to, by Alfred S. Gubb, 159.
Gynecology and electrotherapeutics, conservative, by G. B. Massey, 747.
Hernia, retroperitoneal, by B. G. A. Moynihan, 581.
High frequency currents, by H. Evelyn Crook, 787.
Histology and organography, a manual of normal, by Chas. Hill, 915.
Histology, a text-book of, by Frederick R. Bailey, 452.
Histology, Stöhr's, by F. T. Lewis and P. Stöhr, 787.
Hygiene, the new, by Elie Metchnikoff, 536.

Indications for operation in disease of the internal organs, by Herman Schlesinger, translated by K. W. Monsarrat, 747.
International clinics, edited by A. O. J. Kelly, 245.
International medical annual, 536.
Intestine and stomach, the technique of operations on the, by Alfred H. Gould, 747.
Jahresbericht über die Leistungen und Fortschritte auf dem Gebiete der Erkrankungen des Urogenital-apparattes, 747.
Kosmetische Hautleiden, by S. Jessner, 329.
Letters from a surgeon of the Civil War, compiled by Martha D. Perry, 76.
Lungs, lectures on diseases of the, by James A. Linsay, 787.
Malpractice suit, how to suppress a, by Thomas H. Shastid, 831.
Manuel d'histologie pathologique, by V. Corneil and L. Ranvier, 620.
Massage et gymnastique medicale, manuel pratique de, by J. E. Marfort, 1002.
Materia medica, a syllabus of, by Warren Coleman, 245.
Materia medica and therapeutics, a practical treatise on, by John V. Shoemaker, 368.
Materia medica, practical, for nurses, by Emily A. M. Stoney, 664.
Medical diagnosis, by Charles L. Greene, 831.
Medical diagnosis, by J. J. G. Brown and W. J. Ritchie, 1046.
Medical diagnosis, aids to, by Arthur Whiting, 872.
Medical epitome series; Pathology, general and special, by John Stenhouse and John Ferguson, 411.
Medicine, elements of practical, by Alfred H. Carter, 284.
Mercer's company lectures on recent advances in the physiology of digestion, by E. H. Starling, 620.
Micrology, animal, by Michael F. Guyer, 703.
Minor maladies and their treatment, by Leonard Williams, 581.
Moral philosophy of medicine, conferences on the, 117.
Nervenkrankheit und Lektüre, by H. Oppenheim, 1046.
Nervous diseases, the diagnosis of, by Purves Stewart, 284.
Nierenchirurgie, by C. Garré and O. Ehrhardt, 1046.
Nose and throat, a guide to diseases of the, by Charles A. Parker, 411.
Nose and throat, diseases of the, by J. B. Ferguson, 1002.
Nose, throat, and ear, diseases of the, by Charles P. Grayson, 284.
Nouveau traité de médecine et de thérapeutique. Intoxications, by P. Carnot and collaborators, 620.
Nurses, lectures for, 368.
Obstetrics, aids to, by Samuel Nall, 245.
Obstetrics, a text-book of, by Berton C. Hirst, 33.
Obstetrics for nurses, by Joseph B. De Lee, 329.
Obstetrics, the practice of, by J. Clifton Edgar, 620.
Obstetrics, the practice of, by Reuben Peterson, 411.
Ohr, Operationen am, by B. Heine, 76.
Ophthalmic operations, a text-book of, by Harold Grimsdale and Elmore Brewerton, 872.
Organotherapy, rational, with reference to urosemiology, by A. von Poehl and collaborators, translated by Karl Schülin, 33.
Orthopedic surgery, treatise on, by Royal Whitman, 581.
Pain, abdominal, by A. E. Maylard, 284.
Pastoral medicine, essays on, by Austin O'Malley and J. J. Walsh, 33.
Pathology, a manual of, by G. McConnell, 831.
Pathology, a text-book of, by Alfred Stengel, 915.
Pathology, text-book of comparative, by Th. Kitt and W. C. Cadbury, 329.
Photoscopy, skiascopy, or retinoscopy, by Mark D. Stevenson, 117.
Phthisis, pulmonary, its diagnosis, prognosis, and treatment, by H. H. Thompson, 284.
Physiology, an introduction to, by William C. Porter, 76.
Physiology, essentials of human, by D. Noel Patton, 497.
Plaster-of-Paris and how to use it, by Martin H. Ware, 915.
Practical medicine series; Anatomy, physiology, pathology, dictionary, by Gustavus P. Head, W. A. Evans, Adolph Gehrmann, and William Healy, 915; Pediatrics, Orthopedic Surgery, edited by Gustavus P. Head, Isaac A. Abt, John Ridlon, and Gilbert L. Bailey, 245; Skin and venereal diseases, nervous and mental diseases, by Gustavus P. Head, W. L. Baum, Hugh T. Patrick, and William Healy, 915.
Prescription writing, a manual of, by Mathew D. Mann and Edward C. Mann, 787.
Progressive medicine, edited by Hobart Amory Hare, 581.
Prostate, clinical lectures on enlargement of the, by P. J. Freyer, 581.
Psychology, experimental, by Edward B. Tichener, 329.
Regeneration des familles et races tarées, by E. Contet, 747.
Régime pathologique et régime parfait, by F. Cayla, 1046.
Retinoscopy in the determination of refraction, by James Thorington, 245.
Roentgen Strahlen im Dienste der Neurologie, by W. Fürnrohr, 1046.
Rythmotherapy, by Samuel S. Wallian, 497.
Sauerstofftherapie, Handbuch der, by Max Michaelis, 787.
Self-propelled vehicles, by James E. Homans, 620.
Sex, studies in the physiology of, by Havelock Ellis, 411.
Sterilite chez le femme, by E. Hugon, 1046.
Stomach and intestines, diseases, by Boardman Reed, 536.
Stomach, diseases of the, by Max Einhorn, 76.
Surgery, American practice of, edited by Joseph D. Bryant and Albert H. Buck, 497.
Surgery, its principles and practice, edited by William Williams Keen, 664.

Dipsophinia, 947.
Disease, remarks on the treatment of and so-called "authorities," 1029; the prevention of, 391.
Ditman, Norman E., the theory of the toxic origin of pernicious anemia, 175.
Diuresis, the life saving value of, 835.
Diver's paralysis with scarlet fever, 73.
Dock, George, Dr. Knopf misquoted, 864.
Dorsal foot reflex, the, 1044.
Doty, appointment of Dr., 402.
Douglas, Richard, the treatment of acute diffuse peritonitis, 302.
Dourine, the trypanosome of, 947.
Doyen, the suit against Dr., 310, 357.
Dracontiasis, etiology and prophylaxis of, 243.
Dropsy, the causation of renal, 817.
Drug eruption, with unusual manifestations, 869.
Drum membrane, paracentesis of the, 626.
Duality of man, the, 1041.
Duodenal fistula, its surgical treatment, 412.
Duodenum, congenital stenosis of the, 1046; myxofibroma of the, 582; perforation of the by a hairpin, 115; ulcer of the, diagnosis and treatment of, 85.
Dupuytren's contraction cured by medical means, 144.
Dusts, industrial, 611.
Dutton memorial, for a, 612.
Dysentery, the serum treatment of, 399.

E.

Ear, hints on the treatment of the middle, 564; intranasal conditions in the etiology of diseases of the, 261.
Eclampsia, renal decapsulation in, 290; renal decapsulation for, 859; the connection of lactic acid with, 534.
Eczema, diet in the treatment of, 44; neurotic, 34; neurotic, with general alopecia, 373.
Edema, acute pulmonary, 776; angioneurotic and other essential in children, 625.
Edgar, J. Clifton, gonorrhea during pregnancy, 687.
Education considered from a medical point of view, 196; popular in matters medical, 857.
Egg white, the effects of on animals, 836.
Einhorn, Max, a new blood test, 937.
Electrotrammata, somatic and psychic, 588.
Elixirs, the dangers of, 600.
Embalming fluids, poisonous, 235.
Embolism, 434; coincident of several arteries, 701.
Empyema in children, 1010; the surgical treatment of, 456, 1060.
Endocarditis, chronic bacterial, 81; acetosalicylic acid in rheumatic, 577; infective, cured by a vaccine, 440; mycotic with emboli, 455.
Endothelioma of the skin, 112.
Endurance and diet, 525.
Enteritis and appendicitis, 746.
Enzymes, the physiological action of the pancreatic, 885.
Eosinophiles, diagnostic value of the, in the blood, 560.
Epididymitis, antigonococcus serum in, 107; treatment of gonorrheal, 63.
Epilepsy, strontium bromide in the treatment of, 608; the etiology of, 189.
Epispadias, a new method of operation for, 505.
Epithelioma of the eyelid treated by radium, 330.
Erdmann, John F., appendicitis in infants and children, 750.
Eructations in heart patients, 660.
Erysipelas, tubercle and, 1001.
Erythema induratum, 783; nodosum, the etiology of, 451.
Erythromelalgia, 951.
Esophagus, cured stricture of the, 413; diverticulum of the, 496; the removal of foreign bodies from the, 672; the surgical anatomy of the, 750.
Esperanto, 437, 614.
Ethyl chloride, the present status of, as an anesthetic, 570.
Eustachian tube, the, its anatomy, movements, etc., 931.
Examinations, the evils of, in medical education, 523.
Expert testimony, remarks on medical, 181; to control, 655.
Eye bath, a sterile, 212.
Eyeglasses for school children, 571.
Eyelids, syphilitic lesions of the, 202.
Eyes, the examination of students', 533.
Eyesight in relation to compensation, 114.
Eyestrain and epilepsy, 783; and other diseases due to crossing, crowding, and damming of the retinal vessels, 893; as the cause of headache, 72, 533; in school children, 999; mistaken for appendicitis and gallstones, 1041.

F.

Facial hemispasm of peripheral origin, 937.
Famine in China, 235.
Fanoni, Antonio, a case of intestinal obstruction due to persistence and anomaly of the urachus; operation; recovery; 900.
Farmers, rebellious, 572.
Fat necrosis, observations on, 243.
Federal Food and Drugs Act, the scope of the, 28.
Federal Health Board, for a, 693.
Feild, Edward E., the prevention of disease, 301.
Femur, fractures of the, 113.
Fenger, memorial to Dr. Christian, 20, 108.
Ferrer, José M., brief report of a case of trichiniasis, 351.
Fetal malformations, 62.
Fever, hemoglobinuric, 951; hysterical, 730; long continued, 1088; the continued, of Georgia, 963.
Fibroid, degenerating, complicating pregnancy, 622.
Field, C. Everett, a sterile eye bath, 212.
Filaria among the troops in Jamaica, 158.
Finger, traumatic amputation of, 412.
Fire department, board of surgeons for the, 822.
Fischer, Louis, recurrent coryza in children, 230.
Fisher, Jessie W., report of two cases of dementia paralytica, one associated with a large hemorrhagic lesion, the other with atrophy of the optic tract, 5.
Flat foot from the viewpoint of neurology, 57.
Florida State Medical Association, 739.
Fly, the house, and disease dissemination, 134.
Food and drug inspection, board of, 737.
Food, and drug inspectors needed, 108; factor, the, of the twentieth century, 283.
Forceps, a pair of, in the abdominal cavity for ten years, 366.

Formaldehyde, ammonia for counteracting the fumes of, 576; disinfection, dangers of fire in, 867; in the disinfection of rooms, 112.
Foster, death of Sir Michael, 236.
Foster, Nellis B., the stomach tube in diagnosis.
Fowler, in memory of Dr., 529, 612, 696.
Fractures, delayed union in, 797; motor boat, 412.
France, foreign physicians in, 611.
Frankfort, a new university in, 236.
Fresh air treatment in hospital wards, 213, 246.
Fridenberg, Percy, mental symptoms in nasal affections, 1071.

Plastic operations, causes of failure in, 623.
Pleurisy, experimental, fibrous, 834; is an herpetic origin of possible? 769; the treatment of with iodide of potassium, 263.
Pneumococcus and typhoid infections, 200.
Pneumonia, a case of apyretic, 332; and heart disease, the use of calcium salts in, 578; and typhoid fever, the treatment of, 720; calcium salts in the treatment of, 952; cardiac dilatation in, 430; contusion, 702, in children, the hydriatic treatment of, 267; paralyses, 65; poisoning by CO_2 in, 870; pathogenic, 158; streptococcus, 262; the abortive treatment of, 426; the fresh air treatment of, 614; the quinine treatment of, 113; the treatment of, by fresh air and saline solution, 507.
Poison squad tests, an inquiry into the, 108.
Polish Physicians and Scientists, Congress of, 350, 822.
Politzer, retirement of Prof., 605.
Polyomyelitis, electrical treatment of, 185.
Polyserositis, 663.
Pooley, Thomas R., a method of operation on the lip, 111.
Porter, William Henry, indicanuria, its etiology and practical significance, 980.
Practice, an unoccupied field of, 1035.
Practitioners, reminiscences of early, in New York, 120, 161.
Prager, Paul, a new method of identification superseding dactyloscopy, 1065.
Pregnancy, abdominal, with fetal retention for 21 years, 75; cystoma complicating, 1033; diagnosis of early, with reference to a particular sign, 597, 624; extrauterine an unusual, a specimen of, 333; extrauterine, external hemorrhage with, 011; extrauterine, laparotomy for infected, 334; multiple, 358; ovarian, 286, 1044; the fever of, 63; the pathogenesis of the vomiting of, 65; toxemia of, 120; vomiting of, 662.
Proprietary medicines, 141.
Prostate, electrical treatment of congestion of the, 744; hypertrophy of the, 002; massage of the and seminal vesicles, 1061; sarcoma of the, 020.
Prostatectomy, 020.
Prostatitis, 000.
Proteids, the disadvantages of low in infant feeding, 1000.
Protozoa and disease, 699; diagnosis of pathogenic, 000.
Psoriasis, atypical, 36; of the scalp and hands only, 335; the urine in, 63
Psychiatry, open-air treatment of, 246.
Psychometer, the electric, 179.
Psychosis, operative treatment of traumatic, 533.
Pubiotomy, 580, 617, 794.
Public Health Defense League, 145.
Puerperal thrombophlebitis of the pelvic veins, 162.
Puerperium, hypothermia with slow pulse in the, 756.
Pulmonary diseases in relation to life in assurance, 952; edema, death from, in periamygdalitis, 115; regurgitation, two cases of, 1000.
Pulsus bisferiens, 784.
Pupillary reaction, a new, 654.
Pure food bill, a State, 400.
Pus tubes in the male, 731.
Pyelitis in childhood, 734; in infancy and childhood, with remarks on the urine, 285.
Pyelonephritis, the diagnosis of, 1000.
Pyloric stenosis, the medical treatment of congenital, 577.
Pylorus, congenital stenosis of the, 950; stenosis of the, following the absorption of caustics, 335.

Q.

Quinine injections and tetanus, 493; is the efficacy of in malaria more apparent than real? 28.
Quinquaud's sign, the significance of, 1035.

R.

Rabies, 67; the fallacy of the rapid diagnosis of, 407; to restrict the spread of, 945.
Race suicide, 187.
Rachitis, the diagnosis and treatment of, 1000; the etiology of, 860.
Radius, dislocation of the semilunar bone complicating fracture of the, 533; fracture of the upper end of the, 582.
Railway accident mortality, 777.
Ray Brook Tuberculosis Sanatorium, 486.
Raynaud's disease, 826; of syphilitic origin, 374.
Recompense, a heraldic, 694.
Rectum, an operation for prolapse of the, 601; the after-treatment in excision of the, 608.
Red Cross Congress, 572, 903; aid to China, 109.
Reid, John J., the use of pilocarpine for the relief of pruritus, especially in regard to pruritus vulvæ, 858.
Respiratory tract, bacteriology of the, 827; catarrh of the upper, 584; the surgery of foreign bodies in the, 307.
Retropharyngeal growths, 578.
Retroversion operation, a new, 194.
Rheumatism and its treatment, 89; chronic articular and arthritis deformans, 746; in children, 281; the microorganism of, 1001.
Rheumatoid diseases, 201.
Rhinitis, atrophic, 73; in children, 28.
Rhinopharyngitis mutilans, 464.
Rhinoplasty, a new method of, 797.
Rhinoscleroma, improved under radiotherapy, 36; treated with the x-ray, 532.
Rhode Island State Medical Society, 1080.
Richardson, Hubert., arrested mental development, 604.
Richardson, resignation of Dr. W. L., 822.
Roadways chemically treated, 902.
Robinson, Beverley, proprietary medicines, 141.
Robinson, Jubilee of Dr. Byron, 319.
Robinson, William J., pilocarpine as an adjuvant in the treatment of syphilis, 988.
Rockefeller Institute, scholarships and fellowships of the, 234.
Rockwell, A. D., phototherapy in nervous disease, 474.

Roentgen ray, a comment on the, as applied to prostatic enlargement, 902, 924; a method of locating foreign bodies with the, 119; table, a new, 586; applications of the, in dermatology, 782; complications caused by the application of, 410; death from, 738; findings, 743; the toxic reaction following exposure to the, 773; transparency of the cranial bones to, 535; treatment of Hodgkin's disease, etc., 352; treatment, rule as to negligence in, 444.
Ronginsky, A. J., some aspects of sterility and its treatment, 1024.
Rose, A., a complete edition of the ancient Greek medical writers, 153; election of, to a Greek society, 822.
Roseola, venous compression as a diagnostic method in latent, 61.
Round ligaments, finding the, 283.
Rubella, severe types of, 860.
Russell, Colin K., supernumerary cervical ribs and their effect on the brachial plexus and subclavian artery, 253.
Russell, the late Dr. Julia W., 402.
Rutherford, J. G., the trypanosome of dourine, 947.

S.

St. Gregory's Hospital, a charter for, 275.
St. Luke's Hospital, bequest to, 994.
Sacroiliac joints, affections of the, 412 668.
Safety, the factors of in the organism, 364.
Sahli's desmoid reaction, 61, 204.
Saline infusions, the action of, in bacterial toxemia, 570.
Saliva, the effect of on bacteria, 18.
Salt and sugar injections in infants, 953.
Salt solution as an irrigating fluid, 355; the subcutaneous injection of, in children, 819.
Sanatorium Gabriels, 520; treatment the physiological therapy of, 202.
Sanitation, for a national department of, 993; the march of, 950.
Sarcoma of the liver in a child, 869; of the tendon sheaths, 579; uveal, 29.
Sausage, standardized, 528.
Scarlatina, complications of, 451; in Boston, 108; incubation of, 282; is it a streptococcus disease? 618; persistency of infection in, 107; streptococcus erythema and, 913; the exanthem of and its counterfeits, 74.
Schadle, Jacob E., the antrum of Highmore as an etiological factor in the production of hay fever (so-called), 841.
School children, eyeglasses for, 1038; statistics relating to, 402; children, the inspection of, 441; hygiene, department of, 318; medical inspection in public, 992.
Schwann, a monument to Theodor, 274.
Sciatica, the injection treatment of, 232; treatment of chronic, 197.
Scleroderma and myositis, 197; cured by mercurial treatment, 496.
Scopolamine anesthesia in obstetric practice, 367; morphine anesthesia, 671; morphine-chloroform narcosis, 535; morphine narcosis in labor, 663; narcoses, two hundred 989; poisoning, 783.
Scorbutic symptoms caused by the typhoid bacillus, 185.
Scranton, typhoid epidemic, the, 21, 326.
Scripture, E. W., the treatment of stuttering, 771.
Scurvy in Russia, 862.
Seasickness, to prevent, 528
Sea water, hypodermic injections of, 580.
Sediments, a convenience in examining, 32.
Senility, premature, 109.
Septicemia in lying-in hospitals, the open-air treatment of, 246; meningococcus, 1000.
Serratus, causation and treatment of paralysis of the, 1044.
Serum, sterilized horse in surgery, 1017.
Sewage disposal problem, the, 108.
Sex, determining the, of the fetus, 325.
Sheffield, Herman B., vulvovaginitis in children, with special reference to the gonorrheal variety and its complications, 767.
Sheldon, John G., the preappendicitis state, 732.
Shellfish from polluted waters, 571.
Shiels, George F., a few remarks on medical expert testimony, 181.
Shock, conditions of the vessels during, 449.
Sigmoid flexure, resection of the, 216.
Sinus, variations in the frontal, 196.
Skin, danger signals from the, 199; disease of the, caused by a canine parasite, 1044; diseases, electricity in the treatment of, 75; tropical ulcerations of the, 953.
Skull, a case of depressed fracture of the, 748.
Slander, a suit for, 821.
Sleep, the reflexes during, 410.
Sleeping sickness, 578; the present means of combating, 327.
Smallpox, cases of, 528, 655, 906; in Missouri, 358.
Smith, Emmet L., asthma, observations on 300 cases, 1068.
Smith, retirement of Dr. Andrew H., 1037.
Smith, Stephen, suggestions of a plan of organizing a hospital system for the city of New York, 1.
Smoke nuisance award, 694.
Snake bite, deaths from, in India, 66; the treatment of, 828.
Society for the Suppression of Unnecessary Noises, 108, 527, 1079; of Sanitary and Moral Prophylaxis, 572.
Society Reports:
American Climatological Association, 830.

Thoracic compression, some unusual results of, 637; disease, abdominal symptoms of, 1011; duct, a new disease of the, 204; injuries and abdominal rigidity, 905.
Thorax, a simple method for performing resection of the, 709
Throat diseases caused by misuse of the voice, 16.
Thyroid activity, the relation of diet to, 578; disease, the surgical treatment of, 110; extract, the influence of on the development of the embryo, 188.
Thyroidectomy, the technique of, [illegible]
Tick fever, intermittent, 618.
Tics in children and their treatment, 313.
Tobacco factories, pregnancies, and abortions of women employed in, 17; legislation against, 694; nicotine-free, 611; smoke, the pungency of, 776; smoking in Austria 67; the experimental effects of on the nervous system, 1072; to restrict the use of, 945.
Tongue, neuralgia of the, 75; the scrotal, 735.
Tonsillar infection, remote effects of, 1042.
Tonsils, relation of the to infection and infectious diseases, 341; removal of enlarged, 661.
Townsend, Terry M., massage of the prostate and seminal vesicles, 1061.
Toronto Academy of Medicine, 1038.
Tracheostenosis, thymic, 912.
Trachoma in school children, 777; radiotherapy in, 189.
Transposition of the viscera, 754.
Trenwith, W. D., a suction and instillation sound, for use in the treatment of chronic posterior urethritis with involvement of the prostatic follicles, 419.
Trichiniasis, brief report of a case of, 351; on the East Side, 358.
Trinidad, plague in, 904.
Tropics, clothing for the, 653.
Trypanosomes, 113.
Tsetse fly disease, to study the, 821.
Tub, the Saturday night, 080.
Tubercle bacilli, split products of the, 1051; stains for distinguishing from perlsucht bacilli, 535; the rapid demonstration of, 860.
Tuberculide, 35.
Tuberculin test, the 868.
Tuberculosis aërotherapy in, 157, 1053; a committee on bovine, 834; and milk, 105, 672; and the railroads, 156; are children with, liable to be sources of infection? 833; control of, 273; crusade, the sanatorium in the, 157; diet in pulmonary, 1074; digestive conditions in pulmonary, 963; experimental in the rabbit, 871; human and animal, 355; in Chicago, the fight against, 527; in infancy, 834; in the navy, 318; Koch's emulsion of bacilli in the diagnosis of incipient, 307; laryngeal, 267; mistakes in the diagnosis of pulmonary, 327; movement in New York, progress of the, against, 904; observations on the treatment of in Arizona, 646; of early life, advances in the knowledge of, 832; of the bronchial glands, 860; of the eye, treated with tuberculin, 746; of the hip joint, excision in, 950; of the intestine, occult blood in, 1053; of the kidney, surgical treatment of, 162; of the tongue, 30; open air treatment of bone and joint, 1041; opsonins in, 745, 746; pleural pressure after death from, 1052; prognosis in pulmonary, 95; pulmonary, the modern hygienic home treatment of 717; pyrexia in, 1019; State sanatorium for in Illinois, 235; suboccipital, 20; the action of garlic in, 861; the early diagnosis of pulmonary, 244; the economic aspects of bovine, 608; the frequency of, 189; the home sanatorium treatment of, 313; the induction of autovaccination in, by the *x*-rays, 282; the leucocytes in complications of, 1053; the prognostic value of the diazo reaction in 480; the public control of, 820; the serum diagnosis of, 198; the transmissibility of bovine, 833; the treatment of, 107; the treatment of surgical by hyperemia, 830, 016; the use of the *x*-ray in surgical, 917; treatment of surgical at the

seaside, 786; vaccines in, 1051; *x*-ray findings in, 785.
Tuberculous cows in New Jersey, 571; glands, the *x*-ray treatment of, 112; infection of the lung, the manner in which it takes place, 270; municipal care of the, 18; poor, the treatment of the, 906; pus, a method of identifying, 439; ulceration, the treatment of, 148.
Tumors, growth and infectivity of, 1085; immediate microscopical diagnosis of, 243; malignant, the scientific criterion of, and Jensen's mouse tumor, 24, 403; multiple, 35; the transference of in dogs by the sexual act, 31.
Turbinate hypertrophy, 408; primary cancer of the, 432.
Turck, Fenton B., a clinical view of ulcer of the stomach, 850.
Twins, an early case of operation for the separation of joined, 566.
Typhoid bacilli carriers, 32, 818, 924.
Typhoid fever, appendicitis in, 365; and pneumonia, the treatment of, 729; bacteriological examinations of the blood in, 408, 541; complicated by abscesses of the kidney and pneumonia, 390; epidemics in Berwick, Pa., Scranton, and Pittsburg, 66, 108, 326, 53, 1038; excretion of the agglutinins of, in the urine, 914; from infected milk, 912; in children, 874; inoculation in the English army, 609, 1043; in Pennsylvania, 149; intestinal perforation in, 965; management of the intestinal tract in, 538; nitrogenous metabolism in, 537; on the Connecticut, 401; operations during, 605; perforations in, 1084; perforation in, and blood pressure, 912; quinine in, 144; simulating meningitis, 409; spine, treatment of, 743; spine, the treatment of, 539; sulphate of copper in, 531; the diagnosis of perforation in, 414; the diazo reaction, bacteriemia, and the Widal reaction in, 914; the responsibility of the country practitioner for the existence of, 859.

U.

Ulcer, the treatment of rodent, by zinc ions, 409; ulnar nerve, analgesia of the from pressure and in tabes, 32.
Underfeeding and its associated ills, 205.
Ureteral calculus, three cases of detected by *x*-ray and removed by operation, 330.
Urethra, congenital stricture of the, 701.
Urethral abscess and calculi, 282; discharge, treatment of chronic, 240
Uric acid, the influence of chocolate and coffee on, 185.
Urinary diseases, the internal and external remedies in, 800; fistula, ligature of the renal vessels for, 1085.
Urine of children, albumin and casts in the, 248; shreds in the, in relation to diagnosis, 448; the, in early life, 247; the, in infectious diseases, 248; the, in pregnancy, 167, 249; the specific gravity of, 272.
Urobilinuria in typhoid, 663.
Urticaria and influenza, 1043.
Utah State Medical Association, 863.
Uterine adnexa, conservative surgery on the, 217, 287; contractions, the effect of quinine on, 355; relaxation, 19.
Uterus, clinical symptoms and microscopical findings in cancer of the, 518; dilating the gravid, 700; dystocia following fixation of the, 163; fibroids of the, complicated by pregnancy, 911; fibroma of the, with anemia, 871; fibromyomata of the, 715; foreign bodies in the, 207; four specimens of fibroids of the, 334; galvanism in the treatment of fibroids of the, 352; inoperable cancer of the, 744; inversion of the, 754; metastatic carcinoma of the, 703; operation for prolapse of the, 1078; parasitic myomata of the, 964; subinvolution of the in gynecology, 407; the surgical treatment of fibroids of the, 335; the value of the cystoscopic examination in cancer of the, 805; treatment of cancer of the, 1045; treatment of inversion of the, 861; treatment of myoma of the, 282.

V.

Vaccination, compulsory and anti-vaccination, 251, 441.
Vaccine therapy of surgical infections, 1006.
Vaginal entrance, anomalies of, 671; section as an operation of choice, 164.
Vaginitis in children, gonorrheal, and its complications, 767.
Vale, Frank P., inaccuracy of Dare's hemoalkalinometer, 858.
Valentine, Ferd. C., massage of the prostate and seminal vesicles, 1061.
